

RNA synthesis, regulation of gene expression

© Department of Biochemistry 2013
(E.T.)

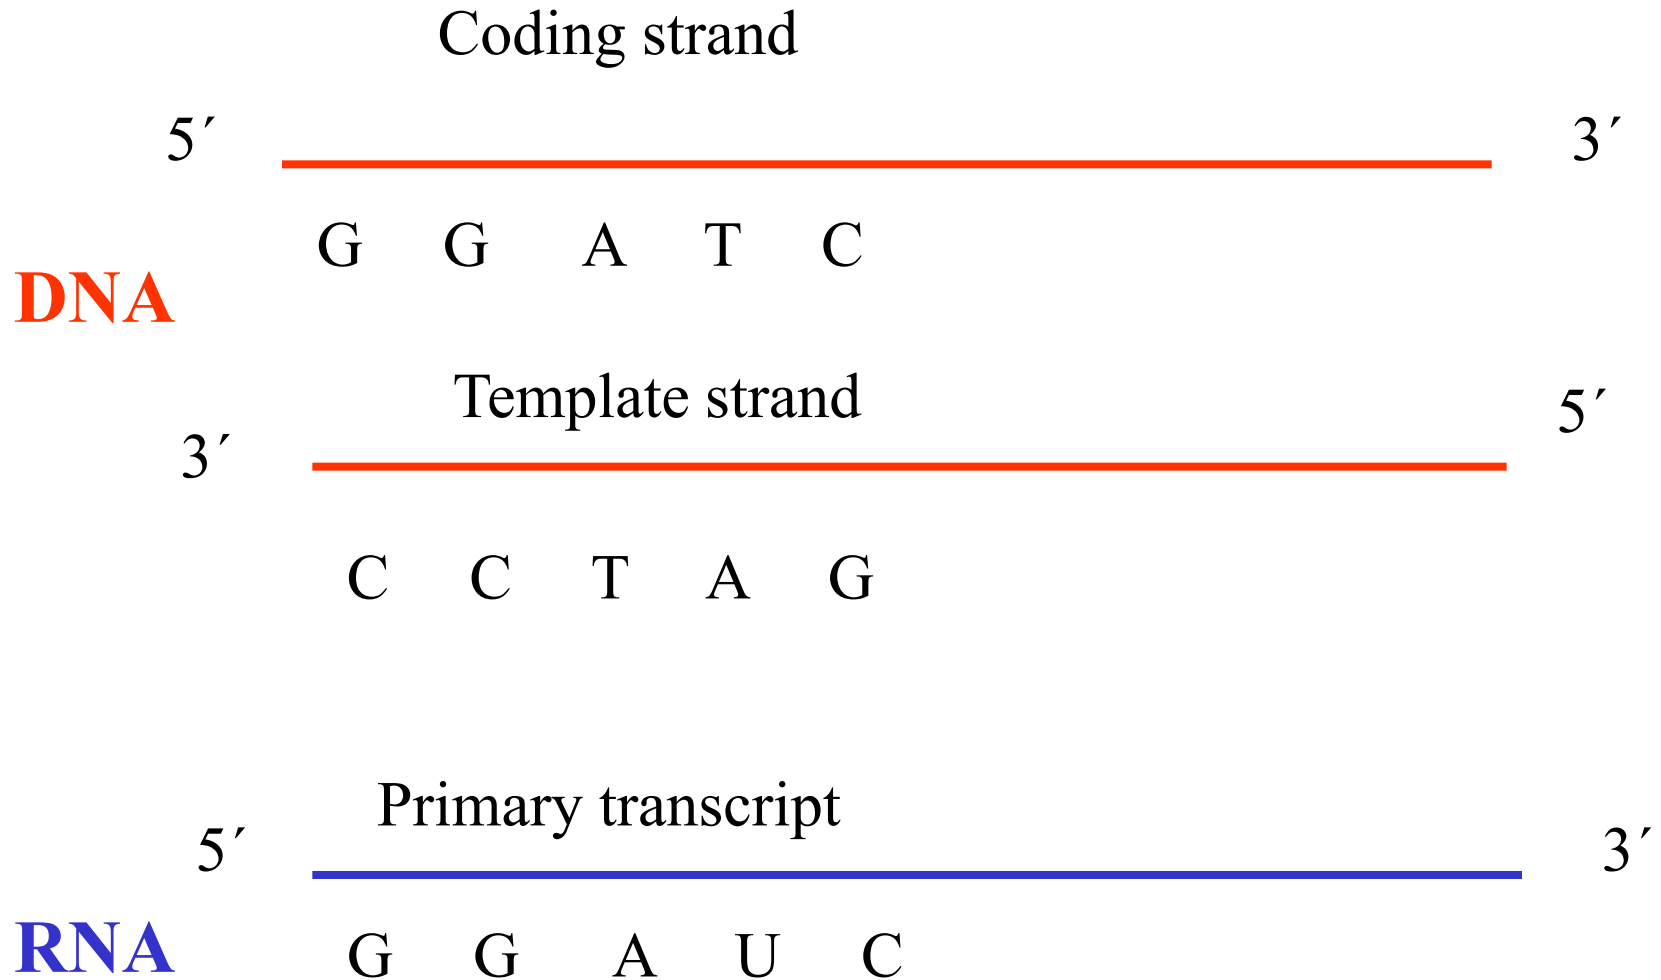

Transcription

Synthesis of RNA from a DNA template

Only one strand of double helix DNA is transcribed – **template strand**.

The second strand is **coding strand** (its sequence is identical with primary transcript only U is replaced by T)

Terminology

RNA transcript is synthesized in the 5' → 3' direction

For transcription are necessary:

dsDNA

RNA-polymerase

ATP, GTP, CTP, UTP

Mg²⁺ ions

Replication x Transcription

Characteristic	replication	transcription
Enzymes:	DNA-polymerases	RNA-polymerases
Location:	On chromosome at S phase	Selected fragment of DNA
Initiation:	RNA primer is necessary	no primer is necessary
Procedure:	Both strands are copied	Only one strand is copied
Control:	Proofreading and DNA repair	polymerase do not include proofreading
nucleotides:	dATP, dGTP, dCTP, dTTP	ATP, GTP, UTP, CTP

Transcription is carried out by DNA-dependent RNA polymerases (transcriptases)

Prokaryotes:

- only one polymerase composed of 5 subunits plus sigma factor.
- it transcribes all forms of RNA

Eukaryotes

4 different RNA polymerases

RNA pol I – synthesis of r RNA (in nucleolus)

RNA pol II – synthesis of mRNA (nucleus)

RNA pol III – synthesis of tRNA, 5S RNA (nucleus)

RNA pol IV - synthesis of mitochondrial RNA

The mechanism of the action is the same, they recognize various promoters

Amanitine (bacterial toxin from *Amanita phalloides*) - cyclic octapeptide with unusual amino acids

Inhibitor of eukaryotic RNA polymerase (mainly of II-type)

Three phases of transcription

- initiation
- elongation
- termination

Mechanism of RNA polymerase function

- Synthesis of RNA occurs in 5' → 3' direction
- Nucleotides ATP, GTP, CTP, UTP are necessary
- Each nucleotide pairs with the complementary nucleotide on the DNA template
- Polymerase catalyzes formation of phosphodiester bond between 3'-OH end of ribose on growing RNA-strand and α -phosphate bonded to 5'-OH of ribose new nucleotide
- the energy for polymeration is provided by cleavage of NTP and release of diphosphate
- In contradistinction to DNA polymerases, RNA polymerases don't exhibit any nuclease (proof-reading) activity so that they cannot correct mismatches.

Terminology of transcription

Promoter – specific sequence on DNA template about 40 nucleotides long lying in upstream position to the initiation site

Transcription unit - sequence of nucleotides in DNA that codes for a single RNA molecule, along with the sequences necessary for its transcription; normally contains a promoter, an RNA-coding sequence, and a terminator

Boxes (elements): small sequences in the promoter region

Cis-acting sequences: lying on the same molecule of DNA that is transcribed, near the gene

Trans-acting factors : proteins that bind to these DNA sequences and facilitate or prevent binding of DNA polymerase (genes for their synthesis are lying on different chromosomes)

Primary transcript - RNA product synthesized in direction $5' \rightarrow 3'$

Initiation of transcription

- RNA polymerase (RNAP) binds to specific nucleotide sequences – **promoters**
- stable complexes with template DNA strand and RNA at the promoter region are formed

The promoter contains characteristic **consensus sequences** (common conserved regions that are found in certain area of all genes)

Promoter in DNA of prokaryotes

In position ~ -10 TATAAT box (Pribnow box)

In position ~ -35 another sequence TTGACA

These sequences are recognized by σ -factor of prokaryotic RNA polymerase

Transcription in prokaryotes

Initiation:

Binding of RNA-polymerase to promotor region of DNA by sigma subunit

Local unwinding of DNA caused by RNA polymerase

Pairing of ribonucleotide bases with template strand and formation of several phosphodiester bonds between nucleotides

RNA polymerase is inhibited by antibiotics rifampicine

Transcription in prokaryotes

Elongation:

Release of sigma subunit from RNA polymerase

RNA polymerase moves along the template strand, unwinding of double helix

Formation of covalent ester bonds among the nucleotides

Newly formed RNA is released

Termination signal – transcription is finished. Newly synthesized RNA separates from DNA template.

Termination

Termination signals usually contain a palindromic (selfcomplementary) GC-rich region and an AT-rich region.

Thus the mRNA transcripts of this DNA palindrome can pair to form a hairpin structure with a stem and loop followed by a sequence of more uracil base – RNA transcripts end within or just after them

Transcription in eukaryotes

It is far more complicated than transcription in prokaryotes

DNA is temporarily released from chromatin structure

Most active are relaxed parts of chromatin – euchromatin

Relaxation of chromatin is mediated by acetylation of lysine residue at the amino terminus of histone proteins by the action of histone acetyltransferase

Promoter u eukaryotes (RNA polymerase II)

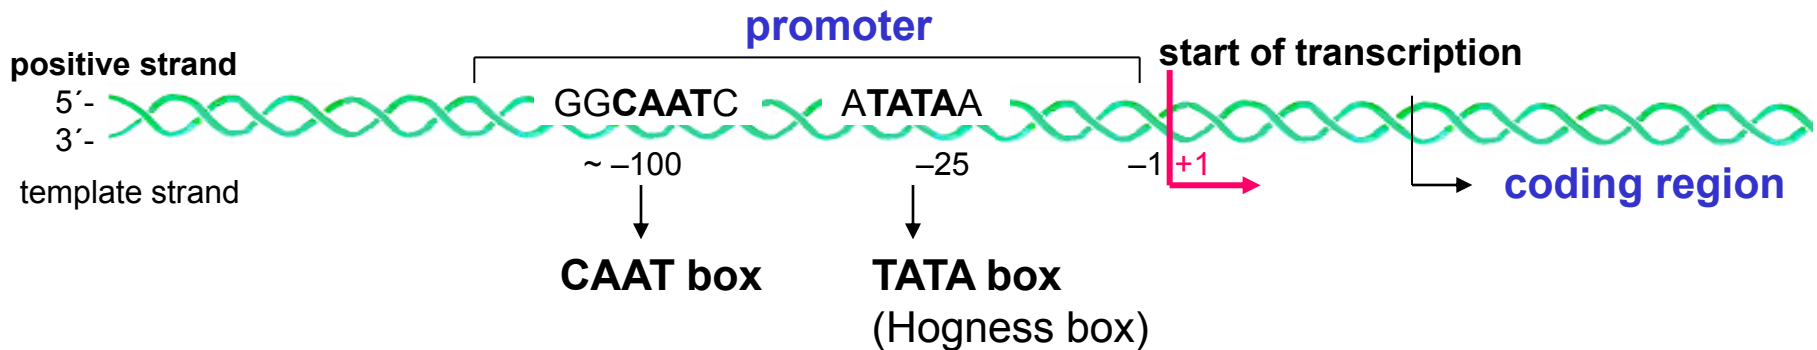

Transcription factors mediate the binding of RNA polymerase and the initiation of transcription.

Many **transcription factors** are involved that bind to different regions of DNA

Boxes in the promotor of eukaryotes:

TATA (analogic to Pribnow sequence)

Sometimes present CAAT

in basal gene expression
specifies the frequency of
initiation

directs TF II D and
RNA pol II to the correct site

Transcription factors in eukaryotes

Basal transcription factors

transcription factors bound onto the promoter

Are necessary for transcription of all genes

Gene specific transcription factors

bind to regulatory DNA sequences distant from promoters.

Basal transcription factors in eukaryotes

- They must be attached to RNA polymerase before the transcription starts and are at the same time associated with promoter sequences
- They are necessary for recognition of promoter and facilitate the binding of RNA polymerase
- Polymerase II and transcription factors bound onto the promoter form a complex called the **basal transcription apparatus**. It regulates basal gene expression
- At least six basal transcription factors in eukaryotes

Basal TF = are necessary for transcription of all genes

Basal transcription factors

TFIID – the biggest of basal factors of transcription - 11 subunits

One of the subunits is TBP (TATA box binding protein).

TBP binds to TATA box, the other subunits reacts also with TBP and RNA polymerase

One of factors is an ATP-dependent **helicase** that separates the DNA duplex for the **polymerase II**

Polymerase II then slides to the start of transcription and initiate transcription

Gene specific regulatory proteins (factors)

Specific transcription factors - proteins that bind to **specific regulatory DNA sequences (enhancers, silencers, HRE)** lying on the same chromosome, distant from promoters (very often in large distance).

They act as activators or repressors of the given gene transcription.

Specific transcription factors interact with mediator proteins (coactivators, corepressors) that are in contact with basal transcription factors.

A typical gene coding synthesis of a protein in eukaryotes has many binding sites for specific transcription factors in the template DNA strand

Regulation of a typical eukaryotic gene by a specific transcription factor

Examples of specific transcription factors

Specific transcription factors are proteins whose specific effect is often activated by cellular signal pathways:

Examples of specific transcription factors and their activation

- a) Intracellular receptors activated by binding of hydrophobic hormones
- b) Membrane receptors of hormones producing second messenger after the binding of hormone. One of the effects of second messenger is activation of protein kinase that activates transcription factor by phosphorylation
- c) Ras signal pathway activated by binding various growth factors on membrane receptor is terminated by phosphorylation of transcription factors (proteins Fos, Jun, Myc a dalších)
- d) SREBP (sterol regulatory element binding protein) activated at low sterol concentration in the cell
- e) Binding of cytokine to membrane receptors activates JAK-STAT signal pathway. Phosphorylated STAT protein functions as transcription factor.

a) Intracellular receptors of hormones are specific transcription factors

- **receptors** of steroidal (thyroidal) hormones are present in cytoplasm or nucleus in inactive form. They bind inhibitory protein in inactive form (e.g. heat shock protein).
- hormone permeates across the plasmatic membrane to the cell and is specifically bonded to the receptor in cytoplasm or nucleus
- inhibitory protein is separated, the complex hormone-receptor is formed, the conformation of receptor protein is changed
- the complex hormone receptor is translocated to the nucleus
- the complex hormone-receptor acts as the specific transcription factor in the nucleus and binds to DNA at hormone response element (HRE)
- the complex hormone-receptor attached to DNA reacts at the same time with coactivator (mediator protein) that is in contact with basal transcription complex. Thereby is transcription of a gene stimulated or inhibited.

Example: Initiation of transcription by cortisol

- cortisol in plasma is transferred by CBG (corticosteroid-binding globulin)
- hydrophobic molecule difuses into a cell

Inactive form of a glucocorticod receptor is present in cytoplasm and is associated with dimer of hsp 90 protein (chaperon) and other proteins

Initiation of transcription by cortisol - continuation

Binding sites of the glucocorticoid receptor

Dimeric complex cortisol-receptor binds to dsDNA at the specific GRE sequence (glucocorticoid response element), it means on HRE (hormone response element) specific for glucokortikoids.

Initiation of transcription by cortisol - continuation

Active complex cortisol-receptor **binds onto DNA** at the specific sequence **GRE** (glucocorticoid response element, one of the HRE – hormone response elements).

The **coactivator** and specific **hormone response element-binding proteins** (HREB-proteins) are also attached. This complex supports initiation of transcription on the promoter by means of **mediator proteins**.

GR dimer – intracellular glucocorticoid receptor (dimer)

GRE – glucocorticoid response element

GREB protein – GRE binding protein (a specific transcription factor)

Intracellular receptors for hydrophobic hormones

- Members of the nuclear receptor superfamily (there is known more than 150 proteins).
- Present in cytoplasm or nucleus
- Main group are steroidal-thyroidal receptors

Examples:

Androstane receptor AR

Estrogen receptor ER

Progesterone receptor PR

Glucocorticoid receptor GR

Mineralocorticoid receptor MR

Transcription factors that bind onto regulatory DNA sequences

comprise mostly one of the **typical structural motifs**:

helix-turn (or loop)-helix, zinc-finger, and leucine zipper.

Only the small part of protein molecule (called DNA-binding domain) is responsible for the interaction with DNA. It is usually represented by two adjacent α -helical segments.

helix-turn-helix

zinc finger

leucine zipper

Zinc finger, e.g., occurs in DNA binding domains of steroid-hormone receptors. **NRS** (nucleotide recognition signal) is a part of α -helix containing amino acid sequence that is able to recognize specific regulatory sequence of nucleotides in the major groove DNA.

Transcription factors are attached to DNA usually in the major groove.

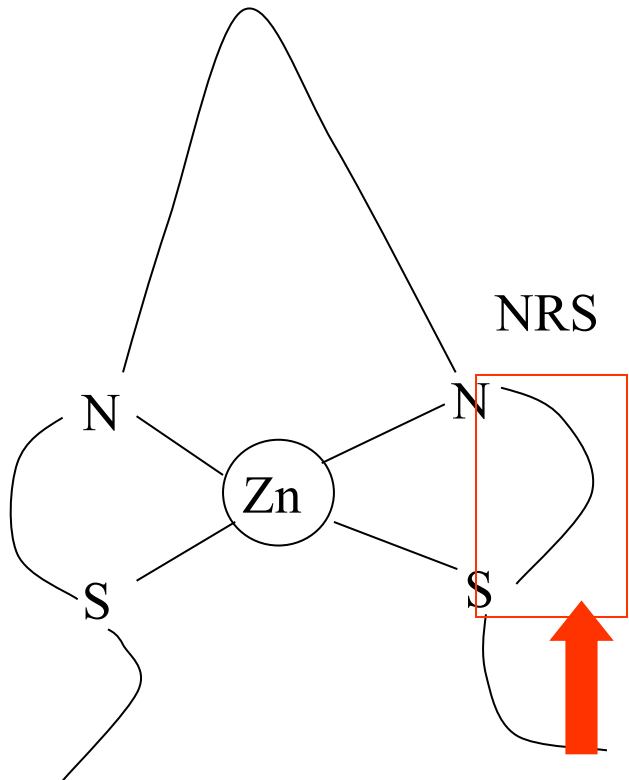

Zinc finger

E.g. binding domains of steroidal hormone receptors.

Zn^{2+} is chelated by four ligands either by histidine(N) or by cysteine (S)

Zn^{2+} maintains the tertiary structure of the domain

NRS (nucleotide recognition signal) is a part of α -helix containing the sequence of amino acids that serves for recognition of specific sequence in major groove DNA

Initiation of transcription - summarization

- Transcription is initiated only after all transcription factors are attached
- The completed assembly of transcription factors and RNA polymerase bind to the promoter, forming a transcription initiation complex.
- RNA polymerase is attached to the transcription factors and DNA in promoter region
- It melts 10-15 nucleotide base pairs around the transcription start site, allowing for ribonucleotides to bind to the template strand.
- After the first bond is synthesized, the RNA polymerase must clear the promoter, most of transcription factors are separated

Elongation phase

As transcription proceeds, RNA polymerase traverses the template strand and uses base pairing complementarity with the DNA template to create an RNA copy.

capping enzyme (CE)

methyltransferase (MT)

Both those enzymes modify

the 5'-end of the nascent

transcript to **5'-m⁷Gppp-cap**

Capping of mRNA

7-methylguanosine is attached by 5'-5' phosphate bond to the 5'-terminal end of the mRNA

Complex of proteins is then bonded to the cap that prevents RNA from the action of 5'-exonucleases and enable the transport of RNA through the nuclear pores

Čapka je také nutná pro zahájení translace

Termination in eukaryotes

no perspicuous termination signal has been found.

Transcripts produced by DNA polymerase II are released from the transcription apparatus after the polyadenylation signal AAUAAA and the GU- or U-rich sequence that is able to bind cleavage stimulation factor (CStF) had been transcribed.

The terminal sequences of the transcripts are decomposed in the course of 3'-polyadenylation (not encoded by template DNA).

Eukaryotic transcription and translation are separated in space and time

Prokaryotes

Eukaryotes

Differences between prokaryotes and eukaryotes

Prokaryotes - transcription occurs in the cytoplasm. Translation of the mRNA into proteins also occurs in the cytoplasm.

DNA is much more accessible to RNA polymerase than DNA in eukaryotes.

RNA polymerase interacts directly with prokaryotic DNA.

mRNA produced as a result of transcription is not modified in prokaryotic cells.

Eukaryotes - transcription occurs in the cell's nucleus. mRNA then moves to the cytoplasm for translation.

Eukaryotic DNA is wrapped around histones to form nucleosomes.

Eukaryotic DNA is packed to form chromatin.

Other proteins mediate the interaction between RNA polymerase and DNA in eukaryotes.

Eukaryotic cells modify mRNA by RNA splicing, 5' end capping, and addition of a polyA tail.

Processing of primary transcripts

- Primary transcript is precise copy of precursor template DNA with exception of T→U
- Primary transcripts of **tRNA** and **rRNA** are posttranscriptionally modified by nucleases in both prokaryotes and eukaryotes
- Prokaryotic **mRNA** is practically identical with primary transcript (is used for translation before the synthesis finishes)
- Eukaryotic **mRNA** is significantly modified

Processing of eukaryotic mRNA

The primary transcript is hnRNA

It is a transcript of the structural gene at which the coding sequences (exons) alter with non-coding sequences (introns or intervening sequences).

Non-coding sequences must be removed during processing

Processing of hnRNA in nucleus

- Chemical modification (capping at 5' terminal) – prevents mRNA against 5'-endonucleases and it is also the marker recognized in proteosynthesis.
- Splicing (removal of introns)
- Polyadenylation (addition of polyA on 3' terminal) – it prevents against the 3' exonucleases

Splicing of hnRNA

Splicing is ensured by the action of small nuclear complexes – spliceosomes

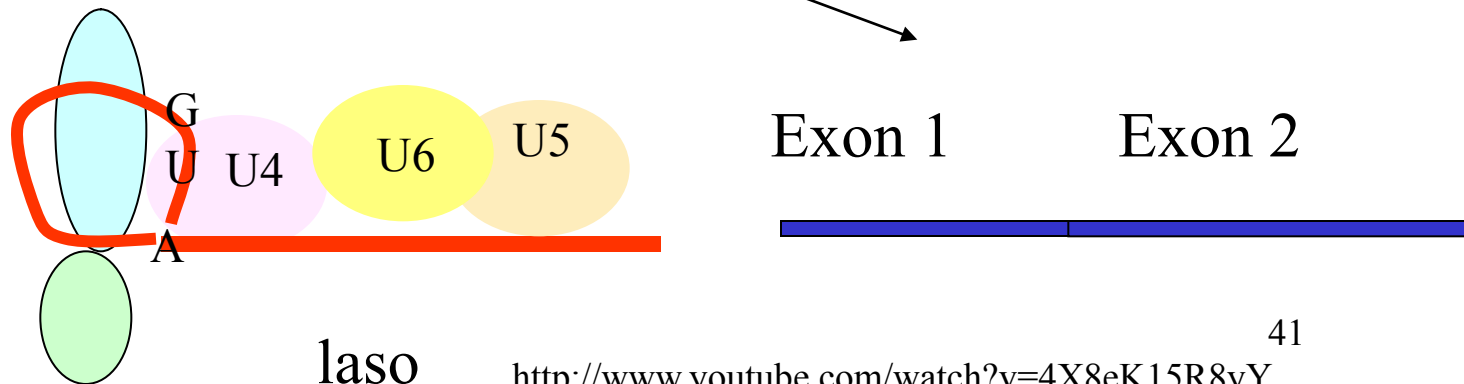

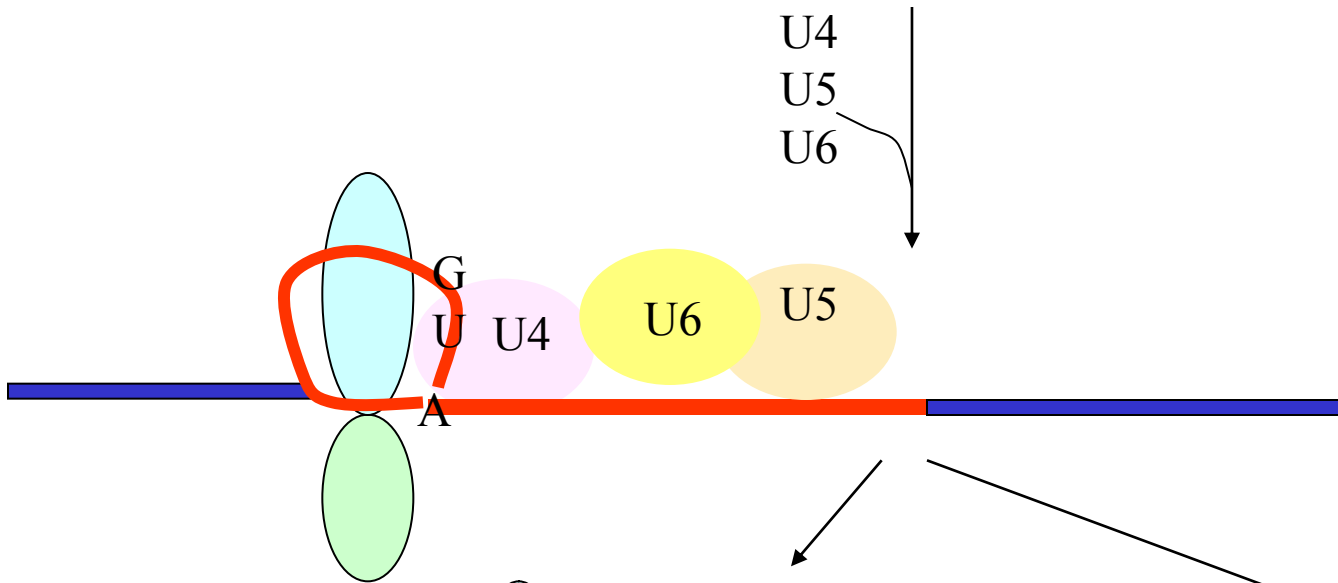

Spliceosomes contain five small RNA rich in uracil (U1, U2, U4, U5 and U6)

Small RNAs are associated with proteins and form snRNPs (small nuclear ribonucleoprotein particles).

Nucleotide sequence AGGU determine the splice sites. These sequences are recognized by snRNPs.

Splicing

Mechanisms of RNA-splicing

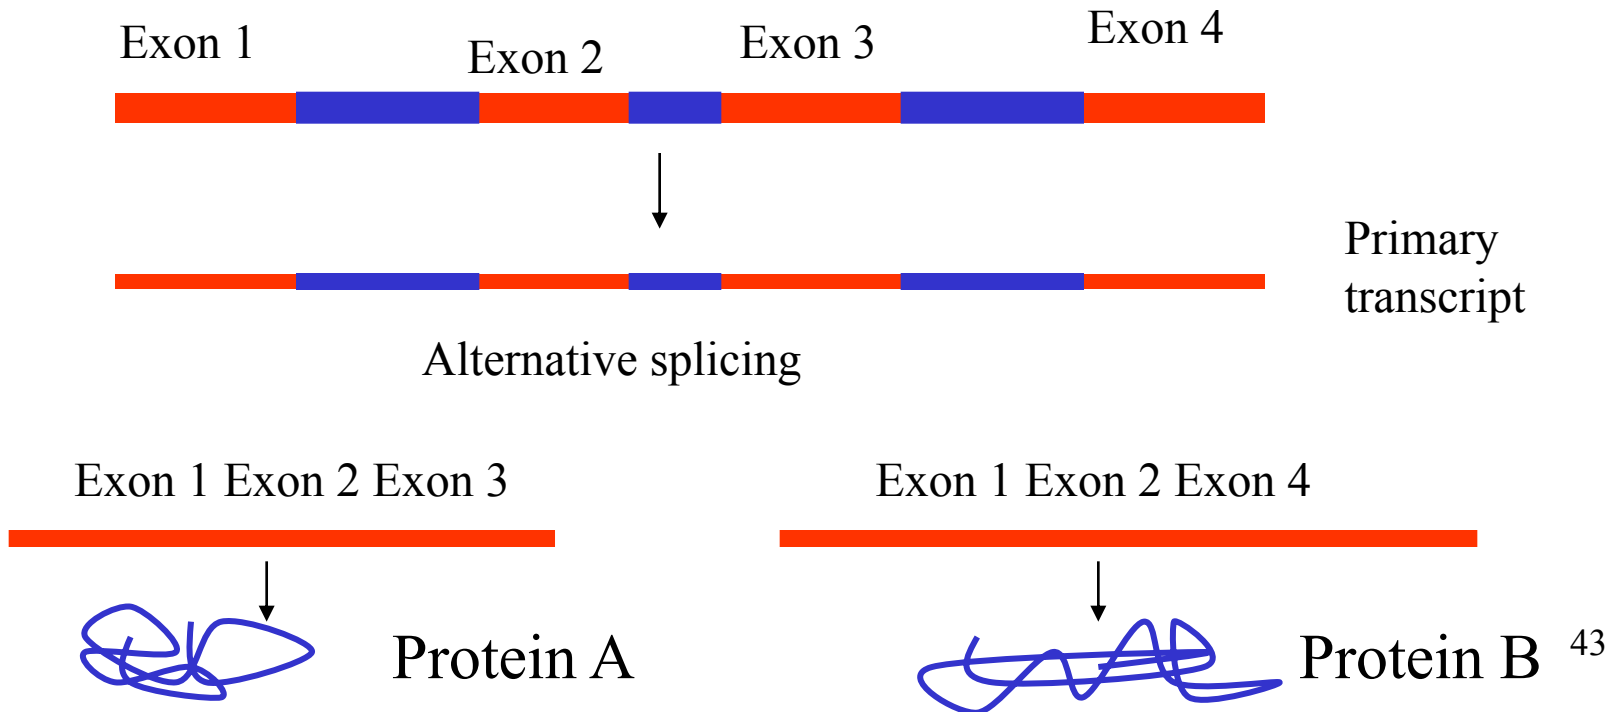

2'-OH group of adenine nucleotide attaches phosphate in the position 5' of guanine nucleotide at the place of splicing and forms a lariat. The chain on the 3' end of exon 1 is interrupted, 3'-OH become free and attaches the 5'-end of exon 2

Alternative splicing

Alternative splicing – various groups of exon originating from one gene form various molecules of mRNA that provide various proteins

Alternative splicing of m RNA

In many cases, the splicing process can create a range of unique proteins by varying the exon composition of the same messenger RNA. Alternative splicing can occur in many ways. Exons can be extended or skipped, or introns can be retained.

Splice site mutations

Mutation at splice sites can lead to improper splicing and production of aberrant proteins

E.g. β - thalassemia:

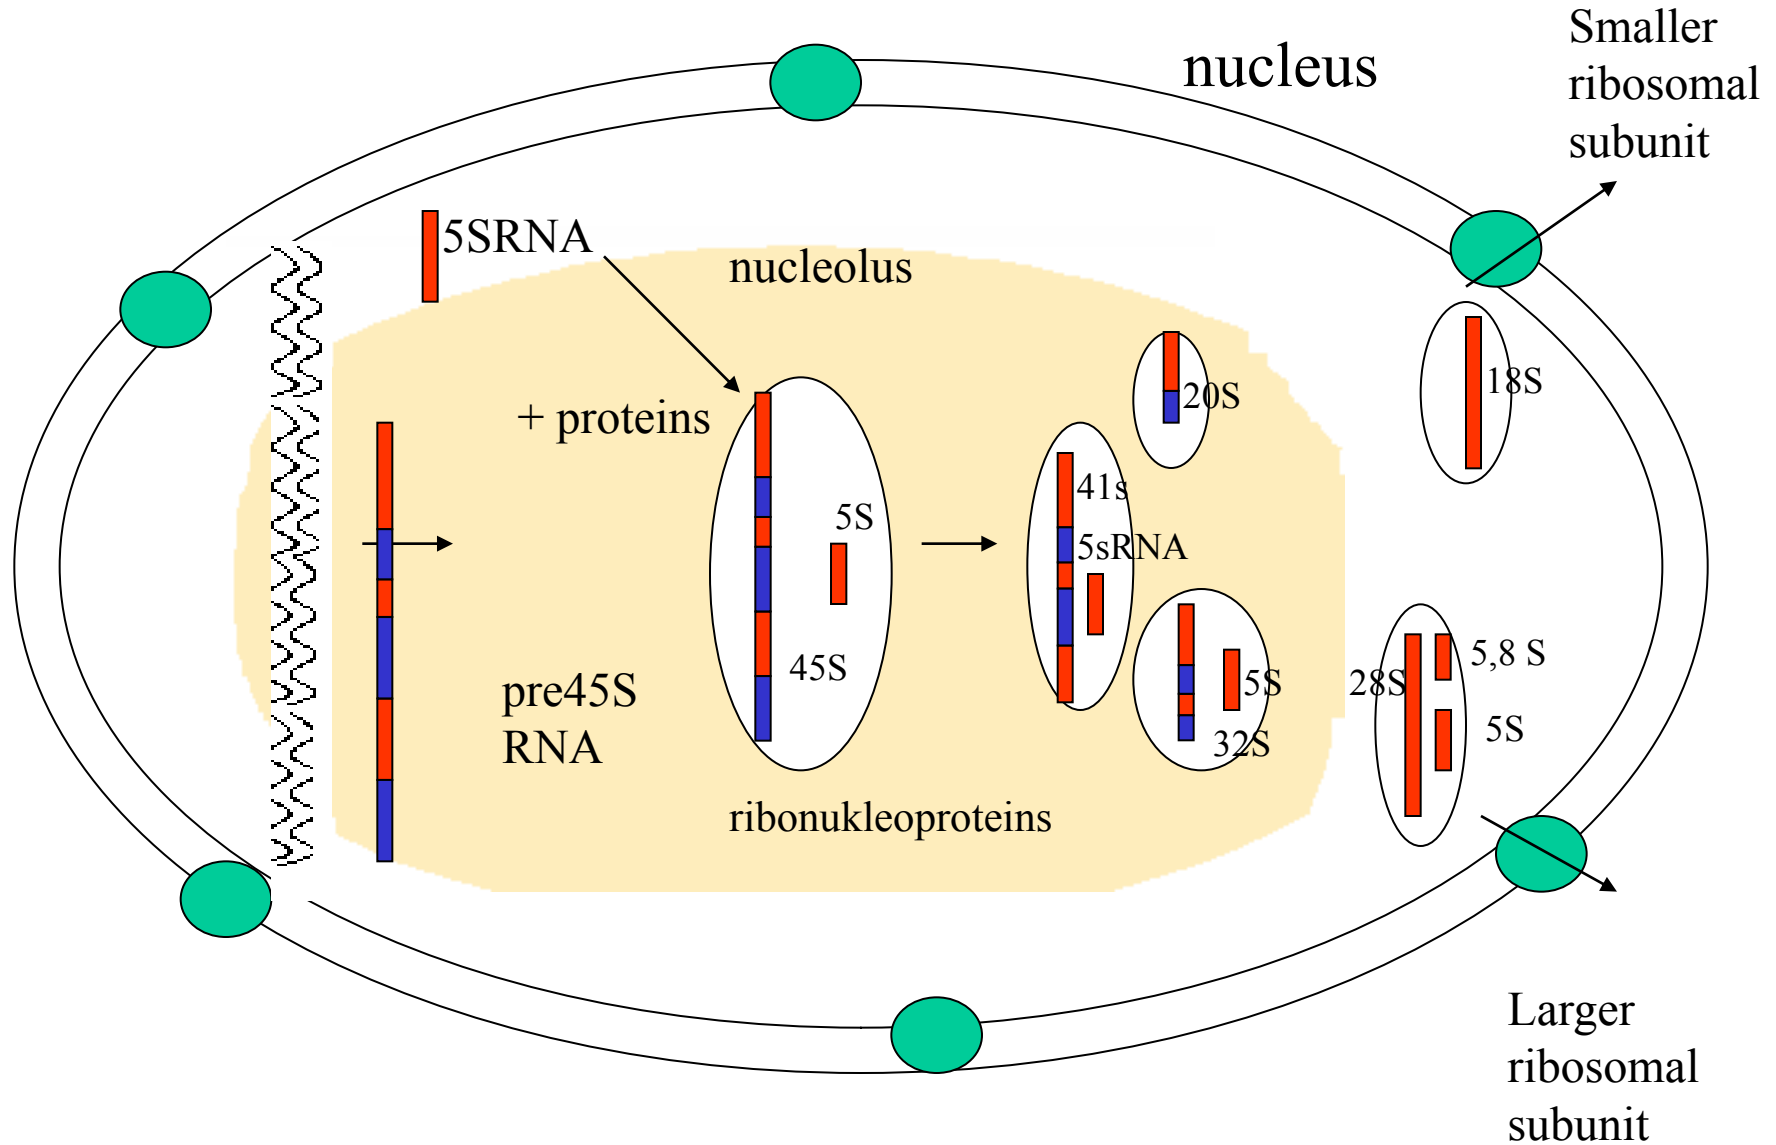

β -subunit of hemoglobin is not formed in sufficient amount

It results from point mutation in β -globin gene where the
G \rightarrow A mutation occurs

This creates a new splice acceptor site nineteen nucleotides upstream from the normal splice acceptor

A faulty beta-globin protein is made, leading to severe anemia.

Syntéza eukaryotic rRNA

Processing of 45 S eukaryotic rRNA

Synthesis of eukaryotic rRNA

Nucleolus:

45S RNA is synthesized in form of preRNA

Complexation with proteins – formation of ribonucleoproteins

Methylation and shortening

5S RNA is synthesized in nucleoplasm, it migrates into the nucleolus and is attached to ribonucleoproteins

Transport of shortened RNAs to nucleoplasm and through nuclear pores to cytoplasm. Formation of ribosomes.

Synthesis of eukaryotic tRNA

Synthesis in a form of pre t-RNA in the nucleus

Removal of nucleotide sequences on 5', 3' terminal and nucleotide intron in the anticodon loop

Modification of bases: methylation of uracil to thymine

dehydrogenation of uracil

formation of pseudouridine (C-C bond
between uracil and ribose)

deamination of adenosine to inosine

Addition of CCA sequence on 3' end

Migration to cytoplasm

Examples of tRNA processing:

Modification of some bases

Regulation of gene expression

Gene expression – formation of proteins or RNA products

Generally only small fraction of genes in a cell are expressed at any time

Gene expression is regulated differently in prokaryotes and eukaryotes

The main features of gene expression in prokaryotes

- only one DNA in the cell
- DNA is not complexed with histones
- nucleus is not separated from cytoplasm
- transcripts of genes do not include introns
- translation and transcription occur simultaneously

Regulation of gene expression in prokaryotes

Regulation is less complex than in the multicellular eukaryotes

Gene expression is regulated mainly by controlling the initiation of gene transcription.

The most extensively studied is bacterium *E. coli*. Its genome includes 4×10^6 base pairs → *E. coli* should be able to make several thousands of proteins

Under normal conditions they synthesize only about 600-800 different proteins.

Many genes are inactive and only those genes are expressed that generate the proteins required for growth in that particular environment

Operons theory

Structural genes of bacterias are grouped into units called operons

Operon

- It includes structural genes for proteins that are metabolically related
- Genes in operon are usually coordinately expressed (they are either all „turned on“, or all „turned off“)
- The product of transcription is single polycistronic mRNA
- Transcription is regulated by single promoter which is located in the operon at the 5'-end, upstream from the structural genes

Regulation of RNA polymerase binding by repressors – negative control

repressor is encoded by regulatory gene

Its product, the repressor protein, diffuses to the promoter and binds in the region of the operon called operator

Operator is located within the promoter or near of its 3'-end

Repressor blocks the binding of RNA-polymerase to the promoter

Synthesis of mRNA does not occur

Repressor is controlled by two mechanisms

Induction

Inductor is a small molecule that binds to repressor, changes its conformation and triggers its release from the operator

transcription can start

Inductors: small molecules of nutrients or their metabolites

Corepression

repressor is not active until corepressor is bonded to it. The complex repressor-corepressor binds to operator preventing binding of RNA polymerase

transcription stops

Corepressors: small molecules of nutrients or their metabolites

Example of induction

Induction of *lac* operon in *E.coli* by lactose

Enzymes for metabolizing glucose by glycolysis are produced constitutively

If the milk sugar lactose is available, the cell adapt and begin to produce three additional enzymes required for lactose metabolism

These enzymes are encoded by *lac* operon

A metabolite of lactose (**allolactose** -isomer of lactose that is formed spontaneously) serves as an inducer, binds to the repressor and inactivates it.

RNA polymerase can bind to promotor and transcribe the structural genes of the *lac* operon (β -galactosidase, permease and transacetylase)

Glucose can prevent activation of the *lac* operon (see fig.80)

Example of corepression

Corepression of *trp* operon (synthesis of tryptophane at *E.coli*)

genes for enzymes of tryptophane synthesis (5 enzymes) are located in *trp* operon

Tryptophan is corepressor, it binds to inactive repressor, binds its conformation.

The complex tryptophan-repressor inhibits transcription of operon.

<http://www.biology.ualberta.ca/facilities/multimedia/uploads/genetics/trpoperon2.swf>

Stimulation of RNA polymerase binding - positive control

Regulatory proteins binds to promoter and stimulate the binding of RNA-polymerase

Regulatory protein is activated on the base of presence/or absence of small molecule of nutrient of its metabolite in the cell

Catabolite repression

Example of positive control

Transcription of *lac* operon at E.coli

transcription of *lac* operon is affected by allolactose only when the glucose is absent

Decrease of glucose level results in increase of cAMP (it is not known why)

cAMP binds to its receptor in the cell (cAMP-receptor protein → CRP)

Complex cAMP-CRP binds to the regulatory site of *lac* operon, stimulates the binding of RNA polymerase to promotor and transcription of genes for metabolism of lactose

→ cells metabolize lactose, only when it does not have adequate supply of glucose

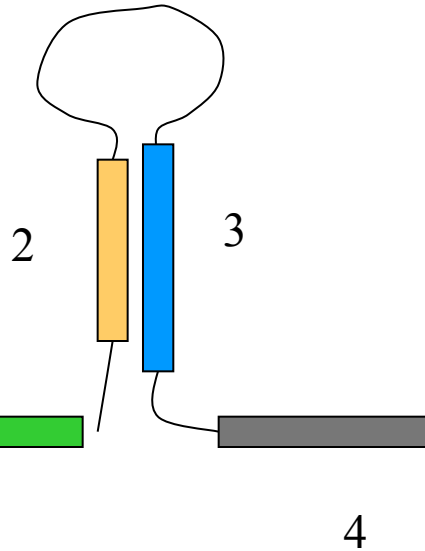

Attenuation of transcription

- Some operons are regulated by process that interrupts (attenuates) transcription after it has been initiated
- The cause is the change of secondary structure of mRNA
- Attenuator („retarder“) is a sequence included in operon
- Processes of translation occurs at the same time with transcription
- The rate of transcription affects the formation of hair-pin loops on mRNA

Attenuation of transcription – trp operon E.coli

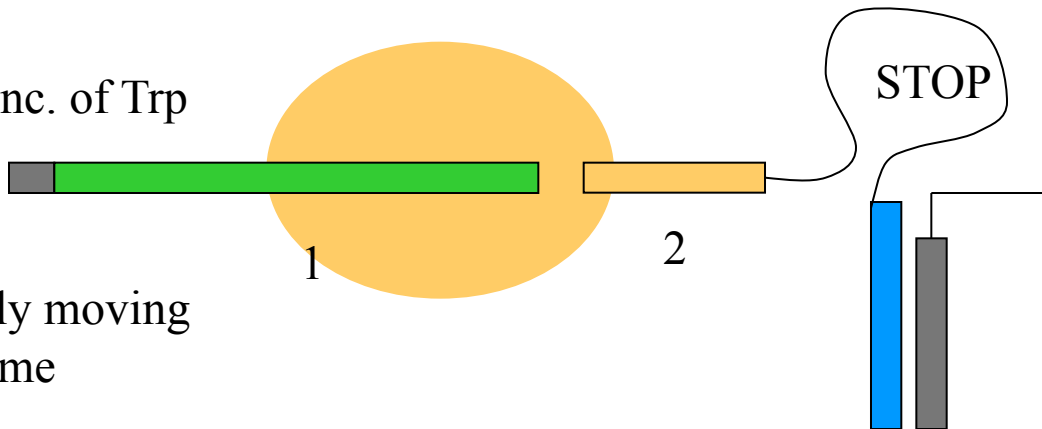

Low conc. of Trp

Sequence 1 contains codones for Trp

Ribosome is attenuated

High conc. of Trp

Quickly moving ribosome

Attenuation

- mRNA is transcribed from the trp operon, ribosomes bind to it and rapidly begin to translate the transcript.
- RNA polymerase is followed by moving ribosome
- near the 5' end of the transcript there are number of codons for trp.
- initially, high levels of trp in the cell result in high levels of trp-tRNA^{trp} and rapid translocation of the transcript
- rapid translocation generates a hairpin loop in the mRNA that serves as a termination signal for RNA polymerase and transcription terminates.
- when trp levels are low, levels of trp-tRNA^{trp} are low and ribosome stall at codons for trp. A different hairpin loop forms in mRNA that does not terminate transcription
- RNA polymerase can complete the transcription
- The level of transcription is regulated by the amount of trp in the cell

Regulation of protein synthesis in eukaryotes

The main features of gene expression in eukaryotes (differences from prokaryote):

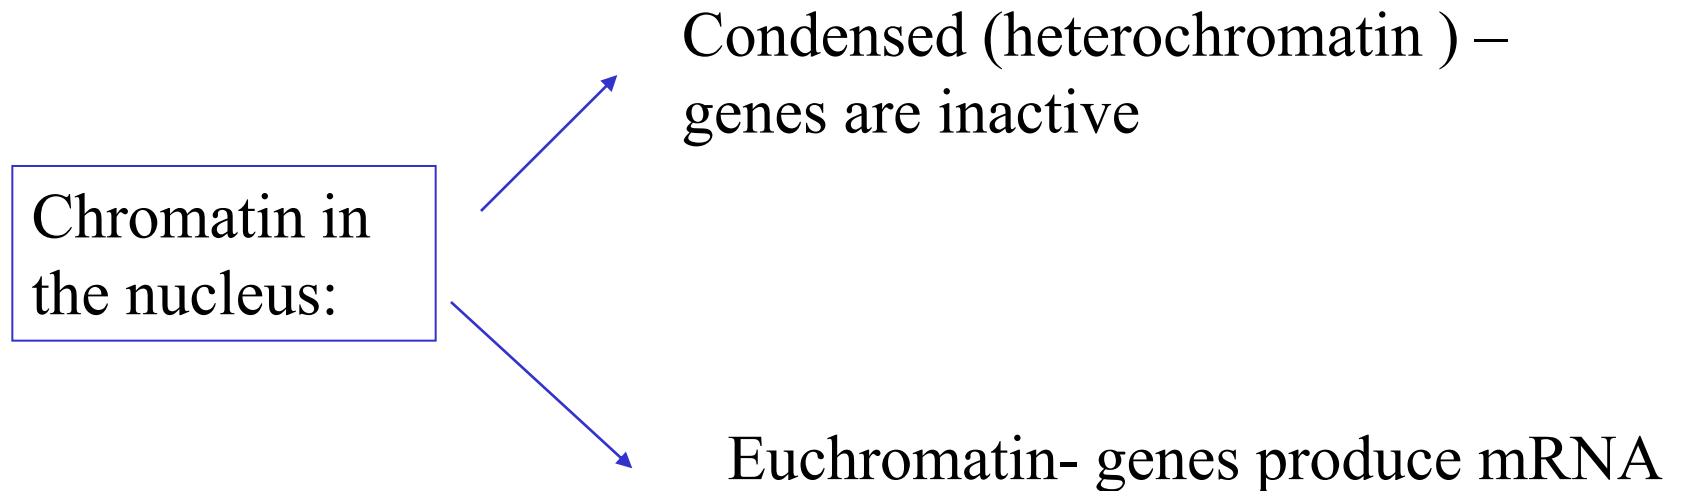

- DNA is organized in nucleosomes of chromatin
- gene must be in an active structure to be expressed in a cell
- operons are not present
- genes encoding metabolically related proteins are located on different chromosomes
- each gene has its promoter
- transcription and translation are separated

Regulation of eukaryotic cells gene expression occurs at multiple level

- A) DNA and the chromosome including chromosome remodeling and gene rearrangement
- B) transcription, primarily through transcription factors affecting binding of RNA polymerase
- C) processing of transcripts
- D) initiation of translation and stability of mRNA

Regulation of availability of genes for transcription

In cells of differentiated tissues only the genes that have some role in the cell are active

Long-term changes in the activity of genes occur during development as chromatin goes from a diffuse to a condensed state and vice versa.

A) Examples of regulation on the chromosom structure level

- Chromatin remodeling
- DNA methylation
- gene rearrangement
- gene amplification
- gene deletion

➤ Chromatin remodeling

- change of chromatin state that results in activation of transcription

→ displacement of nucleosome from chromatin so that the transcription can start

Remodeling mechanisms:

- an ATP driven unwinding of certain section of DNA from nucleosome core
- covalent modification of the histone tails through acetylation or deacetylation (acetylation of ϵ -amino group in side chain of lysin on N-terminals of histones H2A, H2B, H3 and H4).

ATP driven unwinding of certain section of DNA from nucleosome core

Significance of histon-acetyltransferase and histon deacetylase

Histon-acetyltransferase catalyzes acetylation of histones.

This reaction removes a positive charge from the ϵ -amino group of the lysine, thereby reducing the electrostatic interactions between the histones and the negatively charged DNA \rightarrow this results in an easier unwinding. This makes RNA polymerase and transcription factors easier to access the promoter region. Therefore, in most cases, histone acetylation enhances transcription while histone deacetylation represses transcription.

➤ DNA methylation

Methylation of cytosine residues in DNA by SAM → 5-methylcytosine

Methylations are located in GC-rich sequences (GC-islands) that are often near or in the promoter region of gene (postsynthetic modification of DNA – enzym methylase)

Genes that are methylated are less readily transcribed

Example: globin genes are more extensively methylated in nonerythroid cells than in cells in which these genes are expressed (erythroblasts and reticulocytes)

DNA methylation

Initiation of transcription

Transcription is inhibited by methylation

➤ Gene rearrangement

Segments of DNA can move from one location to another in the genome, associating with each other in various ways

Example : rearrangement of genes in cells that produce antibodies (immunoglobulins)
(see Immunology)

➤ Gene amplification

Certain region of a chromosome undergo repeated cycles of DNA replication
The newly synthesized DNA is excised and forms small, unstable chromosomes called double minutes.

They integrate into other chromosomes thereby amplifying the gene in the process.

It is not usual physiological means of regulating of gene expression in normal cells, it occurs in response to certain stimuli

Normally gene amplification occurs through errors during DNA replication and cell division – then cells containing amplified genes may have a growth advantage, if the environmental conditions are appropriate.

Example: patients treated by methotrexate (inhibitor of dihydrofolate reductase) can develop drug resistance.

The cause is that some rapidly dividing cancer cells amplify the gene for dihydrofolate reductase, producing hundreds of copies in the genome. These cells generate large amount of dihydrofolate reductase and normal doses of methotrexate are not longer adequate.

B) Regulation at the level of transcription

Basal regulation of transcription (common for all genes)

Regulation by the components of „basal transcription complex“
(RNA polymerase binding the TATA box, TATA binding proteins and further basal transcription factors binding on promoter or RNA-polymerase)

Genes regulated only in this way:

constitutively expressed genes

Specific regulation of gene expression:

Gene specific transcription factors bind to the specific regulatory sequences.

Regulation of transcription factors

Down(up)-regulation of transcription factors

formation (see SRBP in synthesis of cholesterol)

Modulation by binding of stimulatory and inhibitory ligands (CREBP)

Mutual cooperation of transcription factors

Phosphorylation/ dephosphorylation of transcription factors regulated growth factors, cytokines, peptide hormones atd.

C) Postranscriptional regulation

Alternative splicing

Alternative splicing and variation of the site of polyadenylation cause that one gene can produce various proteins (see the lecture 13)

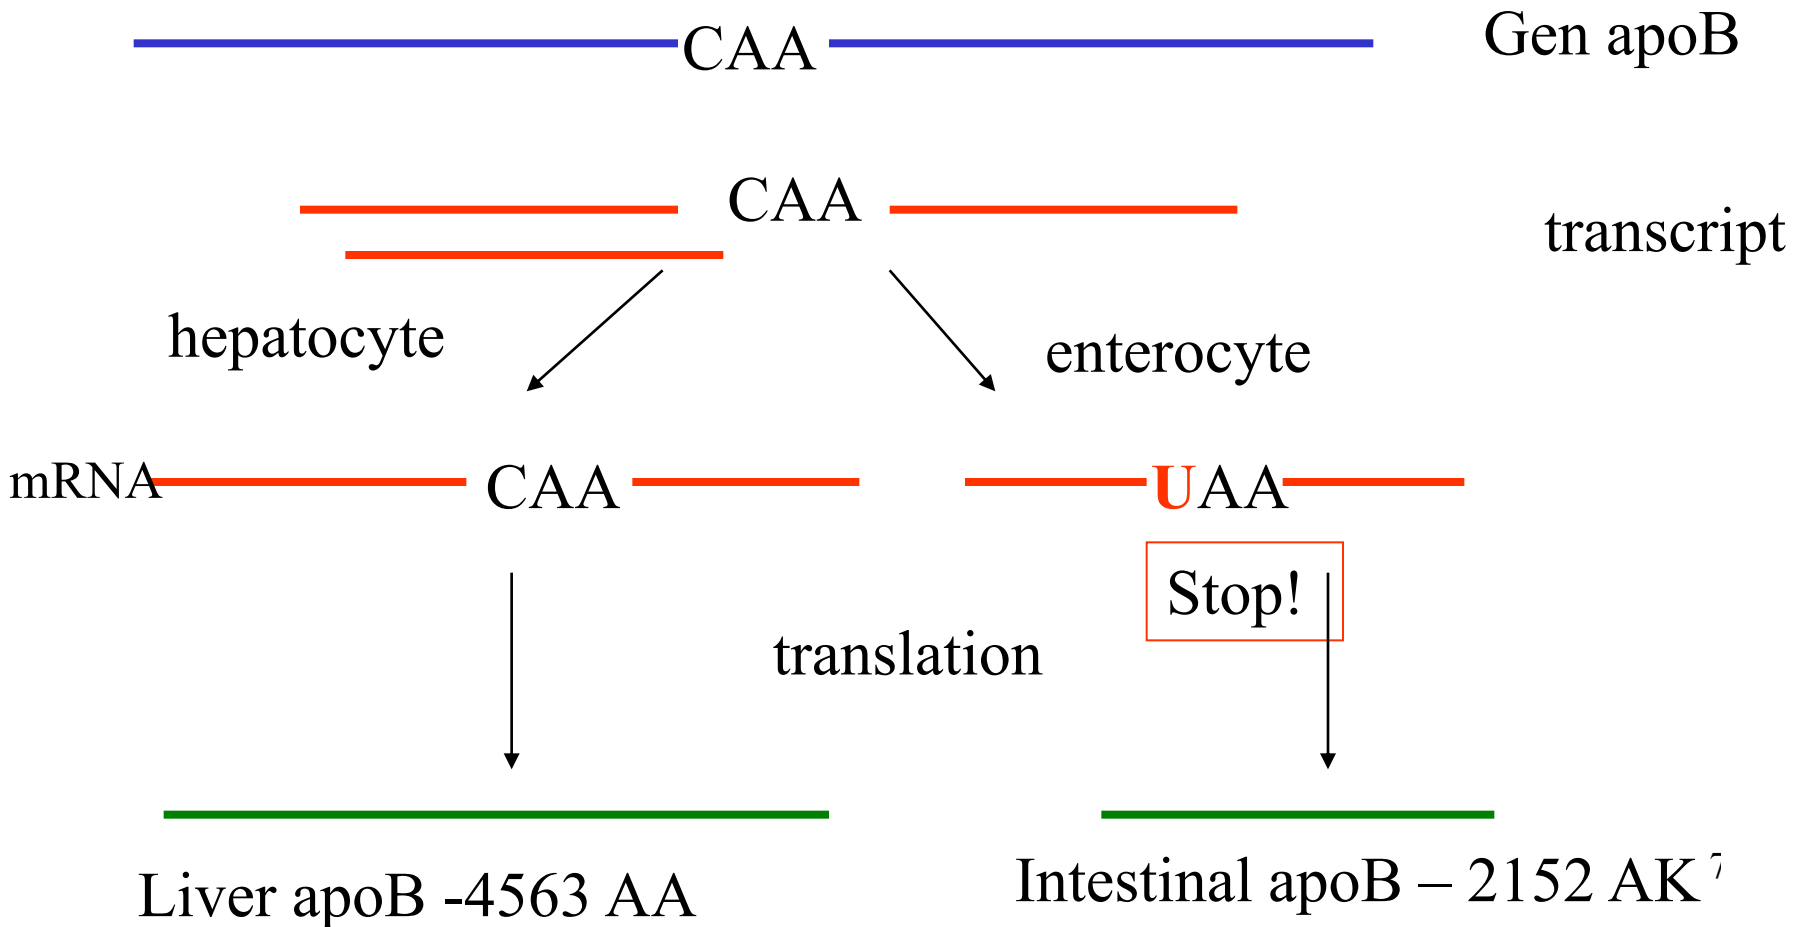

RNA editing

In some instances, RNA is „edited“ after transcription.

Primary transcript and the sequence of gene are the same, but bases are altered or nucleotides are added or deleted after the transcript is synthesized.

RNA editing

synthesis of apoB in hepatocytes and enterocytes

Synthesis apoB in hepatocytes and enterocytes (apo B is a component of chylomicrons and VLDL)

Gen apoB produces protein containing 4563 amino acids in liver

The same gene produces apoB containing only 2152 amino acids in enterocytes

Conversion of C(cytosin) to U (uracil) by deamination of mRNA transcript generates the stop-codon in intestinal mRNA. Thus the protein formed in the enterocyte has only 48% of length in comparison with apoB in liver

D) Regulation at the level of translation

Regulation usually involves the initiation of protein synthesis by eIFs (eukaryotic initiation factors)
