## Contents – practice

Chapter 1. Initial warmup	4
A. Numbers and functions	4
B. Difference equations	9
C. Combinatorics	13
D. Probability	18
E. Plane geometry	28
F. Relations and mappings	41
G. Additional exercises for the whole chapter	47
Chapter 2. Elementary linear algebra	68
A. Vectors and matrices	68
B. Determinants	83
C. Vector spaces and linear mappings	92
D. Properties of linear maps	112
E. Additional exercises for the whole chapter	124
Chapter 3. Linear models and matrix calculus	140
A. Linear optimization	140
B. Difference equations	147
C. Population models	155
D. Markov processes	162
E. Unitary spaces	168
F. Matrix decompositions	172
G. Additional exercises for the whole chapter	203
Chapter 4. Analytic geometry	230
A. Affine geometry	230
B. Euclidean geometry	239
C. Geometry of quadratic forms	255
D. Further exercise on this chapter	270
Chapter 5. Establishing the ZOO	278
A. Polynomial interpolation	278
B. Topology of real numbers and their subsets	287
C. Limits	289
D. Continuity of functions	306
E. Derivatives	309
F. Extremal problems	315
G. L'Hospital's rule	329
H. Infinite series	335
I. Power series	341
J. Additional exercises for the whole chapter	346
Chapter 6. Differential and integral calculus	372
A. Derivatives of higher orders	372
B. Integration	392
C. Power series	426

## Contents – theory

Chapter 1. Initial warmup	4
1. Numbers and functions	4
2. Difference equations	10
3. Combinatorics	14
4. Probability	18
5. Plane geometry	27
6. Relations and mappings	41
Chapter 2. Elementary linear algebra	68
1. Vectors and matrices	68
2. Determinants	81
3. Vector spaces and linear mappings	92
4. Properties of linear mappings	112
Chapter 3. Linear models and matrix calculus	140
1. Linear optimization	140
2. Difference equations	149
3. Iterated linear processes	158
4. More matrix calculus	168
5. Decompositions of the matrices and pseudoinversions	192
Chapter 4. Analytic geometry	230
1. Affine and Euclidean geometry	230
2. Geometry of quadratic forms	252
3. Projective geometry	259
Chapter 5. Establishing the ZOO	278
1. Polynomial interpolation	278
2. Real numbers and limit processes	289
3. Derivatives	312
4. Infinite sums and power series	326
Chapter 6. Differential and integral calculus	372
1. Differentiation	372
2. Integration	392
3. Sequences, series and limit processes	417
Chapter 7. Continuous tools for modelling	450
1. Fourier series	450
2. Integral operators	472
3. Metric spaces	483
Chapter 8. Calculus with more variables	510
1. Functions and mappings on $\mathbb{R}^n$	510
2. Integration for the second time	548
3. Differential equations	562

D. Extra examples for the whole chapter	440	Chapter 9. Continuous models – further selected topics	607
Chapter 7. Continuous tools for modelling	450	1. Exterior differential calculus and integration	607
A. Orthogonal systems of functions	450	2. Remarks on Partial Differential Equations	631
B. Fourier series	454	3. Remarks on Variational Calculus	662
C. Convolution and Fourier Transform	470	4. Complex Analytic Functions	677

## Preface

The motivation for this textbook came from many years of lecturing Mathematics at the Faculty of Informatics at the Masaryk University in Brno. The programme requires introduction to genuine mathematical thinking and precision. The endeavor was undertaken by Jan Slovák and Martin Panák since 2004, with further collaborators joining later. Our goal was to cover seriously, but quickly, about as much of mathematical methods as usually seen in bigger courses in the classical Science and Technology programmes. At the same time, we did not want to give up the completeness and correctness of the mathematical exposition. We wanted to introduce and explain more demanding parts of Mathematics together with elementary explicit examples how to use the concepts and results in practice. But we did not want to decide how much of theory or practice the reader should enjoy and in which order.

All these requirements have led us to the two column format of the textbook, where the theoretical explanation on one side and the practical procedures and exercises on the other side are split. This way, we want to encourage and help the readers to find their own way. Either to go through the examples and algorithms first, and then to come to explanations why the things work, or the other way round. We also hope to overcome the usual stress of the readers horrified by the amount of the stuff. With our text, they are not supposed to read through the book in a linear order. On the opposite, the readers should enjoy browsing through the text and finding their own thrilling paths through the new mathematical landscapes.

In both columns, we intend to present rather standard exposition of basic Mathematics, but focusing on the essence of the concepts and their relations. The exercises are addressing simple mathematical problems but we also try to show the exploitation of mathematical models in practice as much as possible.

We are aware that the text is written in a very compact and non-homogeneous way. A lot of details are left to readers, in particular in the more difficult paragraphs, while we try to provide a lot of simple intuitive explanation when introducing new concepts or formulating important theorems. Similarly, the examples display the variety from very simple ones to those requesting independent thinking.

We would very much like to help the reader:

- to formulate precise definitions of basic concepts and to prove simple mathematical results;
- to perceive the meaning of roughly formulated properties, relations and outlooks for exploring mathematical tools;
- to understand the instructions and algorithms underlying mathematical models and to appreciate their usage.

These goals are ambitious and there are no simple paths reaching them without failures on the way. This is one of the reasons why we come back to basic ideas and concepts several times with growing complexity and width of the discussions. Of course, this might also look chaotic but we very much hope that this approach gives a better chance to those who will persist in their efforts. We also hope, this textbook should be a perfect beginning and help for everybody who is ready to think and who is ready to return back to earlier parts again and again.

To make the task simpler and more enjoyable, we have added what we call "emotive icons". We hope they will spirit the dry mathematical text and indicate which parts should be read more carefully, or better left out in the first round.

The usage of the icons follows the feelings of the authors and we tried to use them in a systematic way. We hope the readers will assign the meaning to icons individually. Roughly speaking, we are using icons to indicate complexity, difficulty etc.:

Further icons indicate unpleasant technicality and need of patience, or possible entertainment and pleasure:

Similarly, we use various icons in the practical column:

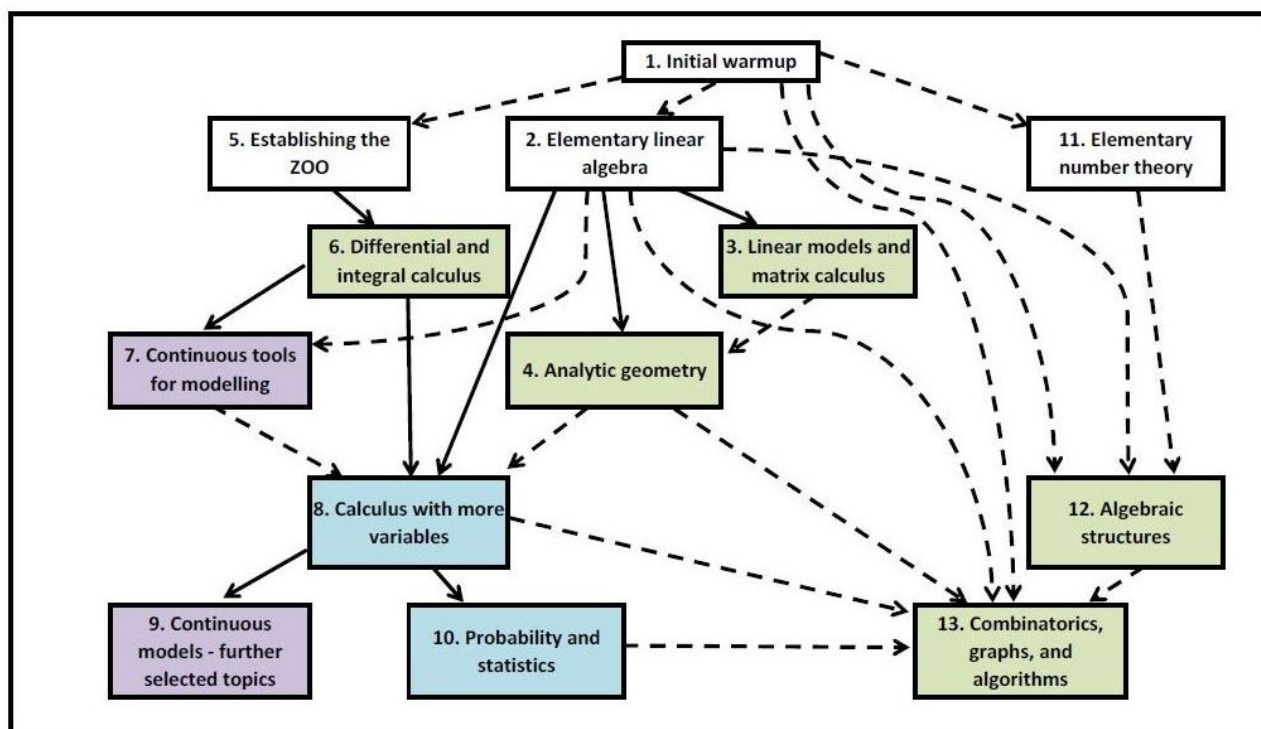

The practical column with the solved problems and exercises should be readable nearly independently of the theory. Without the ambition to know the deeper reasons why the algorithms work, it should be possible to read mainly just this column. In order to help such readers, some definitions and descriptions in the theoretical text are marked in order to catch the eyes easily when reading the exercises. The exercises and theory are partly coordinated to allow jumping there and back, but the links are not tight. The numbering in the two columns is distinguished by using the different numberings of sections, i.e. those like 1.2.1 belong to the theoretical column, while 1.B.4 points to the practical column. The equations are numbered within subsections and their quotes include the subsection numbers if necessary.

In general, our approach stresses the fact that the methods of the so called discrete Mathematics seem to be more important for mathematical models nowadays. They seem also simpler to get perceived and grasped.

However, the continuous methods are strictly necessary too. First of all, the classical continuous mathematical analysis is essential for understanding of convergence and robustness of computations. It is hard to imagine how to deal with error estimates and computational complexity of numerical processes without it. Moreover, the continuous models are often the efficient and effectively computable approximations to discrete problems coming from practice.

As usual with textbooks, there are numerous figures completing the exposition. We very much advise the readers to draw their own pictures whenever necessary, in particular in the later chapters, where we provide only a few.

The rough structure of the book and the dependencies between its chapters are depicted in the diagram below. The darker the color is, the more demanding is the particular chapter (or at least its essential parts). In particular, the chapters 7 and 9 include a lot of material which would perhaps not be covered in the regular course activities or required at exams in great detail. The solid arrows mean strong dependencies, while the dashed links indicate only partial dependencies. In particular, the textbook could support courses starting with any of the white boxes, i.e. aiming at standard linear algebra and geometry (chapters 2 through 4), discrete chapters of mathematics (11 through 13), and the rudiments of Calculus (5, 6, 8).

All topics covered in the book are now included (with more or less details) in our teaching of large four semester courses within our Mathematics minor programme, complemented by numerical seminars. In our teaching, the first semester covers chapters 1 and 2 and selected topics from chapters 3 and 4. The second semester essentially includes chapters 5, 6, and 7. The third semester is now split into two parts. The first one is covered by chapter 8 (with only a few glimpses towards the more advanced topics from chapter 9), while the rest of the semester is devoted to the rudiments of the graph theory in chapter 13. The last semester provides large parts of the chapters 11 through 13. Actually, the second semester could be offered in parallel with the first one, while the fourth semester could follow immediately after the first one. Probability and statistics (chapter 10) are offered as separate course in parallel.

## CHAPTER 1

### Initial warmup

“value, difference, position”

– what it is and how to comprehend it?

#### A. Numbers and functions

We can already work with natural, integer, rational and real numbers. We explain why rational numbers are not sufficient for us (although computers are actually not able to work with any other) and we recall the complex numbers (because even the real numbers are not adequate for some calculations).

**1.A.1.** Show that the integer 2 does not have a rational square root.

**Solution.** Already the ancient Greeks knew that if we prescribe the area of square as  $a^2 = 2$ , then we cannot find a rational  $a$  to satisfy it. Why?

Assume we know that  $(p/q)^2 = 2$  for natural numbers  $p$  and  $q$  that do not have common divisors greater than 1 (otherwise we can further reduce the fraction  $p/q$ ). Then  $p^2 = 2q^2$  is an even number. Thus, on the left-hand side  $p^2$  is even. Therefore so is  $p$  because the alternative that  $p$  is odd would imply the contradiction that  $p^2$  is odd. Hence,  $p$  is even and so  $p^2$  is divisible by 4. So  $q^2$  is even and so  $q$  must be even too. This implies that  $p$  and  $q$  both have 2 as a common factor, which is a contradiction.  $\square$

The goal of this first chapter is to introduce the reader to the fascinating world of mathematical thinking.

The name of this chapter can be also understood as an encouragement for patience. Even the simplest tasks and ideas are easy only for those who have already seen similar ones. A full knowledge of mathematical thinking can be reached only through a long and complicated course of study.

We start with the simplest thing: numbers.

They will also serve as the first example of how mathematical objects and theories are built. The entire first chapter will become a quick tour through various mathematical landscapes (including germs of analysis, combinatorics, probability, geometry).

Perhaps sometimes our definitions and ideas will look too complicated and not practical enough. The simpler the objects and tasks are, the more difficult the mastering of depth and all nuances of the relevant tools and procedures might be. We shall come back to all of the notions again and again in the further chapters and hopefully this will be the crucial step in the ultimate understanding.

Thus the advice: do not worry if you find some particular part of the exposition too formal or otherwise difficult – come back later for another look.

#### 1. Numbers and functions

Since the dawn of time, people want to know “how much” about something they have, or “how much” is something worth, “how long” will a particular task take, etc. The answer for such ideas is usually some kind of “number”. We consider something to be a number, if it behaves according to the usual rules – either according to all the rules we accept, or maybe only to some of them. For instance, the result of multiplication does not depend on the order of multiplicands. We have the number zero whose addition to another number does not change the result. We have the number one whose product with another number does not change the result. And so on.

The simplest example of numbers are the positive integers which we denote  $\mathbb{Z}^+ = \{1, 2, 3, \dots\}$ . The natural numbers consist of either just the positive integers, or the positive integers together with the number zero. The number zero is

**1.A.2. Remark.** It can be proved that for all positive natural numbers  $n$  and  $x$  the  $n$ -th root  $\sqrt[n]{x}$  of  $x$  is either natural or it is not rational, see 1.G.1.

Next, we work out some examples with complex numbers. If you are not familiar with the basic concepts and properties of complex numbers, consult the paragraphs 1.1.3 through 1.1.4 in the other column.

**1.A.3.** Calculate  $z_1 + z_2$ ,  $z_1 \cdot z_2$ ,  $\bar{z}_1$ ,  $|z_2|$ ,  $\frac{z_1}{z_2}$ , for

- a)  $z_1 = 1 - 2i$ ,  $z_2 = 4i - 3$ ;
- b)  $z_1 = 2$ ,  $z_2 = i$ .

**Solution.**

- a)  $z_1 + z_2 = 1 - 3 - 2i + 4i = -2 + 2i$ ,  $z_1 \cdot z_2 = 1 \cdot (-3) - 8i^2 + 6i + 4i = 5 + 10i$ ,  $\bar{z}_1 = 1 + 2i$ ,  $|z_2| = \sqrt{4^2 + (-3)^2} = 5$ ,  $\frac{z_1}{z_2} = \frac{z_1 \bar{z}_2}{|z_2|^2} = \frac{1 \cdot (-3) + 8i^2 + 6i - 4i}{25} = -\frac{11}{25} + \frac{2}{25}i$ .
- b)  $z_1 + z_2 = 2 + i$ ,  $z_1 \cdot z_2 = 2i$ ,  $\bar{z}_1 = 2$ ,  $|z_2| = 1$ ,  $\frac{z_1}{z_2} = \frac{2}{i} = -2i$ .

□

**1.A.4.** Determine

$$\left| \frac{(2+3i)(1+i\sqrt{3})}{1-i\sqrt{3}} \right|.$$

either considered to be a natural number, as is usual in computer science, or not a natural number as is usual in some other contexts.

Thus the set of natural numbers is either  $\mathbb{Z}^+$ , or the set  $\mathbb{N} = \{0, 1, 2, 3, \dots\}$ . To count “one, two, three, ...” is learned already by children in their pre-school age. Later on, we meet all the integers  $\mathbb{Z} = \{\dots, -2, -1, 0, 1, 2, \dots\}$  and finally we get used to floating-point numbers. We know what a 1.19-multiple of the price means if we have a 19% tax.

**1.1.1. Properties of numbers.** In order to be able to work properly with numbers, we need to be careful with their definition and properties. In mathematics, the basic statements about properties of objects, whose validity is assumed without the need to prove them, are called *axioms*.

We list the basic properties of the operations of addition and multiplication for our calculations with numbers, which we denote by letters  $a, b, c, \dots$ . Both operations work by taking two numbers  $a, b$ . By applying addition or multiplication we obtain the resulting values  $a + b$  and  $a \cdot b$ .

PROPERTIES OF NUMBERS

**Properties of addition:**

- (CG1)  $(a + b) + c = a + (b + c)$ , for all  $a, b, c$
- (CG2)  $a + b = b + a$ , for all  $a, b$
- (CG3) there exists 0 such that for all  $a$ ,  $a + 0 = a$
- (CG4) for all  $a$  there exists  $b$  such that  $a + b = 0$ .

The properties (CG1)-(CG4) are called the properties of a *commutative group*. They are called respectively *associativity*, *commutativity*, *the existence of a neutral element* (when speaking of addition we usually say zero element), and *the existence of an inverse element* (when speaking of addition we also say the negative of  $a$  and denote it by  $-a$ ).

**Properties of multiplication:**

- (R1)  $(a \cdot b) \cdot c = a \cdot (b \cdot c)$ , for all  $a, b, c$
- (R2)  $a \cdot b = b \cdot a$ , for all  $a, b$
- (R3) there exists 1 such that for all  $a$ ,  $1 \cdot a = a$
- (R4)  $a \cdot (b + c) = a \cdot b + a \cdot c$ , for all  $a, b, c$ .

The properties (R1)-(R4) are called respectively *associativity*, *commutativity*, *the existence of a unit element* and *distributivity of addition with respect to multiplication*. The sets with operation  $+$ ,  $\cdot$  that satisfy the properties (CG1)-(CG2) and (R1)-(R4) are called *commutative rings*. Two further properties of multiplication are:

- (F) for every  $a \neq 0$  there exists  $b$  such that  $a \cdot b = 1$ .
- (ID) if  $a \cdot b = 0$ , then either  $a = 0$  or  $b = 0$  or both.

The property (F) is called *the existence of an inverse element with respect to multiplication* (this element is then denoted by  $a^{-1}$ ). For normal arithmetic, this is called the reciprocal of  $a$ , the same as  $1/a$  or  $\frac{1}{a}$ .

**Solution.** Since the absolute value of the product (ratio) of any two complex numbers is the product (ratio) of their absolute values and every complex number has the same absolute value as its complex conjugate, we have that

$$\begin{aligned} \left| \frac{(2+3i)(1+i\sqrt{3})}{1-i\sqrt{3}} \right| &= |2+3i| \cdot \frac{|1+i\sqrt{3}|}{|1-i\sqrt{3}|} = |2+3i| \\ &= \sqrt{2^2+3^2} = \sqrt{13}. \quad \square \end{aligned}$$

**1.A.5.** Simplify the expression  $(5\sqrt{3} + 5i)^n$  for  $n = 2$  and  $n = 12$ .

**Solution.** Using binomial theorem for  $n = 2$  we get

$$(5\sqrt{3} + 5i)^2 = 75 + 10\sqrt{3} \cdot 5i - 25 = 50 + 50\sqrt{3}i.$$

Taking powers one by one or doing an expansion using binomial theorem are in the case  $n = 12$  too much time-consuming. Let us rather write the number in polar form

$$5\sqrt{3} + 5i = 10 \left( \frac{\sqrt{3}}{2} + \frac{i}{2} \right) = 10 \left( \cos \frac{\pi}{6} + i \sin \frac{\pi}{6} \right)$$

and using de Moivre theorem we easily obtain

$$(5\sqrt{3} + 5i)^{12} = 10^{12} \left( \cos \frac{12\pi}{6} + i \sin \frac{12\pi}{6} \right) = 10^{12}. \quad \square$$

**1.A.6.** Determine the distance  $d$  of the numbers  $z, \bar{z}$  in the complex plane for

$$z = \frac{\sqrt{3}\sqrt{3}}{2} - i \frac{3}{2}.$$

**Solution.** It is not difficult to realize that complex conjugates are in the complex plane symmetric with respect to the  $x$ -axis and the distance of a complex number from the  $x$ -axis equals its imaginary part. That gives  $d = 3$ .  $\square$

**1.A.7.** Express the number  $z_1 = 2 + 3i$  in polar form. Express the number  $z_2 = 3(\cos(\pi/3) + i \sin(\pi/3))$  in algebraic form.

**Solution.** The absolute value of  $|z_1|$  (the distance of the point with Cartesian coordinates  $[2, 3]$  in the plane from the origin) is  $\sqrt{2^2 + 3^2} = \sqrt{13}$ . From the right triangle in the diagram we compute  $\sin(\varphi) = 3/\sqrt{13}$ ,  $\cos(\varphi) = 2/\sqrt{13}$ . Thus  $\varphi = \arcsin(3/\sqrt{13}) = \arccos(2/\sqrt{13}) \doteq 56.3^\circ$ . In total,

$$\begin{aligned} z_1 &= \sqrt{13} \left( \frac{2}{\sqrt{13}} + i \cdot \frac{3}{\sqrt{13}} \right) \\ &= \sqrt{13} \left( \cos \left( \arccos \left( \frac{2}{\sqrt{13}} \right) \right) + i \sin \left( \arcsin \left( \frac{3}{\sqrt{13}} \right) \right) \right). \end{aligned}$$

Transition from polar form to algebraic form is even simpler:

$$\begin{aligned} z_2 &= 3 \left( \cos \left( \frac{\pi}{3} \right) + i \sin \left( \frac{\pi}{3} \right) \right) = 3 \left( \frac{1}{2} + i \cdot \frac{\sqrt{3}}{2} \right) \\ &= \frac{3}{2} + i \cdot \frac{3\sqrt{3}}{2}. \quad \square \end{aligned}$$

The property (ID) then says that there exists no “divisors of zero”. A *divisor of zero* is a number  $a$ ,  $a \neq 0$ , such that there is a number  $b$ ,  $b \neq 0$ , with  $ab = 0$ .

**1.1.2. Remarks.** The integers  $\mathbb{Z}$  are a good example of a commutative group. The natural numbers are not such an example since they do not satisfy (CG4) (and possibly do not even contain the neutral element if one does not consider zero to be a natural number). If a commutative ring also satisfies the property (F), we speak of a *field* (often also about a *commutative field*).

The last stated property (ID) is automatically satisfied if (F) holds. However, the converse statement is false. Thus we say that the property (ID) is weaker than (F). For example, the ring of integers  $\mathbb{Z}$  does not satisfy (F) but does satisfy (ID). In such a case we use the term *integral domain*.

Notice that the set of all non-zero elements in the field along with the operation of multiplication satisfies (R1), (R2), (R3), (F) and thus is also a commutative group. However in this case, instead of addition we speak of multiplication. As an example, the set of all non-zero real numbers forms a commutative group under multiplication.

The elements of some set with operations  $+$  and  $\cdot$  satisfying (not necessarily all) stated properties (for example, a commutative field, an integral domain) may be called *scalars*. To denote them we usually use lowercase Latin letters, either from the beginning or from the end of the alphabet.

We will use only these properties of scalars and thus our results will hold for any objects with such properties. This is the true power of mathematical theories – they do not hold just for a specific solved example. Quite the opposite, when we build ideas in a rational way they are always universal. We will try to emphasise this aspect, although our ambitions are modest due to the limited size of this book.

Before coming to any use of scalars, we should make a short formal detour and pay attention to their existence. We shall come back to this in the very end of this chapter, when we shall deal with the formal language of Mathematics in general, cf. the constructions starting in 1.6.5. There we indicate how to get natural numbers  $\mathbb{N}$ , integers  $\mathbb{Z}$ , and rational numbers  $\mathbb{Q}$ , while the real numbers  $\mathbb{R}$  will be treated much later in chapter 5.

At this point, let us just remark that it is not enough to pose the axioms of objects. We have to be sure that the given conditions are not in conflict and such objects might exist.

We suppose the readers are sure about the existence of the domains  $\mathbb{N}$ ,  $\mathbb{Z}$ ,  $\mathbb{Q}$  and can handle them easily. The real numbers are usually understood as a dense and better version of  $\mathbb{Q}$ , but what about the domain of complex numbers?

As is usual in mathematics, we will use variables (letters of alphabet or other symbols) to denote numbers, and it does not matter whether we know their value beforehand or not.

**1.A.8.** Express  $z = \cos 0 + \cos \frac{\pi}{3} + i \sin \frac{\pi}{3}$  in polar form.

**Solution.** To express number  $z$  in polar form, we need to find its absolute value and argument. First we calculate the absolute value:

$$\begin{aligned} |z| &= \sqrt{\left(\cos 0 + \cos \frac{\pi}{3}\right)^2 + \sin^2 \frac{\pi}{3}} \\ &= \sqrt{\left(1 + \frac{1}{2}\right)^2 + \left(\frac{\sqrt{3}}{2}\right)^2} = \sqrt{3}. \end{aligned}$$

For the argument  $\varphi$ , we have:

$$\cos \varphi = \frac{\operatorname{Re}(z)}{|z|} = \frac{1 + \frac{1}{2}}{\sqrt{3}} = \frac{\sqrt{3}}{2}, \quad \sin \varphi = \frac{\operatorname{Im}(z)}{|z|} = \frac{1}{2},$$

therefore  $\varphi = \pi/6$ . Thus

$$z = \sqrt{3} \left( \cos \frac{\pi}{6} + i \sin \frac{\pi}{6} \right). \quad \square$$

**1.A.9.** Using de Moivre theorem, calculate

$$\left( \cos \frac{\pi}{6} + i \sin \frac{\pi}{6} \right)^{31}.$$

**Solution.** We obtain

$$\begin{aligned} &\left( \cos \frac{\pi}{6} + i \sin \frac{\pi}{6} \right)^{31} \\ &= \cos \frac{31\pi}{6} + i \sin \frac{31\pi}{6} = \cos \frac{7\pi}{6} + i \sin \frac{7\pi}{6} = -\frac{\sqrt{3}}{2} - i \frac{1}{2}. \end{aligned} \quad \square$$

**1.A.10.** Is the “square root” well defined function in complex numbers?

**Solution.** No, it is only defined as a function with domain being non-negative real numbers and the image being the same set.

In the complex domain, for any complex number  $z$  (except zero) there are two complex numbers such that their square is equal  $z$ . Both can be called square root and they differ by sign (square root of  $-1$  is according to this definition  $i$  as well as  $-i$ ).  $\square$

**1.1.3. Complex numbers.** We are forced to extend the domain of real numbers as soon as we want to see solutions of equations like  $x^2 = b$  for all real numbers  $b$ .

We know that this equation always has a solution  $x$  in the domain of real numbers, whenever  $b$  is non-negative. If  $b < 0$ , then such a real  $x$  cannot exist. Thus we need to find a larger domain, where this equation has a solution.

The crucial idea is to add the new number  $i$  to the real numbers, the *imaginary unit*, for which we require  $i^2 = -1$ . Next we try to extend the definitions of addition and multiplication in order to preserve the usual behaviour of numbers (as summarised in 1.1.1).

Clearly we need to be able to multiply the new number  $i$  by real numbers and sum it with real numbers. Therefore we need to work in our newly defined domain of *complex numbers*  $\mathbb{C}$  with formal expressions of the form  $z = a + ib$ , being called *algebraic form* of  $z$ . The real number  $a$  is called the *real part* of the complex number  $z$ , the real number  $b$  is called the *imaginary part* of the complex number  $z$ , and we write  $\operatorname{Re}(z) = a$ ,  $\operatorname{Im}(z) = b$ . It should be noted that if  $z = a + ib$  and  $w = c + id$  then  $z = w$  implies both  $a = c$  and  $b = d$ . In other words, we can equate both real and imaginary parts. For positive  $x$  we then get  $(i \cdot x)^2 = -1 \cdot x^2$  and thus we can solve the equations as requested.

In order to satisfy all the properties of associativity and distributivity, we define the addition so that we add independently the real parts and the imaginary parts. Similarly, we want the multiplication to behave as if we multiply the pairs of real numbers, with the additional rule that  $i^2 = -1$ , thus

$$\begin{aligned} (a + ib) + (c + id) &= (a + c) + i(b + d), \\ (a + ib) \cdot (c + id) &= (ac - bd) + i(bc + ad). \end{aligned}$$

Next, we have to verify all the properties (CG1-4), (R1-4) and (F) of scalars from 1.1.1. But this is an easy exercise: zero is the number  $0 + i0$ , one is the number  $1 + i0$ , both these numbers are for simplicity denoted as before, that is, 0 and 1. For non-zero  $z = a + ib$  we easily check that  $z^{-1} = (a^2 + b^2)^{-1}(a - ib)$ . All other properties are obtained by direct calculations.

**1.1.4. The complex plane and polar form.** A complex number is given by a pair of real numbers, therefore it corresponds to a point in the real plane  $\mathbb{R}^2$ . Our algebraic form of the complex numbers  $z = x + iy$  corresponds in this picture to understanding the  $x$ -coordinate axis as the real part while the  $y$ -coordinate axis is the imaginary part of the number. The *absolute value* of the complex number  $z$  is defined as its distance from the origin, thus  $|z| = \sqrt{x^2 + y^2}$ .

The reflection with respect to the real axis then corresponds to changing the sign of the imaginary part. We call this operation  $z \mapsto \bar{z} = x - iy$  the *complex conjugation*.

Let us now consider complex numbers of the form  $z = \cos \varphi + i \sin \varphi$ , where  $\varphi$  is a real parameter giving the angle between the real axis and the line from the origin to  $z$  (measured in the positive, i.e. counter-clockwise sense). These

**1.A.11.** Complex numbers are not just a tool to obtain “weird” solutions to quadratic equations. They are necessary to determine solutions to cubic equations, even if these solutions are real. How can we express solution to the cubic equation

$$x^3 + ax^2 + bx + c = 0$$

in real coefficients  $a, b, c$ ? We show a method developed in sixteenth century by Ferro, Cardano, Tartaglia and possibly others. Substitute  $x := t - a/3$  (to remove the quadratic part from the equation) to obtain the equation:

$$t^3 + pt + q = 0,$$

where  $p = b - a^2/3$  and  $q = c + (2a^3 - 9ab)/27$ . Now introduce unknowns  $u, v$  satisfying the conditions  $u + v = t$  and  $3uv + p = 0$ . Substitute the first condition into the previous equation to obtain

$$u^3 + v^3 + (3uv + p)(u + v) + q = 0.$$

Now use the second equation to eliminate  $v$ . This yields

$$u^6 + qu^3 - \frac{p^3}{27} = 0,$$

which is a quadratic equation in the unknown  $s = u^3$ . Thus

$$u = \sqrt[3]{-\frac{q}{2} \pm \sqrt{\frac{q^2}{4} + \frac{p^3}{27}}}$$

By back substitution, we obtain

$$x = -p/3u + u - a/3.$$

In the expression for  $u$  there is cube root. In order to obtain all three solutions we need to work with complex roots. The equation  $x^3 = a, a \neq 0$ , with the unknown  $x$  has exactly three solutions in the domain of complex numbers (the fundamental theorem of algebra, see (12.2.8) on page 867). All these three solutions are called cube roots of  $a$ . Therefore the expression  $\sqrt[3]{a}$  has three meanings in the complex domain. If we want a single meaning for that expression, we usually consider it to be the solution with the smallest argument.

**1.A.12.** Show that the roots  $\xi_1, \xi_2, \dots, \xi_n$  of the equation  $x^n = 1$  form the vertices of the regular  $n$ -gon in the plane of the complex numbers.

**Solution.** The argument of the roots is given by de Moivre theorem, namely the argument multiplied by  $n$  has to be a multiple of  $2\pi$ , the absolute value has to be one, so the roots are  $\xi_k = \cos(k\frac{2\pi}{n}) + i \sin(k\frac{2\pi}{n}), k = 1, \dots, n$ , which are indeed the vertices of a regular polygon.  $\square$

numbers describe all points on the unit circle in the complex plane. Every non-zero complex number  $z$  can be then written as

$$z = |z|(\cos \varphi + i \sin \varphi).$$

For given  $z \neq 0$ ,  $\varphi$  is unique if  $0 \leq \varphi < 2\pi$ . The number  $\varphi$  is called the argument of the complex number  $z$  and this form of  $z$  is called the *polar form* of the complex number. This way of writing the complex numbers is very convenient for understanding the multiplication.

Consider the numbers  $z = |z|(\cos \varphi + i \sin \varphi)$  and  $w = |w|(\cos \psi + i \sin \psi)$  and calculate their product

$$\begin{aligned} z \cdot w &= |z|(\cos \varphi + i \sin \varphi)|w|(\cos \psi + i \sin \psi) \\ &= |z||w|(\cos \varphi \cos \psi - \sin \varphi \sin \psi \\ &\quad + i(\cos \varphi \sin \psi + \sin \varphi \cos \psi)) \\ &= |z||w|(\cos(\varphi + \psi) + i \sin(\varphi + \psi)). \end{aligned}$$

The last equality is a result of the addition formulas for trigonometric functions (we shall deal with them in more detail later in our discussion of rotations in the plane, see the page 37).

Division is equally easy. If  $z = |z|(\cos \varphi + i \sin \varphi) \neq 0$ , then  $w = |z|^{-1}(\cos \varphi - i \sin \varphi)$  satisfies  $zw = wz = 1$ , hence we can write  $w = z^{-1} = 1/z$ .

We can summarize (and iterate the application of the previous formula on the product of the number  $z$  with itself):

POLAR FORM AND DE MOIVRE THEOREM

Consider two complex numbers  $z = |z|(\cos \varphi + i \sin \varphi)$  and  $w = |w|(\cos \psi + i \sin \psi)$  in polar forms. Then if  $n$  is an integer, positive or negative,

$$\begin{aligned} zw &= |z||w|(\cos(\varphi + \psi) + i \sin(\varphi + \psi)) \\ z^n &= |z|^n(\cos(n\varphi) + i \sin(n\varphi)). \end{aligned}$$

**1.1.5. Functions.** In most tasks we do not deal just with numbers, i.e. with individual values of scalars. More often the values are associated to each of the elements in a set of objects.

Formally we talk about a *mapping*  $f : A \rightarrow B$  assigning to each element  $x$  in the *domain* set  $A$  the value  $f(x)$  in the *codomain* set  $B$ . The set of all images  $f(x) \in B$  is called the *range* of  $f$ .

The set  $A$  or  $B$  can be a set of numbers, but there is nothing to stop them being sets of other objects. The mapping  $f$ , however it is described, must unambiguously determine a unique member of  $B$  for each member of  $A$ .

In another terminology, the member  $x \in A$ , is often called the *independent variable*. Then  $y = f(x) \in B$ , is called the *dependent variable*. We also say that the value  $y = f(x)$  is a *function* of the independent variable  $x$  in the domain of  $f$ .

For now, we shall restrict ourselves to the case where the codomain  $B$  is a subset of scalars and we shall talk about *scalar functions*.

**1.A.13.** Show that the roots  $\xi_1, \xi_2, \dots, \xi_n$  of the equation  $x^n = 1$  satisfy

$$\sum_{i=1}^n \xi_i = 0.$$

**Solution.** Let  $\xi_1$  be the root with the smallest positive argument. The other roots satisfy  $\xi_k = \xi_1^k$  (see the previous example), thus

$$\sum_{i=1}^n \xi_i = \prod_{i=1}^n \xi_i^i = \xi_1 \frac{\xi_1^n - 1}{\xi_1 - 1} = 0,$$

where we have summed up the geometric sequence  $\xi_1, \dots, \xi_n$ .  $\square$

More examples about complex numbers can be found in the end of the chapter, starting at [1.G.2](#).

**1.A.14.** Solve the equation

$$x^3 + x^2 - 2x - 1 = 0.$$

**Solution.** This equation has no rational roots (methods to determine rational roots will be introduced later, see [\(?\)](#)). Substitution into formulas obtained in [1.A.11](#) yields  $p = b - a^2/3 = -7/3, q = -7/27$ . It follows that

$$u = \frac{\sqrt[3]{28 \pm 12\sqrt{-147}}}{6}.$$

We can theoretically choose up to six possibilities for  $u$  (two for the choice of the sign and three independent choices of the cubic root). But we obtain only three distinct values for  $x$ . By substitution into the formulas, one of the roots is of the form

$$\frac{14}{\sqrt[3]{3(28 - 84i\sqrt{3})}} + \frac{\sqrt[3]{28 - 84i\sqrt{3}}}{6} - \frac{1}{3} \doteq 1.247,$$

similarly for the other two (approximately  $-0.445$  and  $-1.802$ ). As noted before, we see that even if we have used complex numbers during the computation, all the solutions are real.  $\square$

### B. Difference equations

Difference equations (also called recurrence relations) are relations between elements of a sequence, where an element of the sequence depends on previous elements. To solve a difference equation means finding an explicit formula for  $n$ -th

(that is, arbitrary) element of the sequence.

The simplest way to define a function appears if  $A$  is a finite set. Then we can describe the function  $f$  by a table or a listing showing the image of each member of  $A$ . We have certainly seen many examples of such functions:

Let  $f$  denote the pay of a worker in some company in certain year. The values of independent variable, that is, the domain of the function, are individual workers  $x$  from the set of all considered workers. The value  $f(x)$  is their pay for the given year. Similarly we can talk about the age of students or their teachers in years, the litres of beer and wine consumed by individuals from a given group, etc.

Another example is a food dispensing machine. The domain of a function  $f$  would be the button pushed together with the money inserted to determine the selection of the food item

Let  $A = \{1, 2, 3\} = B$ . The set of equalities  $f(1) = 1, f(2) = 3, f(3) = 3$ , defines a function  $f : A \rightarrow B$ . Generally, as there are 3 possible values for  $f(1)$ , and the same for  $f(2)$ , and  $f(3)$ , there are 27 possible functions from  $A$  into  $B$  in total.

But there are other ways to define a function than as a table. For example, the function  $f$  can denote the area of a planar region. Here, the domain consists of subsets of the plane (e.g. all triangles, circles or other planar regions with a defined area). The range of  $f$  consists of the respective areas of the regions. Rather than providing a list of areas for a finite number regions, we hope for a formula allowing us to compute the functional value  $f(P)$  for any given planar region  $P$  from a suitable class.

Of course, there are many simple functions given by formulae, e.g.  $f(x) = 3x + 7$  with  $A = B = \mathbb{R}$  or  $A = B = \mathbb{N}$ .

Not all functions can be given by a formula or list. For example, let  $f(t)$  denote the speed of the car at time  $t$ . For any given car and time  $t$ , we know there will be the functional values  $f(t)$  denoting its speed. Which can of course be measured approximately, but usually not by a formula.

Another example: Let  $f(n)$  be the  $n^{\text{th}}$  digit in the decimal expansion of  $\pi \doteq 3.1415\dots$ . So for example  $f(4) = 5$ . The value of  $f(n)$  is defined but unknown if  $n$  is large enough.

The mathematical approach in modelling real problems often starts from the indication of certain dependencies between some quantities and aims at explicit formulas for functions which describe them. Often a full formula is not available but we may obtain the values  $f(x)$  at least for some instances of the independent variable  $x$ , or we may be able to find a suitable approximation.

We shall see all of the following types of expressions of the requested function  $f$  in this book:

- exact finite expression (like the function  $f(x) = 3x + 7$  above);
- infinite expression (we shall come to that only much later in chapter 5 when introducing the limit processes);
- description of how the function's values change under a given change of the independent variable (this behaviour will be displayed under the name difference equation in a moment and under different circumstances later on);

If an element of the sequence is determined only by the previous element, we call it a first order difference equation. This is a common real world problem, for instance when we want to find out how long will repayment of a loan take for fixed monthly repayment, or when we want to know how much shall we pay per month if we want to repay a loan in a fixed time.

**1.B.1.** Michael wants to buy a new car. The car costs €30 000. Michael wants to take out a loan and repay it with a fixed month repayment. The car company offers him a loan to buy the car with yearly interest of 6%. The repayment starts at the end of the first month of the loan. Michael would like to finish repaying the loan in three years. How much should he pay per month?

**Solution.** Let  $P$  denote the sum Michael has to pay per month. After the first month Michael repays  $P$ , part of it is a repayment of the loan, part of it pays the interest. Let  $d_k$  stand for the loan after  $k$  months and write  $C = 30\,000$  for the price of the car, and  $u = \frac{0.06}{12}$  for the monthly interest rate. We know  $d_0 = C = 30\,000$  and after the first month there is

$$d_1 = C - P + u \cdot C.$$

In general, after the  $k$ -th month we have

$$(1) \quad d_k = d_{k-1} - P + u d_{k-1} = (1 + u)d_{k-1} - P.$$

Using the relation (1) from paragraph 1.2.3 we obtain  $d_k$  given by (we write  $a = 1 + u$ )

$$d_k = d_0 a^k - P \left( \frac{a^k - 1}{a - 1} \right).$$

Repaying the loan in three years means  $d_{36} = 0$ , thus

$$\begin{aligned} P &= 30\,000 \left( \frac{(1 + u)^{36} u}{(1 + u)^{36} - 1} \right) \\ &= 30\,000 \left( \frac{(12.06/12)^{36} (0.06/12)}{(12.06/12)^{36} - 1} \right) \doteq 912.7. \quad \square \end{aligned}$$

Note that the recurrence relation (1) can be used for our case as long as all  $y(n)$  are positive, that is, as long as Michael still has to repay something.

**1.B.2.** Consider the case from the previous example. For how long would Michael have to pay, if he repays €500 per month?

**Solution.** Setting as before  $a = (1 + \frac{0.06}{12}) = 1.005$ ,  $C = 30\,000$  the condition  $d_k = 0$  gives the equation

$$a^k = \frac{\frac{P}{a-1}}{\frac{P}{a-1} - C} = \frac{200P}{200P - C}.$$

- approximation of a not computable function with a known one (usually including some error estimates – this could be the case with the car above, say we know it goes with some known speed at the time  $t = 0$ , we break as much as possible on a known surface and we compute the decrease of speed with the help of some mathematical model);
- finding only the probability of possible values of the function. For example the function giving the length of life of a given group of still living people, in dependence of some health related parameters.

**1.1.6. Functions defined explicitly.** Let us start with the most desirable case, when the function values are defined by a computable finite formula. Of course, we shall be interested also in the efficiency of the formulas, i.e. how fast the evaluations would be. In principle, real computations can involve only a finite number of summations and multiplications of numbers. This is how we define the *polynomials*, i.e. function of the form  $f(x) = a_n \cdot x^n + \dots + a_1 \cdot x + a_0$ , where  $a_0, \dots, a_n$  are known scalars,  $x$  is the unknown variable whose value we can insert.  $x^n = 1 \cdot x \cdot \dots \cdot x$  means the  $n$ -times repeated multiplication of the unit by  $x$  (in particular,  $x^0 = 1$ ), and  $f(x)$  is the value of the indicated sum of products. This is fairly well computable formula for each  $n \in \mathbb{N}$ . The choice  $n = 0$  provides the constants (i.e. constant functions)  $a_0$ .

The next example is more complicated.

#### FACTORIAL FUNCTION

Let  $A = \mathbb{Z}^+$  be the set of positive integers. For each  $n \in \mathbb{Z}^+$ , define the factorial function by

$$n! = n(n-1)(n-2) \dots 3 \cdot 2 \cdot 1.$$

For convenience we also define  $0! = 1$ . (We will see why this is sensible later on). It is easy to see that  $n! = n \cdot (n-1)!$  for all  $n \geq 1$ .

So  $1! = 1$ ,  $2! = 2 \cdot 1 = 2$ ,  $3! = 3 \cdot 2 \cdot 1 = 6$ ,  $6! = 720$  etc.

The latter example deserves more attention. Notice that we could have defined the factorial by setting  $A = B = \mathbb{N}$  and giving the equation  $f(n) = n \cdot f(n-1)$  for all  $n \geq 1$ . This does not yet define  $f$ , but for each  $n$ , it does determine what  $f(n)$  is in terms of its predecessor  $f(n-1)$ . This is sometimes called a *recurrence relation*. After choosing  $f(0) = 1$ , the recurrence now determines  $f(1)$  and hence successively  $f(2)$  etc., and so a function is defined. It is the factorial function as described above.

## 2. Difference equations

The factorial function is one example of a function which can be defined on the natural numbers by means of a recurrence relation. Such a situation can often be seen when formulating mathematical models that describe real systems in practice.

By taking logarithms of both sides, we obtain

$$k = \frac{\ln(200P) - \ln(200P - C)}{\ln a},$$

which for  $P = 500$  gives approximately  $k = 71.5$ , thus Michael would be paying for 72 months (the last repayment would be less than €500).  $\square$

**1.B.3.** Determine the sequence  $\{y_n\}_{n=1}^\infty$ , which satisfies the following recurrence relation

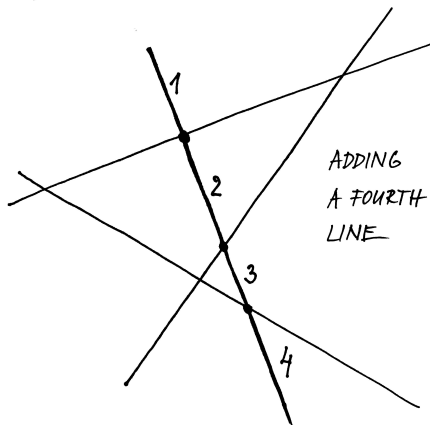

$$y_{n+1} = \frac{3y_n}{2} + 1, \quad n \geq 1, \quad y_1 = 1. \quad \circ$$

Linear recurrences can naturally appear in geometric problems:

**1.B.4.** Suppose  $n$  lines divide the plane into regions. What is the maximum number of regions that can be formed in this way?

**Solution.** Let the number of regions be  $p_n$ . If there is no line in the plane, then the whole plane is one region, thus  $p_0 = 1$ . If there are  $n$  lines, then adding an  $(n + 1)$ -st line increases the number of regions by the number of regions this new line intersects. If no lines are parallel and no three lines intersect at the same point, the number of regions the  $(n + 1)$ -st line crosses is one plus the number of its intersections with the previous lines (the crossed area will then be divided into two, thus the total number increases by one at every crossing).

The new line has at most  $n$  intersections with the already-present  $n$  lines. The segment of the line between two intersections crosses exactly one region, thus the new line crosses at most  $n + 1$  regions.

Thus we obtain the recurrence relation

$$p_{n+1} = p_n + (n + 1).$$

We will observe here only a few simple examples and return to this topic in chapter 3.

**1.2.1. Linear difference equations of first order.** A general *difference equation of the first order* (or *first order recurrence*) is an expression of the form

$$f(n + 1) = F(n, f(n)),$$

where  $F$  is a known function with two arguments (independent variables). If we know the “initial” value  $f(0)$ , we can compute  $f(1) = F(0, f(0))$ , then  $f(2) = F(1, f(1))$  and so on. Using this, we can compute the value  $f(n)$  for arbitrary  $n \in \mathbb{N}$ .

An example of such an equation is provided by the factorial function  $f(n) = n!$  where:

$$(n + 1)! = (n + 1) \cdot n!$$

In this way, the value of  $f(n + 1)$  depends on both  $n$  and the value of  $f(n)$ , and formally we would express this recurrence in the form  $F(x, y) = (x + 1)y$ .

A very simple example is  $f(n) = C$  for some fixed scalar  $C$  and all  $n$ . Another example is the *linear difference equation of first order*

$$(1) \quad f(n + 1) = a \cdot f(n) + b,$$

where  $a \neq 0$  and  $b$  are fixed scalars.

Such a difference equation is easy to solve if  $b = 0$ . Then it is the well-known recurrent definition of the geometric progression. We have

$$f(1) = af(0), \quad f(2) = af(1) = a^2f(0), \quad \text{and so on.}$$

Hence for all  $n$  we have

$$f(n) = a^n f(0).$$

This is also the relation for the *Malthusian population growth* model. This is based on the assumption that population size grows with a constant rate when measured at a sequence of fixed time intervals.

We will prove a general result for first order equations with variable coefficients, namely:

$$(2) \quad f(n + 1) = a_n \cdot f(n) + b_n.$$

We use the usual notation for sum  $\sum$ , and the similar notation for the product  $\prod$ . We use also the convention that when the index set is empty, then the sum is zero and the product is one.

**1.2.2. Proposition.** The general solution of the first order difference equation (2) from the previous paragraph with the initial condition  $f(0) = y_0$  is for  $n \in \mathbb{N}$  given by the formula

$$(1) \quad f(n) = \left( \prod_{i=0}^{n-1} a_i \right) y_0 + \sum_{j=0}^{n-2} \left( \prod_{i=j+1}^{n-1} a_i \right) b_j + b_{n-1}.$$

**PROOF.** We use *mathematical induction*. The result clearly holds for  $n = 1$  since  $f(1) = a_0 y_0 + b_0$ .

Assuming that the statement holds for some fixed  $n$ , we compute:

for which  $p_0 = 1$ . We obtain an explicit formula for  $p_n$  either by applying the formula in 1.2.2 or directly:

$$\begin{aligned} p_n &= p_{n-1} + n = p_{n-2} + (n-1) + n \\ &= p_{n-3} + (n-2) + (n-1) + n = \dots = p_0 + \sum_{i=1}^n i \\ &= 1 + \frac{n(n+1)}{2} = \frac{n^2 + n + 2}{2}. \end{aligned}$$

Recurrence relations can be more complex than those of first order. We show an example of combinatorial problem, for whose solution a recurrence relation can be used.

**1.B.5.** How many words of length 12 that consist only of letters  $A$  and  $B$ , but do not contain a sub-word  $BBB$ , are there?

**Solution.** Let  $a_n$  denote the number of words of length  $n$  consisting of letters  $A$  and  $B$  but without  $BBB$  as a sub-word. Then for  $a_n$  ( $n \geq 3$ ) the following recurrence holds

$$a_n = a_{n-1} + a_{n-2} + a_{n-3},$$

since the words of length  $n$  that satisfy the given condition either end with an  $A$ , or with an  $AB$ , or with an  $ABB$ . There are  $a_{n-1}$  words ending with an  $A$  (preceding the last  $A$  there can be an arbitrary word of length  $n-1$  satisfying the condition). Analogously for the two remaining groups. Further, it is easily shown that  $a_1 = 2$ ,  $a_2 = 4$ , and  $a_3 = 7$ . Using the recurrence relation we can then compute

$$a_{12} = 1705.$$

We could also derive an explicit formula for  $n$ -th element of the sequence using the theory, which we will develop in the chapter 3.

**1.B.6. Partial difference equations.** The recurrence relation in the next problem has a more complex form in comparison to the form we have dealt with in our theory. So we cannot evaluate the arbitrary member in our sequence  $P_{(k,l)}$  explicitly. We can only evaluate it by a subsequent computing from previous elements. Such an equation is called partial difference equation, since the terms of the equation are indexed by two independent variables  $(k, l)$ .

The score of a basketball match between the teams of Czech Republic and Russia after the first quarter is 12 : 9 for the Russian team. In

how many ways could the score have developed?

$$\begin{aligned} f(n+1) &= a_n \left( \prod_{i=0}^{n-1} a_i \right) y_0 + \sum_{j=0}^{n-2} \left( \prod_{i=j+1}^{n-1} a_i \right) b_j + b_{n-1} \\ &\quad + b_n \\ &= \left( \prod_{i=0}^n a_i \right) y_0 + \sum_{j=0}^{n-1} \left( \prod_{i=j+1}^n a_i \right) b_j + b_n, \end{aligned}$$

as can be seen directly by multiplying out.

Note that for the proof, we did not use anything about the scalars except for the properties of commutative ring.

There is another approach to the proof which explains the name "linear". First observe that with all  $b_n = 0$ , the formula from the proposition is obvious. Next observe, that dealing with two sequences  $y_n, y'_n$  solving 1.2.2(2), their difference  $z_n = y_n - y'_n$  must be a solution to the "homogenized" equation  $f(n+1) = a_n \cdot f(n)$ . On the contrary, knowing such sequences  $z_n$  and  $y_n$ , then their sum  $y'_n = z_n + y_n$  must be a solution of 1.2.2(2). Thus, we could just guess and check that the second term of (1) solves our equation. In particular, the following corollary can be proved very easily this way. Try to complete this line of arguments in detail!

**1.2.3. Corollary.** The general solution of the linear difference equation (1) from 1.2.1 with  $a \neq 1$  and initial condition  $f(0) = y_0$  is

$$(1) \quad f(n) = a^n y_0 + (1 + \dots + a^{n-1})b = a^n y_0 + \frac{1 - a^n}{1 - a} b.$$

**PROOF.** If we set  $a_i$  and  $b_i$  to be constants and use the general formula 1.2.2(1), we obtain

$$f(n) = a^n y_0 + b \left( 1 + \sum_{j=0}^{n-2} a^{n-j-1} \right).$$

We observe that the expression in the bracket is  $(1 + a + \dots + a^{n-1})$ . The sum of this geometric progression follows from  $1 - a^n = (1 - a)(1 + a + \dots + a^{n-1})$ .

The proof of the former proposition is a good example of a mathematical result, where the verification is quite easy, as soon as someone tells us the theorem. Mathematical induction is a natural method of proof.

Note that for calculating the sum of a geometric progression we silently assumed the existence of the inverse element for non-zero scalars. But actually, we derived the formula in a way manifesting that the division is always possible if our scalars do not allow for divisors of zero.

In particular, notice that the formula (1) is valid with integer coefficients  $a, b$  and integer initial conditions. Here, we know in advance that each  $f(n)$  is an integer. Thus our formula necessarily gives correct integer solutions, although living in the extension of  $\mathbb{Z}$  to the rational numbers  $\mathbb{Q}$ .

**Solution.** We can divide all possible evolutions of the quarter with the final score  $k : l$  into six mutually exclusive possibilities, according to which team scored, and how much was it worth (1, 2 or 3 points). If we denote by  $P_{(k,l)}$  the number of ways in which the score could have developed for a quarter that ended with  $k : l$ , then for  $k, l \geq 3$  the following recurrence relation holds:

$$P_{(k,l)} = P_{(k-3,l)} + P_{(k-2,l)} + P_{(k-1,l)} + P_{(k,l-1)} + P_{(k,l-2)} + P_{(k,l-3)}.$$
 Using the symmetry of the problem,  $P_{(k,l)} = P_{(l,k)}$ . Further, for  $k \geq 3$ :

$$P_{(k,2)} = P_{(k-3,2)} + P_{(k-2,2)} + P_{(k-1,2)} + P_{(k,1)} + P_{(k,0)},$$

$$P_{(k,1)} = P_{(k-3,1)} + P_{(k-2,1)} + P_{(k-1,1)} + P_{(k,0)},$$

$$P_{(k,0)} = P_{(k-3,0)} + P_{(k-2,0)} + P_{(k-1,0)},$$

which, along with the initial condition, gives  $P_{(0,0)} = 1$ ,  $P_{(1,0)} = 1$ ,  $P_{(2,0)} = 2$ ,  $P_{(3,0)} = 4$ ,  $P_{(1,1)} = 2$ ,  $P_{(2,1)} = P_{(1,1)} + P_{(0,1)} + P_{(2,0)} = 5$ ,  $P_{(2,2)} = P_{(0,2)} + P_{(1,2)} + P_{(2,1)} + P_{(2,0)} = 14$ . Hence by repeatedly using the above equations, we obtain eventually

$$P_{(12,9)} = 497178513.$$

□

We will discuss recurrent formulas (difference equations) of higher order with constant coefficients in chapter 3.

### C. Combinatorics

In this section we use natural numbers to describe some indivisible items located in real life space, and deal with questions as how to compute the number of their (pre)orderings, choices, and so on. In many of these problems, "common sense" is sufficient. We just need to use the rules of *product* and *sum* in the right way, as we show in the following examples:

**1.C.1.** Mother wants to give John and Mary five pears and six apples. In how many ways can she divide the fruits among them? (We consider the pears to be indistinguishable. We consider the apples to be indistinguishable. The possibility that one of the children gets nothing is not excluded.)

The linear difference equation 1.2.1(1) can be neatly interpreted as a mathematical model for finance, e.g. savings or loan payoff with a fixed interest rate  $a$  and fixed repayment  $b$ . (The cases of savings and loans differ only in the sign of  $b$ ).

With varying parameters  $a$  and  $b$  we obtain a similar model with varying interest rate and repayment. We can imagine for instance that  $n$  is the number of months,  $a_n$  is the interest rate in the  $n$ th month,  $b_n$  the repayment in the  $n$ th month.

**1.2.4. A nonlinear example.** When discussing linear difference equations, we mentioned a very primitive population growth model which depends directly on the momentary population size  $p$ . At first sight, it is clear that such a model with  $a > 1$  leads to a very rapid and unbounded growth.

A more realistic model has such a population change  $\Delta p(n) = p(n+1) - p(n)$  only for small values of  $p$ , that is  $\Delta p/p \sim r > 0$ . Thus if we want to let the population grow by 5% for a time interval only for small  $p$ , then we choose  $r$  to be 0.05. For some limiting value  $p = K > 0$  the population may not grow. For even greater values it may even decrease, for instance if the resources for the feeding of the population are limited, or if individuals in a large population are obstacles to each other etc.

Assume that the values  $y_n = \Delta p(n)/p(n)$  change linearly in  $p(n)$ . Graphically we can imagine this dependence as a line in the plane of the variables  $p$  and  $y$ . This line passes through the point  $[0, r]$ , so that  $y = r$  when  $p = 0$ . This line also passes through  $[K, 0]$  since this gives the second condition, namely that when  $p = K$  the population does not change. Thus we set

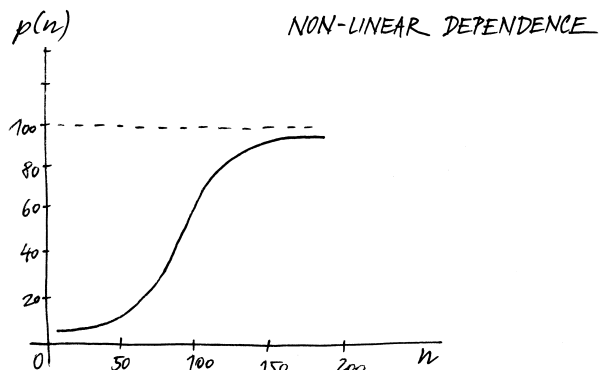

$$y = -\frac{r}{K}p + r.$$

By setting  $y = y_n = \Delta p(n)/p(n)$  and  $p = p(n)$  we obtain

$$\frac{p(n+1) - p(n)}{p(n)} = -\frac{r}{K}p(n) + r.$$

By multiplying, we obtain a difference equation of first order with  $p(n)$  present as both a first and a second power.

$$(1) \quad p(n+1) = p(n)\left(1 - \frac{r}{K}p(n) + r\right).$$

**Solution.** The five pears can be divided in six ways (it is determined by the number of pears given to John, the rest goes to Mary.) The six apples can be divided in seven ways. These divisions are independent. Using the rule of product, the total number is  $6 \cdot 7 = 42$ .  $\square$

**1.C.2.** Determine the number of four-digit numbers, which either start with the digit 1 and do not end with the digit 2, or that end with the digit 2 but do not start with the digit 1 (of course, the first digit must not be zero).

**Solution.** The set of numbers described in the statement consists of two disjoint sets. The total number is then obtained by summing the number of numbers in these two sets. In the first set there are numbers of the form “1XXY” where  $X$  is an arbitrary digit and  $Y$  is any digit except 2. Thus we can choose the second digit in ten ways, independently of that the third digit in ten ways and again independently the fourth digit in nine ways. These three choices then uniquely determine a number. By multiplication, there are  $10 \cdot 10 \cdot 9 = 900$  of such numbers. Similarly in the second set we have  $8 \cdot 10 \cdot 10 = 800$  numbers of the form “YXX2” (for the first digit we have only eight ways, since the number cannot start with zero and one is forbidden). By addition, the solution is  $900 + 800 = 1700$  numbers.  $\square$

In the following examples we will use the notions of combinations, and permutations (possibly with repetitions).

**1.C.3.** During a conference, 8 speakers are scheduled. Determine the number of all possible orderings in which two given speakers do not speak one right after the other.

**Solution.** Denote the two given speakers by  $A$  and  $B$ . If  $B$  follows directly after the speaker  $A$ , we can consider it as a speech by a single speaker  $AB$ . The number of all orderings where  $B$  speaks directly after  $A$  is therefore  $7!$ , the number of permutations of seven elements. By symmetry, the number of all orderings where  $A$  speaks directly after  $B$  is also  $7!$ . Since the number of all possible orderings of eight speakers is  $8!$ , the solution is  $8! - 2 \cdot 7!$ .  $\square$

**1.C.4.** How many rearrangements of the letters of the word PROBLEM are there, such that

- a) the letters B and R are next to each other,
- b) the letters B and R are not next to each other.

**Solution.** a) The pair of letters B and R can be assumed to be a single indivisible “double-letter”. In total we have six

Try to think through the behaviour of this model for various values of  $r$  and  $K$ . In the diagram we can see the results for parameters  $r = 0.05$  (that is, five percent growth in the ideal state),  $K = 100$  (resources limit the population to the size 100), and as  $p(0) = 2$  we have initially two individuals.

Note that the original almost exponential growth slows down later. The population size approaches the desired limit of 100 individuals. For  $p$  close to one and  $K$  much greater than  $r$ , the right side of the equation (1) is approximately  $p(n)(1 + r)$ . That is, the behaviour is similar to that of the Malthusian model. On the other hand, if  $p$  is almost equal to  $K$ , the right hand side of the equation is approximately  $p(n)$ . For an initial value of  $p$  greater than  $K$  the population size will decrease. For an initial value of  $p$  less than  $K$  the population size will increase.<sup>1</sup>

### 3. Combinatorics

A typical “combinatorial” problem is to count in how many ways something can happen. For instance, in how many ways can we choose two different sandwiches from the daily offering in a grocery shop?

In this situation we need first to decide what we mean by different. Do we then allow the choice of two “identical” sandwiches? Many such questions occur in the context of card games and other games.

The solution of particular problems, usually involves either some multiplication of particular results (if the individual possibilities are independent) or some addition (if their appearance is disjoint). This is demonstrated in many examples in the problem column (cf. several problems starting with 1.C.1).

**1.3.1. Permutations.** Suppose we have a set of  $n$  (distinguishable) objects, and we wish to arrange them in some order. We can choose a first object in  $n$  ways, then a second in  $n - 1$  ways, a third in  $n - 2$  ways, and so on, until we choose the last object for which there is only one choice. The total number of possible arrangements is the product of these, hence there are exactly  $n! = n(n - 1)(n - 2) \dots 3 \cdot 2 \cdot 1$  distinct orders of the objects. Each ordering of the elements of a set  $S$  is called a *permutation* of the elements of  $S$ . The number of permutations on a set with  $n$  elements is  $n!$ .

We can identify the elements in  $S$  by numbering them (using the digits from one to  $n$ ), that is, we identify  $S$  with the set  $S = \{1, \dots, n\}$  of  $n$  natural numbers. Then the permutations correspond to the possible orderings of the numbers from one to  $n$ . Thus we have an example of a simple mathematical theorem and this discussion can be considered to be its proof.

<sup>1</sup>This model is called the *discrete logistic model*. Its continuous version was introduced already in 1845 by Pierre Franois Verhulst. Depending on the proportions of the parameters  $r$ ,  $K$  and  $p(0)$ , the behaviour can be very diverse, including chaotic dynamics. There is much literature on this model.

distinct letters and there are  $6!$  words of six indivisible letters. We have to multiply this by two, since the double-letter can be either BR or RB. Thus the solution is  $2 \cdot 6!$ .

b) The events in b) form the complement to the part a) in the set of all rearrangements of the seven-letters. The solution is therefore  $7! - 2 \cdot 6!$ .  $\square$

**1.C.5.** In how many ways can an athlete place 10 distinct cups on 5 shelves, given that all 10 cups fit on any shelf?

**Solution.** Add 4 indistinguishable items, say separators, to the cups. The number of all distinct orderings of cups and separators is  $14!/4!$  (the separators are indistinguishable). Each placement of cups into shelves corresponds to exactly one ordering of cups and separators. It is enough to say that the cups before the first separator in the ordering are placed in the first shelf (preserving the order), the cups between the first and the second separator in the second shelf, and so on. Thus the required number is  $14!/4!$ .  $\square$

**1.C.6.** Determine the number of four-digit numbers with exactly two distinct digits. (Recall that the first digit must not be 0.)

**Solution. First solution.** If 0 is one of the digits, then there are 9 choices for the other digit, which must also be the first digit. There are three numbers with a single 0, three numbers with two 0's, and just one number with three 0's. Thus there are  $9(3+3+1)=63$  numbers which contain the digit 0. Otherwise, choose the first digit for which there are 9 choices. There are then 8 choices for the other digit and  $3+3+1$  numbers for each choice, making  $9 \cdot 8 \cdot (3+3+1) = 504$  numbers which do not contain the digit 0. The solution is  $504+63=567$  numbers.

**Second solution.** The two distinct digits used for the number can be chosen in  $\binom{10}{2}$  ways. From the two chosen digits we can compose  $2^4 - 2$  distinct four-digit numbers (we subtract the 2 for the two four digit numbers which use only one of the chosen digits). In total we have  $\binom{10}{2}(2^4 - 2) = 630$  numbers. But in this way, we have also computed the numbers that start with zero. Of these there are  $\binom{9}{1}(2^3 - 1) = 63$ . Thus the solution is  $630 - 63 = 567$  numbers.  $\square$

**1.C.7.** There are 677 people at a concert. Do some of them have the same (ordered) pair of name initials?

**Solution.** There are 26 letters in the alphabet. Thus the number of all possible name initials are  $26^2 = 676$ . Thus at least two people have the same initials.  $\square$

NUMBER OF PERMUTATIONS

**Proposition.** The number  $p(n)$  of distinct orderings of a finite set with  $n$  elements, is given by the factorial function:

$$(1) \quad p(n) = n!$$

Suppose  $S$  is a set with  $n$  elements. Suppose we wish to choose and arrange in order just  $k$  of the members of  $S$ , where  $1 \leq k \leq n$ . This is called a  $k$ -permutation without repetition of the  $n$  elements. The same reasoning as above shows that this can be done in

$$v(n, k) = n(n-1)(n-2) \cdots (n-k+1) = \frac{n!}{(n-k)!}$$

ways. The right side of this result also makes sense for  $k = 0$ , (there is just one way of choosing nothing), and for  $k = n$ , since  $0! = 1$ .

Now we modify the problem, this time where the order of selection is immaterial.

**1.3.2. Combinations.** Consider a set  $S$  with  $n$  elements. A  $k$ -combination of the elements of  $S$  is a selection of  $k$  elements of  $S$ ,  $0 \leq k \leq n$ , when order does not matter.

For  $k \geq 1$ , the number of possible results of a subsequential choosing of our  $k$  elements, is  $n(n-1)(n-2) \cdots (n-k+1)$  (a  $k$ -permutation). We obtain the same  $k$ -tuple in  $k!$  distinct orders. Hence the number of  $k$ -combinations is

$$\frac{n(n-1)(n-2) \cdots (n-k+1)}{k!} = \frac{n!}{(n-k)!k!}$$

If  $k = 0$ , the same formula is still true, since  $0! = 1$ , and there is just one way to select all  $n$  elements.

COMBINATIONS

**Proposition.** The number  $c(n, k) = \binom{n}{k}$  of combinations of  $k$ -th degree among  $n$  elements, where  $0 \leq k \leq n$ , is

$$(1) \quad c(n, k) = \frac{n(n-1) \cdots (n-k+1)}{k(k-1) \cdots 1} = \frac{n!}{(n-k)!k!}$$

We pronounce the *binomial coefficient*  $\binom{n}{k}$  as “ $n$  over  $k$ ” or “ $n$  choose  $k$ ”. The name stems from the *binomial expansion*, which is the expansion of  $(a+b)^n$ . If we expand  $(a+b)^n$ , the coefficient of  $a^k b^{n-k}$  is the number of ways to choose a  $k$ -tuple from  $n$  parentheses in the product (from these parentheses, we take  $a$ , from the others, we take  $b$ ). Therefore we have

$$(2) \quad (a+b)^n = \sum_{k=0}^n \binom{n}{k} a^k b^{n-k}$$

Note that only distributivity, commutativity and associativity of multiplication and summation was necessary. The formula (2) therefore holds in every commutative ring.

**1.C.8.** New players meet in a volleyball team (6 people). How many handshakes are there when everybody shakes once with everybody else? How many handshakes are there if everybody shakes hands once with each opponent after playing a match?

**Solution.** Each pair of players shakes hands at the introduction. The number of handshakes is then the combination  $c(6, 2) = \binom{6}{2} = 15$ . After a match each of the six players shakes hands six times (with each of six opponents). Thus the required number is  $6^2 = 36$ .  $\square$

**1.C.9.** In how many ways can five people be seated in a car for five people, if only two of them have a driving licence? In how many ways can 20 passengers and two drivers be seated in a bus for 25 people?

**Solution.** For the driver's place we have two choices and the other places are then arbitrary, that is, for the second seat we have four choices, for the third three choices, then two and then 1. That makes  $2 \cdot 4! = 48$  ways. Similarly in the bus we have two choices for the driver, and then the other driver plus the passengers can be seated among the 24 seats arbitrarily. First choose the seats to be occupied, that is,  $\binom{24}{21}$ . Among these seats the people can be seated in  $21!$  ways. The solution is  $2 \cdot \binom{24}{21} 21! = \frac{24!}{3}$  ways.  $\square$

**1.C.10.** Determine the number of distinct arrangements which can arise by permuting the letters in each individual word in the sentence "Pull up if I pull up" (the arising arrangements and words do not have to make any sense).

**Solution.** Let us first compute the number of rearrangements of letters in individual words. From the words "pull" we obtain  $4!/2$  distinct anagrams (permutation with repetition  $P(1, 1, 2)$ ), similarly "up" and "if" yields two. Therefore, using the rule of product, we have  $\frac{4!}{2} \cdot 2 \cdot 2 \cdot 1 \cdot \frac{4!}{2} \cdot 2 = 1152$ . Notice, that if the resulting arrangement should be a palindromic one again, there would be only four possibilities.  $\square$

**1.C.11.** In how many ways can we insert five golf balls into five holes (into every hole one ball), if we have four identical white balls, four identical blue balls and three identical red balls?

**Solution.** First solve the problem in the case that we have five balls of every colour. In this case it amounts to free choice of five elements from three possibilities (there is a choice out of

We present a few simple propositions about binomial coefficients – another simple example of a mathematical proof. If needed, we define  $\binom{n}{k} = 0$  whenever  $k < 0$  or  $k > n$ .

**1.3.3. Proposition.** For all non negative integers  $n$ , we have

- (1)  $\binom{n}{k} = \binom{n}{n-k} \quad 0 \leq k \leq n$ .
- (2)  $\binom{n+1}{k+1} = \binom{n}{k} + \binom{n}{k+1} \quad 0 \leq k \leq n-1$ .
- (3)  $\sum_{k=0}^n \binom{n}{k} = 2^n$
- (4)  $\sum_{k=0}^n k \binom{n}{k} = n2^{n-1}$ .

**PROOF.** The first formula in the proposition is immediate directly from the formula 1.3.2(1). If we expand the right-hand side of (2), we obtain

$$\begin{aligned} \binom{n}{k} + \binom{n}{k+1} &= \frac{n!}{k!(n-k)!} + \frac{n!}{(k+1)!(n-k-1)!} \\ &= \frac{(k+1)n! + (n-k)n!}{(k+1)!(n-k)!} \\ &= \frac{(n+1)!}{(k+1)!(n-k)!} \end{aligned}$$

which is the left-hand side of (2).

In order to prove (3), we use *mathematical induction* again. Mathematical induction consists of two steps. In the initial step, we establish the claim for  $n = 0$  (in general, for the smallest  $n$  the claim should hold for). In the inductive step we assume that the claim holds for some  $n$  (and all smaller numbers). We use this to prove that this implies the claim for  $n + 1$ . The principle of *mathematical induction* then asserts that the claim holds for every  $n$ .

The claim (3) clearly holds for  $n = 0$ , since  $\binom{0}{0} = 1 = 2^0$ . It holds also for  $n = 1$ . Now assume that the claim holds for some  $n \geq 1$ . We must prove the corresponding claim for  $n + 1$  using the claims (2) and (3). We calculate

$$\begin{aligned} \sum_{k=0}^{n+1} \binom{n+1}{k} &= \sum_{k=0}^{n+1} \left( \binom{n}{k-1} + \binom{n}{k} \right) \\ &= \sum_{k=-1}^n \binom{n}{k} + \sum_{k=0}^{n+1} \binom{n}{k} = 2^n + 2^n = 2^{n+1}. \end{aligned}$$

Note that the formula (3) gives the number of all subsets of an  $n$ -element set, since  $\binom{n}{k}$  is the number of all subsets of size  $k$ . Note also that (3) follows from 1.3.2(2) by choosing  $a = b = 1$ .

To prove (4) we again employ induction, as we did in (3). For  $n = 0$  the claim clearly holds. The inductive assumption says that (4) holds for some  $n$ . We calculate the corresponding sum for  $n + 1$  using (2) and the inductive assumption. We obtain

three colours for every hole), that is permutations with repetitions (see ). We have

$$V(3, 5) = 3^5.$$

Now subtract the configurations where there are either balls of one colour (there are three such), or exactly four red balls (there are  $2 \cdot 5 = 10$ ; we first choose the colour of the non-red ball – two ways – and then the hole it is in – five ways). Thus we can do it in

$$3^5 - 3 - 10 = 230$$

ways.  $\square$

**1.C.12.** In how many ways can we insert into three distinct envelopes five identical 10-bills and five identical 100-bills such that no envelope stays empty?

**Solution.** First compute the number of insertions ignoring the non-emptiness condition. It is an example of 3-combinations with repetition from 5 elements, and since we insert the 10-bills and 100-bills independently, we have  $c(7, 2)^2 = \binom{7}{2}^2$  ways. Now subtract the insertions such that exactly one envelope is empty and then the insertions such that two are empty. We have  $C(2, 7)^2 - 3(C(1, 6)^2 - 2) - 3 = \binom{7}{2}^2 - 3(6^2 - 2) - 3 = 336$ .  $\square$

**1.C.13.** For any fixed  $n \in \mathbb{N}$ , determine the number of all solutions to the equation

$$x_1 + x_2 + \dots + x_k = n$$

in the set of non-negative integers.

**Solution.** Every solution  $(r_1, \dots, r_k)$ ,  $\sum_{i=1}^k r_i = n$  can be uniquely encoded as a sequence of separators and ones, where we first write  $r_1$  ones, then a separator, then  $r_2$  ones, then another separator, and so on. Such sequence then clearly contains  $n$  ones and  $k - 1$  separator. Every such sequence clearly determines some solution of the given equation. Thus there are exactly that many solutions as there are sequences, that is,  $\binom{n+k-1}{n}$ .  $\square$

**1.C.14.** In how many ways could the English Premier League have finished, if we know that no two of the three teams Newcastle United, Crystal Palace and Tottenham Hotspur are “adjacent” in the final table? (There are 20 teams in the league.)

**Solution.** *First approach.* We use the inclusion-exclusion principle. From the number of all possible resulting tables

$$\begin{aligned} \sum_{k=0}^{n+1} k \binom{n+1}{k} &= \sum_{k=0}^{n+1} k \left( \binom{n}{k-1} + \binom{n}{k} \right) \\ &= \sum_{k=-1}^n (k+1) \binom{n}{k} + \sum_{k=0}^{n+1} k \binom{n}{k} \\ &= \sum_{k=0}^n \binom{n}{k} + \sum_{k=0}^n k \binom{n}{k} + \sum_{k=0}^n k \binom{n}{k} \\ &= 2^n + n2^{n-1} + n2^{n-1} = (n+1)2^n. \end{aligned}$$

This completes the inductive step and the claim is proven for all natural  $n$ .  $\square$

The second property from above allows us to write down all the binomial coefficients into the *Pascal triangle*.<sup>2</sup> Here, every coefficient is obtained as a sum of the two coefficients situated right “above” it:

$n = 0 :$	1							
$n = 1 :$		1	1					
$n = 2 :$			1	2	1			
$n = 3 :$			1	3	3	1		
$n = 4 :$			1	4	6	4	1	
$n = 5 :$			1	5	10	10	5	1

Note that in individual rows we have the coefficients of individual powers in the expression (2). For instance the last given row says

$$(a + b)^5 = a^5 + 5a^4b + 10a^3b^2 + 10a^2b^3 + 5ab^4 + b^5.$$

**1.3.4. Choice with repetitions.** The ordering of  $n$  elements, where some of them are indistinguishable, is called a *permutation with repetitions*.

Among  $n$  given elements, suppose there are  $p_1$  elements of the first kind,  $p_2$  elements of the second kind,  $\dots$ ,  $p_k$  of the  $k$ -th kind, where  $p_1 + p_2 + \dots + p_k = n$ . Then the number of permutations with repetitions of these elements is denoted as  $P(p_1, \dots, p_k)$ .

We consider the orderings which differ only in the order of indistinguishable elements to be identical. Elements of the  $i$ th kind can be ordered in  $p_i!$  ways, thus we have

PERMUTATIONS WITH REPETITIONS

The number of permutations with repetitions is

$$P(p_1, \dots, p_k) = \frac{n!}{p_1! \dots p_k!}.$$

Let  $S$  be a set with  $n$  distinct elements. We wish to select  $k$  elements,  $0 \leq k \leq n$  from  $S$  with repetition permitted. This is called a  $k$ -permutation with repetition. Since the first selection can be done in  $n$  ways, and similarly the second can also be done in  $n$  ways etc. The total number  $V(n, k)$  of  $k$ -permutations with repetitions is  $n^k$ . Hence

<sup>2</sup>Although the name goes back to Blaise Pascal’s treatise from 1653, such a neat triangle configuration of the numbers  $c(n, k)$  were known for centuries earlier in China, India, Greece, etc.

we subtract the tables where some two of the three teams are adjacent and then add the tables where all three teams are adjacent. The number is then

$$20! - \binom{3}{2} \cdot 2! \cdot 19! + 3! \cdot 18! = 18! \cdot 16 \cdot 17.$$

*Second approach.* Let us consider the three teams to be “separators”. The remaining teams have to be divided such that between any two separators there is at least one team. The remaining teams can be arbitrarily permuted, as can the separators. Thus we have

$$\binom{18}{3} \cdot 17! \cdot 3! = 18! \cdot 17 \cdot 16.$$

ways.  $\square$

### D. Probability

We present a few simple exercises for classical probability, where we are dealing with some experiment with only a finite number of outcomes (“all cases”) and we are interested in whether or not the outcome of the experiment belongs to a subset of possible outcomes (“favourable outcomes”). The probability we are trying to determine then equals the number of favourable outcomes divided by the total number of all outcomes. Classical probability can be used when we assume, or know, that each possible outcome has the same probability of happening (for instance, fair dice throwing).

**1.D.1.** What is the probability that the roll of a dice results in a number greater than 4?

**Solution.** There are six possible outcomes (the set  $\{1, 2, 3, 4, 5, 6\}$ ). Two are favourable ( $\{5, 6\}$ ). Thus the probability is  $2/6 = 1/3$ .  $\square$

**1.D.2.** We choose randomly a group of five people from a group of eight men and four women. What is the probability that there are at least three women in the chosen group?

**Solution.** We divide the favourable cases according to the number of men in the chosen group: there can be either two or one. There are eight groups with five people of which one is a man (all women have to be present in such groups, thus it depends only on which man is chosen). There are  $c(8, 2) \cdot c(4, 3) = \binom{8}{2} \cdot \binom{4}{3}$  of groups with two men (we choose two men from eight and then independently three women from four. These two choices can be independently combined and thus using the rule of product we obtain the number of

### $k$ -PERMUTATIONS WITH REPETITIONS

$$V(n, k) = n^k.$$

If we are interested in a choice of  $k$  elements without taking care of order, we speak of  $k$ -combinations with repetitions. At first sight, it does not seem to be easy to determine the number. We reduce the problem to another problem we have already solved, namely combinations without repetitions:

### COMBINATIONS WITH REPETITIONS

**Theorem.** The number of  $k$ -combinations with repetitions from  $n$  elements equals for every  $k \geq 0$  and  $n \geq 1$

$$\binom{n+k-1}{k}.$$

**PROOF.** Label the  $n$  elements as  $a_1, a_2, \dots, a_n$ . Suppose each element labeled  $a_i$  is selected  $k_i$  times,  $0 \leq k_i \leq k$ , so that  $k_1 + k_2 + \dots + k_n = k$ . Each such selection can be paired with the sequence of symbols  $*$  and  $|$  where each  $*$  represents one selection of an element and individual boxes are separated by  $|$  (therefore there are  $n - 1$  of them).

The number of  $*$  in the  $i$ th box is equal to  $k_i$ , so we obtain the sequence

$$\underbrace{* \dots *}_{k_1} | \underbrace{* \dots *}_{k_2} | \dots | \underbrace{* \dots *}_{k_n}.$$

The other way around, from any such sequence we can determine the number of selections of any element (e.g. the number of  $*$  before first  $|$  determines  $k_1$ ).

Having altogether  $k$  symbols  $*$  and  $n - 1$  separators  $|$  we see that there are

$$\binom{n+k-1}{n-1} = \binom{n+k-1}{k}$$

possible sequences and therefore also the same number of the required selections.  $\square$

### 4. Probability

Now we are going to discuss the last type of function description, as listed in the very end of the subsection 1.1.5. Thus, instead of assigning explicit values of a function, we shall try to describe the probabilities of the individual options.

**1.4.1. What is probability?** As a simple example we can use common six-sided dice throwing, with sides labelled as

$$1, 2, 3, 4, 5, 6.$$

If we describe the mathematical model of such throwing with a “fair” dice, we expect by symmetry that every side occurs with the same frequency. We say that “every side occurs with the probability  $1/6$ ”.

such groups). The total number of groups with five people is  $c(12, 5) = \binom{12}{5}$ . The probability, being the quotient of the number of favourable outcomes to the total number of outcomes, is then

$$\frac{8 + \binom{4}{3} \binom{8}{2}}{\binom{12}{5}} = \frac{5}{33}.$$

□

**1.D.3.** From a deck with 108 cards ( $2 \times 52 + 4$  jolly jokers) we draw without returning 4 cards randomly. What is the probability that at least one of them is an ace or a joker?

**Solution.** We can easily determine the probability of the complementary event, that is, in the 4 drawn cards there is none of the 12 cards (8 aces and 4 jokers). This probability is given by the ratio of the number of choices of 4 cards from 96 and the number of choices of 4 cards from 108, that is,  $\binom{96}{4} / \binom{108}{4}$ . The complementary event thus has the probability

$$1 - \frac{\binom{96}{4}}{\binom{108}{4}} \doteq 0.380.$$

□

We give an example for which the use of classical probability is not suitable:

**1.D.4.** What is the probability that the reader of this exercise wins at least 25 million euro in EuroLotto during the next week?

**Solution.** Such a formulation is incomplete, it does not give us enough information. We present a “wrong” solution. The sample space of possible outcomes is two-element: either the reader wins or not. A favourable event is one (win), thus the probability is  $1/2$ . This is clearly a wrong answer. □

**Remark.** In the previous exercise the basic condition of the use of classical probability was violated – every elementary event must have the same probability. In fact, the elementary event has not been defined. EuroLotto has a daily draw with a jackpot of €25 000 000 for choosing 5 correct numbers  $1, \dots, 50$ . There is no other way to win €25 000 000 than to win a jackpot on some of the day during the week. The elementary event would be that a single lotto card with 5 numbers wins a jackpot. Assuming that the reader submits  $k$  lotto cards every day of the week, the probability of winning at least one jackpot during the week is  $\frac{7k}{\binom{50}{5}} \doteq \frac{7k}{2\,118\,760}$ .

But throwing some less symmetric version of a dice with six faces, the actual probabilities of the individual results might be quite different. Let us build a simple mathematical model for this. We shall work with the parameters  $p_i$  for the probabilities of individual sides with two requirements. These probabilities have to be non-negative real numbers and their sum is one, i.e.

$$p_1 + p_2 + p_3 + p_4 + p_5 + p_6 = 1.$$

At this time, we are not concerned about the particular choice of the specific values  $p_i$ , they are given to us. Later on, in chapter 10, we shall link probability with mathematical statistics and then we shall introduce methods how to discuss reliability of such a model for a specific real dice.

**1.4.2. Classical probability.** Let us come back to the mathematical model for the fair dice. We consider the sample space  $\Omega = \{1, 2, 3, 4, 5, 6\}$  of all possible elementary events (each of them corresponding to one possible result of the experiment of throwing the dice). Then we can consider any event as a given subset  $A$  of  $\Omega$ . For example  $A = \{1, 3, 5\}$  describes the result of getting odd number on the resulting side (we count the labels on the sides of the dice). Similarly, the set  $B = A^c = \{2, 4, 6\} = \Omega \setminus A$  is the complementary event of getting even numbered points. The probability of both  $A$  and  $B$  will be  $1/2$ . Indeed,  $|A|/|\Omega| = 1/2$ , where  $|A|$  means the number of elements of a set  $A$ .

This leads to the following obvious generalization:

CLASSICAL PROBABILITY

Let  $\Omega$  be a finite set with  $n = |\Omega|$  elements. The *classical probability* of the event corresponding to any subset  $A \subset \Omega$  is defined as

$$P(A) = \frac{|A|}{|\Omega|}.$$

Such a definition immediately allows us to solve problems related to throwing several fair dice simultaneously. Indeed, we may treat this as throwing independently one dice many times and thus multiplying the probabilities. For example, the event of getting an odd sum of points on two dice is given by adding the probabilities of having an even number on the first one and odd number on the second one and vice versa. Thus the probability will be twice  $1/2 \cdot 1/2$ , which is  $1/2$  as expected.

**1.4.3. Probability space.** Next, we formulate a more general concept of probability covering also the unfair dice example above.

We shall need a finite set  $\Omega$  of all possible states of a system (e.g. results of an experiment), which we call the *sample space*.

Further, the space of all possible *events* is given as the set  $\mathcal{A}$  of all subsets in  $\Omega$ . Finally, we need the function describing the probabilities of occurrence of individual events:

**1.D.5.** There are  $2n$  seats in a row in a cinema. We randomly seat  $n$  men and  $n$  women in the row. What is the probability that no two persons of the same sex sit next to each other?

**Solution.** There are  $(2n)!$  possible seatings. The number of seatings satisfying the given condition is  $2(n!)^2$ . For we have two ways for choosing the positions for men (thus also for women) – either all men sit on odd-numbered places (thus the women sit on even-numbered places), or vice versa. Among these places, both men and women are seated arbitrarily. The resulting probability is thus

$$p(n) = \frac{2(n!)^2}{(2n)!}.$$

In particular,  $p(2) \doteq 0.33$ ,  $p(5) \doteq 0.0079$ ,  $p(8) \doteq 0.00016$ .  $\square$

**1.D.6.** Five persons enter an elevator in a building with eight floors. Each of them leaves the elevator at any floor with the same probability. What is then the probability, that

- i) all of them leave at sixth floor,
- ii) all of them leave at the same floor,
- iii) each of them leaves at a different floor.

**Solution.** The sample space of possible events is the space of all possible ways of leaving the elevator by 5 people. There are  $8^5$  of them.

In the first case there is only one favourable outcome, thus the probability is  $\frac{1}{8^5}$ . In the second case there are eight favourable outcomes, thus the probability is  $\frac{1}{8^4}$ . In the third case, the number of favourable outcomes is given by a five-element variation of eight elements (we choose five floors among eight where some person leaves the elevator and then we choose the order in which they leave the chosen floors).

The probability is then (see 1.3.2 and 1.3.4)

$$\frac{8 \cdot 7 \cdot 6 \cdot 5 \cdot 4}{8^5} \doteq 0.205078125. \quad \square$$

**1.D.7.** Randomly choose a positive integer smaller than  $10^5$ . What is the probability that it will consist only of the digits 0, 1, 5 and that it will be divisible by 5? (Recall that the first digit must not be 0.)

**Solution.** There are  $10^5 - 1$  positive integers smaller than  $10^5$ . Numbers satisfying the condition must begin with either 1 or 5, and end with 0 or 5. Thus there are  $2 \cdot 3^3 \cdot 2$  five digit favourable numbers. There are  $2 \cdot 3^2 \cdot 2$  four digit favourable numbers,  $2 \cdot 3 \cdot 2$  three digit favourable numbers,  $2 \cdot 2$  two digit

PROBABILITY FUNCTION

Let us consider a non-empty fixed sample space  $\Omega$ . The probability function  $P : \mathcal{A} \rightarrow \mathbb{R}$  satisfies

- (1)  $P(\Omega) = 1$
- (2)  $0 \leq P(A)$  for all events  $A$
- (3)  $P(A \cup B) = P(A) + P(B)$  whenever  $A \cap B = \emptyset$ .

Notice that the intersection  $A \cap B$  describes the simultaneous appearance of both events, while the union  $A \cup B$  means that at least one of events  $A$  and  $B$  appear. The event  $A^c = \Omega \setminus A$  is called the *complementary event*.

PROBABILITY

$$P(A \cup B) = P(A) + P(B \setminus A)$$

There are some further straightforward consequences of the definition for all events  $A, B$ :

- (4)  $P(A) = 1 - P(A^c)$
- (5)  $P(\emptyset) = 0$
- (6)  $P(A) \leq 1$  for all events  $A$
- (7)  $P(A) \leq P(B)$  whenever  $A \subset B$
- (8)  $P(A \cup B) = P(A) + P(B) - P(A \cap B)$

The proofs are all elementary. For example,  $A \cup (A^c) = \Omega$  and thus (3) implies (4).

Similarly, we can write  $A = (A \setminus B) \cup (A \cap B)$  and  $A \cup B = (A \setminus B) \cup (B \setminus A) \cup (A \cap B)$  with disjoint unions of sets on the right hand sides. Thus,  $P(A) = P(A \setminus B) + P(A \cap B)$  and  $P(A \cup B) = P(A \setminus B) + P(B \setminus A) + P(A \cap B)$  by (3), which implies the last equality. The remaining three claims are even simpler.

All these properties correspond exactly to our intuition how probability should behave. Probability should be always a real number between zero and one. The event  $\Omega$  includes all possible results of the experiment, so it must have probability one. No result appears with probability zero, the probabilities of disjoint events should add, etc.

Of course, the classical probability on the sample space  $\Omega$  is an example of a probability function. In our more general

favourable numbers, and one one digit favourable number. In total there are  $2 \cdot (3^3 + 3^2 + 3^1 + 1) \cdot 2 + 1 = 2 \cdot (3^4 - 1) + 1 = 2 \cdot 3^4 - 1$  favourable numbers. According to classical probability, we obtain the probability as  $\frac{2 \cdot 3^4 - 1}{10^5 - 1} \doteq 0.0016$ .  $\square$

**1.D.8.** From a sack with five white and five red balls, we draw in succession three balls at random without returning the balls back to the sack. What is the probability that two of them are white and one is red?

**Solution.** Divide the event into a union of three disjoint events, according to in which turn we draw the red ball. The probability that the red ball is drawn as third, second, or first, respectively, is:  $\frac{5}{10} \cdot \frac{4}{9} \cdot \frac{5}{8}$ ,  $\frac{5}{10} \cdot \frac{5}{9} \cdot \frac{4}{8}$ ,  $\frac{5}{10} \cdot \frac{5}{9} \cdot \frac{4}{8}$ . In total  $\frac{5}{12}$ .

**Another solution.** Consider the number of all possible triples of drawn balls,  $\binom{10}{3}$ . There are  $\binom{5}{2} \cdot \binom{5}{1}$  of triples with exactly two white balls (two white balls can be drawn in  $\binom{5}{2}$  ways, and one red ball can join them in five ways). The required probability is then  $\frac{\binom{5}{2} \cdot \binom{5}{1}}{\binom{10}{3}} \doteq \frac{5}{12}$ . We could forget the order, in which the balls were drawn, because every order has the same probability of being drawn. Thus there is  $3!$  more both, favourable as well as total events and their ratio remains unchanged.  $\square$

**1.D.9.** From a hat where there are five white, five red and six black balls we draw balls randomly (and do not return the drawn balls back). What is the probability that the fifth drawn ball is black?

**Solution.** We will solve a more general problem, the probability that the  $i$ -th drawn ball is black. This probability is the same for all  $i$ ,  $1 \leq i \leq 16$  – we can imagine that we draw all balls one by one, and every such sequence (from the first drawn ball to the last one) consisting of five white, five red and six black has the same probability of being drawn. Thus we can use classical probability. There are  $P(5, 5, 6) = \frac{16!}{5! \cdot 5! \cdot 6!}$  of such sequences. The number of sequences where there is a black ball on the  $i$ -th place, the rest arbitrary, equals to the number of arbitrary sequences of five white, five red and five black balls. That is,  $P(5, 5, 5) = \frac{15!}{5! \cdot 5! \cdot 5!}$ . Thus the probability is

$$\frac{P(5, 5, 5)}{P(5, 5, 6)} = \frac{15!}{5! \cdot 5! \cdot 5!} / \frac{16!}{6! \cdot 5! \cdot 5!} = \frac{3}{8}.$$

$\square$

model, the set of all subsets  $\mathcal{A}$  is closed upon union, intersection and taking the complement, and this has been essential in our exposition above. This will continue in all our discussion on probability in the sequel, where we shall have to allow for more general spaces of events  $\mathcal{A}$  in the sets of all subsets in the sample space. We will return to this and more serious generalizations in chapter 10.

**1.4.4. Summing probabilities.** By using mathematical induction, the additivity of probability is easily extended to any (finite) number of mutually exclusive events  $A_i \subset \Omega$ ,  $i = 1, \dots, n$ . That is,

$$P(\cup_{i \in I} A_i) = \sum_{i=1}^n P(A_i),$$

whenever  $A_i \cap A_j = \emptyset$ , for all  $i \neq j$ ,  $i, j = 1, \dots, n$ . Indeed, 1.4.3(3) is the result for  $n = 2$ . If we assume the validity of the formula for some fixed  $n$ , then the union of any  $n + 1$  events  $A_0, A_1, \dots, A_n$  can be split into the union of  $A_0$  and  $A_1 \cup \dots \cup A_n$ . Then by the induction assumption, together with 1.4.3(3) again, the result follows.

In general, the summing of probabilities of event occurrences is much more difficult. The problem is that whenever the events are mutually compatible, the possible results in their intersection are counted multiple times.

We have seen the simplest case of two mutually compatible events  $A$  and  $B$  in 1.4.3(8). For classical probability, it reduces just to counting elements in subsets. Indeed, those elements that belong to both the sets  $A$  and  $B$  count in the formula  $P(A \cup B) = P(A) + P(B) - P(A \cap B)$  twice and thus we have to subtract them once.

Now, we look at the general case. The approach of interactive inclusion and exclusion (potentially too many) elements in some count is a standard method in combinatorics known as the *inclusion-exclusion principle*. We shall exploit this method in our general finite probability spaces.

As we shall see, this is an example of a mathematical theorem, where the hard part is to understand (and find) the formulation of the result. The proof is then relatively simple.

**INCLUSION-EXCLUSION PRINCIPLE**

**1.D.10. Inclusion-exclusion principle.** A secretary has to send six letters to six different people. She puts the letters in the envelopes randomly. What is the probability that at least one person receives the correct intended letter?

**Solution.** We compute the probability of the complementary event – no person receives the correct letter.

The sample space corresponds to all possible orderings of six envelopes. If we denote both the letters and the envelopes by numbers from one to six, then all the favourable events (no letter is assigned to the corresponding envelope) correspond to such orderings of six elements, where the  $i$ -th element is not at the  $i$ -th place ( $i = 1, \dots, 6$ ).

These are the orderings without a fixed point. We compute the number of such orderings using the inclusion-exclusion principle. If we denote by  $M_i$  the set of permutations such that  $i$  is a fixed point (note that permutations in  $M_i$  can also have other fixed points), then the resulting number  $d$  of permutations without a fixed point is

$$d = 6! - |M_1 \cup \dots \cup M_6|$$

The number of elements in the intersection  $M_{i_1} \cap \dots \cap M_{i_k}$ ,  $k = 1, \dots, 6$ , is  $(6 - k)!$  (the order of the elements  $i_1, \dots, i_k$  is fixed, the remaining  $6 - k$  can be ordered arbitrarily). Using the inclusion-exclusion principle we have

$$|M_1 \cup \dots \cup M_6| = \sum_{k=1}^6 (-1)^{k+1} \binom{6}{k} (6 - k)!$$

and thus for the number  $d$  we obtain the relation

$$\begin{aligned} d &= 6! - \sum_{k=1}^6 (-1)^{k+1} \binom{6}{k} (6 - k)! \\ &= \sum_{k=0}^6 (-1)^k \binom{6}{k} (6 - k)! = 6! \sum_{k=0}^6 \frac{(-1)^k}{k!}. \end{aligned}$$

The probability that no person receives “his” letter is then

$$\sum_{k=0}^6 \frac{(-1)^k}{k!} = \frac{53}{144}.$$

The probability we were asked for is

$$1 - \sum_{k=0}^6 \frac{(-1)^k}{k!} = \frac{91}{144}.$$

The diagram explains the situation for three sets  $A, B, C$  for classical probability:

$$\begin{aligned} P(A \cup B \cup C) &= P(A) + P(B) + P(C) - P(A \cap B) \\ &\quad - P(A \cap C) - P(B \cap C) + P(A \cap B \cap C). \end{aligned}$$

Clearly, the probabilities are given by first counting the elements in each set and adding. Then we subtract the sum of those in intersections of pairs of sets, since those elements are counted twice. But we must then add in the number of elements in the intersection of all three.

We shall now follow the same idea in order to write down the formula in the following theorem. It seems plausible that such a formula should work with proper coefficients of the sums of probabilities of intersections of more and more events among  $A_1, \dots, A_k$ , at least in the case of classical probability. The reader will perhaps appreciate that a quite straightforward mathematical induction will verify the theorem in full generality.

**1.4.5. Theorem.** Let  $A_1, \dots, A_k \in \mathcal{A}$  be arbitrary events over the sample space  $\Omega$  with a set of events  $\mathcal{A}$ . Then

$$\begin{aligned} P(\cup_{i=1}^k A_i) &= \sum_{i=1}^k P(A_i) - \sum_{i=1}^{k-1} \sum_{j=i+1}^k P(A_i \cap A_j) \\ &\quad + \sum_{i=1}^{k-2} \sum_{j=i+1}^{k-1} \sum_{\ell=j+1}^k P(A_i \cap A_j \cap A_\ell) \\ &\quad - \dots \\ &\quad + (-1)^{k-1} P(A_1 \cap A_2 \cap \dots \cap A_k). \end{aligned}$$

**PROOF.** For  $k = 1$  the claim is obvious. The case  $k = 2$  is the same as the equality 1.4.3(8), which we have already proved.

Assume that the theorem holds for any number of events up to  $k$ , where  $k \geq 1$ . Now we can work in the induction step with the formula for  $k + 1$  events, where the union of the first  $k$  of them are considered to be the  $A$  in the equation 1.4.3(8) and the remaining event is considered to be the  $B$ :

$$\begin{aligned} P(\cup_{i=1}^{k+1} A_i) &= P((\cup_{i=1}^k A_i) \cup A_{k+1}) \\ &= \sum_{j=1}^k \left( (-1)^{j+1} \sum_{1 \leq i_1 < \dots < i_j \leq k} P(A_{i_1} \cap \dots \cap A_{i_j}) \right) \\ &\quad + P(A_{k+1}) - P((A_1 \cup \dots \cup A_k) \cap A_{k+1}). \end{aligned}$$

This already resembles the formula for  $k + 1$  summed events. But in the first term, expressions containing  $A_{k+1}$  are missing. Also absent is a term allowing for the probability that all the events happen. On the other hand, the last expression should not be there. We can replace it by the expression

$$-P((A_1 \cap A_{k+1}) \cup \dots \cup (A_k \cap A_{k+1}))$$

and for this we can again use the induction, that is, the formula in the statement of the theorem. With a little patience (and a piece of paper long enough to write down all the expressions) we can check that this adds all the missing pieces.  $\square$

**Remark.** Notice that the answer does not change much with a growing number of letters. For  $n$  letters, the probability that the secretary does not assign any of them in correct order is

$$\sum_{k=0}^n \frac{(-1)^k}{k!} \doteq \frac{1}{e}.$$

As we will see later, the sum converges to the value  $1/e$ . In a similar way the exercise 1.G.45 can be solved.

The following exercise is a simple model, which estimates the probability of death of a person in a traffic accident.

**1.D.11.** Approximately 1200 persons die per year at the roads of the Czech Republic. Determine the probability that some person of a chosen group of 500 people dies in the following ten years in a traffic accident. For simplicity, assume that every person has the same “chance” of dying in traffic accident in one year and that this probability is  $1200/10^7$ .

**Solution.** Let us first count the probability that one randomly chosen person does **not** die in ten years in a traffic accident. The probability that he/she does not die in a year is  $(1 - \frac{12}{10^5})$ . The probability that he/she does not die in ten years is then  $(1 - \frac{12}{10^5})^{10}$ . The probability that in ten years none of the given 500 people does not die is again using the product rule (the events are independent)  $(1 - \frac{12}{10^5})^{5000}$ . The probability of the complementary event, that is, some of the chosen people dies, is then

$$1 - \left(1 - \frac{12}{10^5}\right)^{5000} \doteq 0.4512.$$

**Remark.** The model we have used in the previous exercise to describe the given situation is only approximate. The complication is in the condition that every person in the sample has the same probability of dying, which is derived based on the total number of deaths per year. But the number of deaths changes yearly and even if it did not, the population changes. We show one of the possible inaccuracies by a different approach to the solution: if 1200 persons per year dies, then in ten years 12000 persons die. The probability that a certain person dies in ten years can thus be estimated by  $12000/10^7$ . The probability that a specific person does not die in ten years is then  $(1 - \frac{12}{10^4})$  (first two members of binomial expansion of  $(1 - \frac{12}{10^5})^{10}$ ). In total we analogously obtain the estimate

□ **1.4.6. Inclusion-exclusion principle.** As we have mentioned already, a special case of the previous theorem is the one of classical probability.

There the probability of an event  $A$  is strictly proportional to the number of elements in  $A$  (which is just divided by the total size  $n$  of the sample space). Thus, in the formula from the previous theorem, all the probabilities give the sizes of the subsets involved, up to a common factor  $\frac{1}{n}$ .

In this way we can extract from the theorem 1.4.5 the following claim for the size of a general finite set  $M$  and its subsets  $A_1, \dots, A_k$ . As usual we let  $|M|$  denote the number of elements of the set  $M$ .

Of course for every finite set  $M$  and its subsets,

$$|M \setminus (\cup_{i=1}^k A_i)| = |M| - |\cup_{i=1}^k A_i|.$$

Now we use the previous theorem, and express the size of the union on the right side, and we obtain the theorem that is usually called

PRINCIPLE OF INCLUSION-EXCLUSION

$$|M \setminus (\cup_{i=1}^k A_i)| = |M| + \sum_{j=1}^k (-1)^j \sum_{1 \leq i_1 < \dots < i_j \leq k} |A_{i_1} \cap \dots \cap A_{i_j}|$$

The meaning of this result for the special case  $n = 3$  can be visualized easily, see the diagram before the theorem 1.4.5.

**1.4.7. Independent events.** Next, we wish to express possible dependencies among events in a given sample space  $\Omega$  with the probability function  $P$ . We say that the events  $A$  and  $B$  are *stochastically independent* if

$$P(A \cap B) = P(A) \cdot P(B).$$

This definition may remind us of our experiences in combinatorics when counting possibilities for independent choices. For example, dealing with a fair dice, we can define events  $A$  “odd number occurs”,  $B$  “the result is at least 3” and  $C$  “the result is at most 3”. The probabilities are  $P(A) = \frac{1}{2}$ ,  $P(B) = \frac{2}{3}$ ,  $P(C) = \frac{1}{2}$ ,  $P(A \cap B \cap C) = \frac{1}{6} = \frac{1}{2} \cdot \frac{2}{3} \cdot \frac{1}{2} = P(A) \cdot P(B) \cdot P(C)$ , and taking pairs we have  $P(A \cap C) = \frac{1}{3} \neq \frac{1}{2} \cdot \frac{1}{2}$ ,  $P(A \cap B) = \frac{1}{3} = \frac{1}{2} \cdot \frac{2}{3}$ ,  $P(B \cap C) = \frac{1}{6} \neq \frac{2}{3} \cdot \frac{1}{2}$ . Notice, that the stochastic dependence of the pairs  $A, C$  and  $B, C$  corresponds well to our intuition (e.g. there are more odd numbers between the values 1, 2, 3 than between the numbers 4, 5, 6).

This example also shows that we have to be careful with more events. In general, mutually independent sets are defined in this way:

**Definition.** Consider an arbitrary probability function  $P$  on sample space  $\Omega$  and  $k$  events  $A_1, \dots, A_k$  in that space. We say that these events are *stochastically independent* (with respect to the probability function  $P$ ), if for any chosen events  $A_{i_1}, \dots, A_{i_\ell}$ ,  $1 \leq \ell \leq k$  we have

of the probability

$$1 - \left(1 - \frac{12}{10^4}\right)^{500} \doteq 0.4514.$$

We see that both estimates are very close to each other.

The effort to use mathematical knowledge for winning in various gambling games is very old. We look at a very simple example.

**1.D.12.** Alex has \$2500 left over from organizing a summer camp. Alex added \$50 from his savings and decided to go playing roulette. Alex bets only on colour. The probability of winning when betting on colour is  $18/37$ . He begins to bet \$10, and if he loses, in the next bet, he doubles the bet that he made in the previous round. (This is only if he has enough money. If not, he ends the game even if he has some money left.) If he wins, in the next round he bets again \$10. What is the probability that using this strategy he wins another \$2550? As soon as he has already won such an amount, he ends the game.

**Solution.** First count how many times in a row Alex can loose. If he begins with a bet of \$10, then for  $n$  bets he needs

$$10 + 20 + \dots + 10 \cdot 2^{n-1} = 10 \cdot \left(\sum_{i=0}^{n-1} 2^i\right) = 10 \cdot (2^n - 1).$$

The number 2550 is of the form  $10(2^n - 1)$  for  $n = 8$ . Alex can thus bet eight times in a row no matter what the result is. For nine bets he would need  $10(2^9 - 1) = \$5110$  and during the game he will never have such an amount, since as soon as he has \$5100, he stops. Thus in order for him to fail, he must lose eight times in a row. The probability of losing on a single bet is  $19/37$ . So the probability of losing eight times in a row is  $(19/37)^8$ . The probability that in these eight games he wins \$10 (using his strategy) is thus  $1 - (19/37)^8$ . In order to win \$2500, he needs to win 255 times \$10. Again using the product rule the probability of winning is

$$\left(1 - \left(\frac{19}{37}\right)^8\right)^{255} \doteq 0.29.$$

Thus the probability of winning is lower than betting everything at once on colour.  $\square$

**1.D.13.** Individually you can try to solve the previous exercise assuming that Alex has the same strategy as before, but ends only when he has no money (if he cannot afford to double the bet when he lost the previous but still has some money, he begins again with \$10).

$$P(A_{i_1} \cap \dots \cap A_{i_\ell}) = P(A_{i_1}) \cdot \dots \cdot P(A_{i_\ell}).$$

Every subset of a set of stochastically independent events is also stochastically independent. Further, for any two stochastically independent events we compute

$$\begin{aligned} P(A \cap B^c) &= P(A \setminus B) = P(A) - P(A \cap B) = \\ &= P(A)(1 - P(B)) = P(A)P(B^c). \end{aligned}$$

From there we can show that by exchanging one or more events in a set of stochastically independent events by their complements, we again obtain a set of stochastically independent sets.

Sometimes we need to compute the probability that at least one of the stochastically independent set of events occurs. That is, we want to compute  $P(A_1 \cup \dots \cup A_k)$ . In such a situation we can use the De Morgan laws for sets (check them yourselves!)

$$\left(\bigcup_{i \in I} A_i\right)^c = \bigcap_{i \in I} A_i^c, \quad \left(\bigcap_{i \in I} A_i\right)^c = \bigcup_{i \in I} A_i^c.$$

We obtain

$$\begin{aligned} P(A_1 \cup \dots \cup A_k) &= 1 - P(A_1^c \cap \dots \cap A_k^c) \\ &= 1 - (1 - P(A_1)) \cdot \dots \cdot (1 - P(A_k)) \\ &= 1 - \prod_{j=1}^k (1 - P(A_j)). \end{aligned}$$

**1.4.8. Conditional probability.** Often we want to restrict our attention only to events, which lie in a subspace  $H \subset \Omega$ . This means that the events in question will be the intersections  $A \cap H$  of the original events  $A$  with the subset  $H$ . Thus our new probabilities should be proportional to  $P(A \cap H)$ . We would like to have  $H$  in the role of the new sample space.

As an example, we might look again at the model of a fair dice and ask the question “what is the probability that by throwing two dice the result is twice 5, if we know that the sum of the results is 10?”. Of course, we are now having only the possibilities  $4 + 6$  (two times) and  $5 + 5$  (once). So the probability should be  $\frac{1}{3}$ , much greater than the probability  $\frac{1}{36}$  of the same event without any further condition.

Similar situations are reflected in the following definition:

#### CONDITIONAL PROBABILITY

**Definition.** Let  $H$  be an event with non-zero probability in the sample space  $\Omega$  with the probability function  $P$ . The *conditional probability*  $P(A|H)$  of the event  $A$  given  $H$  is defined by the formula

$$P(A|H) = \frac{P(A \cap H)}{P(H)}.$$

The event  $H$  is sometimes called the *hypothesis*.

Now we consider “conditional” probability (see (1.4.8)).

**1.D.14.** What is the probability that when rolling two dice the sum is 7, if we know that neither of the rolls resulted in a 2?

**Solution.** Let  $B$  be the event that neither of the rolls results into 2, and let  $A$  be the event “sum is 7”. The set of all possible outcomes is again denoted by  $\Omega$ . Then

$$P(A|B) = \frac{P(A \cap B)}{P(B)} = \frac{\frac{|A \cap B|}{|\Omega|}}{\frac{|B|}{|\Omega|}} = \frac{|A \cap B|}{|B|}.$$

The number 7 can appear as a sum in four ways if there is no 2, that is,  $|A \cap B| = 4$ ,  $|B| = 5 \cdot 5 = 25$ . Thus

$$P(A|B) = \frac{4}{25}.$$

Note that  $P(A) = \frac{1}{6}$ , that is,  $A$  and  $B$  are not independent.

□

**1.D.15.** Michael has two mailboxes, one at gmail.com and the other at hotmail.com. His username is the same at both servers, but the passwords are different. He does not remember which password corresponds to which server. When typing in the password for accessing his mailbox, he makes a typo with probability 5% (that is, if he tries to type in a specific password, he types what he intended with probability 95%). At the server hotmail.com, Michael typed in the username and a password, but the server told him that something is wrong. What is the probability that he chose the correct password but just mistyped? (Assume that the username is always typed correctly and that making a typo cannot turn wrong password into a good one.)

**Solution.** Let  $A$  be the event that Michael typed in a wrong password at hotmail.com. This event is the union of two disjoint events:

- $A_1$  : he wanted to type in the correct password and mistyped,
- $A_2$  : he wanted to type in the wrong password (the one from gmail.com) and either mistyped it or not.

We are looking for a conditional probability  $P(A_1|A)$  which, according to the formula for conditional probability, is:

$$P(A_1|A) = \frac{P(A_1 \cap A)}{P(A)} = \frac{P(A_1)}{P(A_1 \cup A_2)} = \frac{P(A_1)}{P(A_1) + P(A_2)},$$

where we have used  $P(A_1 \cup A_2) = P(A_1) + P(A_2)$  since  $A_1$  and  $A_2$  are disjoint. We just need to determine the probabilities  $P(A_1)$  and  $P(A_2)$ . The event  $A_1$  is the intersection of two independent events: Michael wanted to type in

As it is obvious from the definition, the hypothesis  $H$  with non-zero probability and the event  $A$  are (stochastically) independent if and only if  $P(A) = P(A|H)$ . The definition also directly implies the “theorem for product of probabilities” – if we have two events  $A_1, A_2$  satisfying  $P(A_1 \cap A_2) > 0$ , then

$$P(A_1 \cap A_2) = P(A_2)P(A_1|A_2) = P(A_1)P(A_2|A_1).$$

All these numbers express (in a different manner) the probability that both events  $A_1$  and  $A_2$  occur. For instance, in the last case we first look whether the first event occurred. Then, assuming that the first has occurred, we look whether the second also occurs. Similarly, for three events  $A_1, A_2, A_3$  satisfying  $P(A_1 \cap A_2 \cap A_3) > 0$  we obtain

$$P(A_1 \cap A_2 \cap A_3) = P(A_1)P(A_2|A_1)P(A_3|A_1 \cap A_2).$$

The probability that three events occur simultaneously can be computed as follows. Compute the probability that the first occurs, then compute the probability that the second occurs under the assumption that the first has occurred. Then compute the probability that the third occurs under the assumption that both the first and the second have occurred. Finally, multiply the results together.

In general, if we have  $k$  events  $A_1, \dots, A_k$  satisfying  $P(A_1 \cap \dots \cap A_k) > 0$ , then the theorem says

$$\begin{aligned} P(A_1 \cap \dots \cap A_k) &= \\ &= P(A_1)P(A_2|A_1) \cdots P(A_k|A_1 \cap \dots \cap A_{k-1}). \end{aligned}$$

Notice that our condition that  $P(A_1 \cap \dots \cap A_k) > 0$  implies that all the hypotheses in the latter formula have got non-zero probabilities and thus all the conditional probabilities make sense. Indeed, each  $A_i$  is at least as big as the intersection and thus its probability is at least as big, thus non-zero, see 1.4.3(7).

**1.4.9. Geometric probability.** In practical problems, the sample space may not be a finite set. The set  $\mathcal{A}$  of all events may not be the entire set of all subsets in  $\Omega$ . To generalise probability to such situations is beyond our scope now, but we can at least give a simple illustration.

Consider the plane  $\mathbb{R}^2$  of pairs of real numbers and a subset  $\Omega$  with known area  $\Omega$ . Events are represented by subsets  $A \subset \Omega$  (again with known areas). For the event set  $\mathcal{A}$  we consider some suitable system of subsets for which we can determine the area. An event  $A$  then occurs if a randomly chosen point from  $\Omega$  belongs to the subregion determined by  $A$ , otherwise the event does not occur.

Consider the problem of randomly choosing two numbers  $a < b$  in the interval  $[0, 1] \subset \mathbb{R}$ . All values  $a$  and  $b$  are chosen with equal probability. The question is “what is the probability that the interval  $(a, b)$  has length at least one half?” The choice of points  $(a, b)$  is actually the choice of a point  $[a, b]$  inside of the triangle  $\Omega$  with vertex points  $[0, 0]$ ,  $[0, 1]$ ,  $[1, 1]$  (see the diagram).

a correct password and Michael mistyped. According to the problem statement, the probability of the first event is  $1/2$  and the probability of the second event is  $1/20$ . In total  $P(A_1) = \frac{1}{2} \cdot \frac{1}{20} = \frac{1}{40}$  (we multiply the probabilities, since the events are independent). Further we have (directly from the problem statement)  $P(A_2) = \frac{1}{2}$ . In total  $P(A) = P(A_1) + P(A_2) = \frac{1}{40} + \frac{1}{2} = \frac{21}{40}$ . We can evaluate

$$P(A_1|A) = \frac{P(A_1)}{P(A)} = \frac{\frac{1}{40}}{\frac{21}{40}} = \frac{1}{21}.$$

□

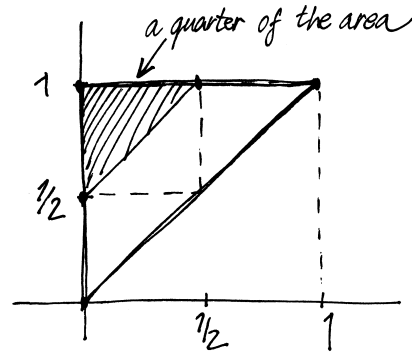

The method of *geometric probability* can be used in the case that the given sample space consists of some region of a line, region, space (where we can determine (respectively) length, area, volume, ...). We assume that the probability, is equal to the ratio of the area of the subregion to the area of the sample space.

**1.D.16.** From Edinburgh Waverley station trains depart every hour (in the direction to Aberdeen). From Aberdeen to Edinburgh they also depart every hour. Assume that the trains move between these two stations with a uniform speed 72 km/h and are 100 meters long. The trip takes 2 hrs in either direction. The trains meet each other somewhere along the route. After visiting an Edinburgh pub, John, who lives in Aberdeen, takes the train home and falls asleep at the departure. During the trip from Edinburgh to Aberdeen he wakes up and randomly sticks his head out of the train for five seconds, on the side of the train where the trains travel in the opposite direction. What is the probability that he loses his head? (We are assuming that there are no other trains involved.)

**Solution.** The mutual speed of the oncoming trains is 40 metres per second, the oncoming train passes John's window for two and a half seconds. The sample space of all outcomes is thus the interval  $(0, 7200)$ . During John's trip two trains pass by John's window in the opposite direction. Any overlap of the 2.5 seconds of the passing time interval with the 5 second time interval when John's head might be sticking out is fatal. Thus, for each train, the space of "favourable" outcomes is an interval of length 7.5 seconds somewhere in the sample space. For two trains, it is double this amount. Thus the probability of losing the head is  $15/7200 \doteq 0.002$ . □

**1.D.17.** In a certain country, a bus departs from town A to town B once a day at a random time between eight a.m. and

We can imagine this as a description of a problem where a very tired guest at a party tries to divide a sausage with two cuts into three pieces for himself and his two friends. What is the probability that the middle part will be at least half of the sausage?

Thus we need to determine the area of the subset which corresponds to points with  $b \geq a + \frac{1}{2}$ , that is, the interior of the triangle  $A$  bounded by the points  $[0, \frac{1}{2}]$ ,  $[0, 1]$ ,  $[\frac{1}{2}, 1]$ . We find  $P(A) = (1/8)/(1/2) = \frac{1}{4}$ .

Similarly, if we ask for the probability that some of the three guests will get at least half of the sausage, then we have to add the probabilities of two other events:  $B$  saying  $a \geq 1/2$  and  $C$  given as  $b \leq 1/2$ . Clearly they correspond to the lowest and the most right top triangles and thus they have got probabilities  $1/4$ , too. Thus the requested probability is  $3/4$ .

Equivalently we could have asked for the complementary event "all of them get less than a half" which clearly corresponds to the middle triangle and thus has probability  $1/4$ .

Try to answer on your own the question "what is the minimal prescribed length  $\ell$  such that the probability of choosing an interval  $(a, b)$  of length at least  $\ell$  is one half?"

**1.4.10. Monte Carlo methods.** One efficient method for computing approximate values is simulation by the relative occurrence of a chosen event.

We present an example. Let  $\Omega$  be the unit square with vertices at  $[0, 0]$ ,  $[1, 0]$ ,  $[0, 1]$ , and  $[1, 1]$ . Let  $A$  be the intersection of  $\Omega$  with the unit disk centred at the origin. Then  $\text{area } A = \frac{1}{4}\pi$ . Suppose we have a reliable generator of random numbers  $a$  and  $b$  between zero and one. We then compute relative frequencies of how often  $a^2 + b^2 < 1$ . That is, that  $[a, b] \in A$ . Then the result (after a large number of attempts) should approximate the area of a quarter unit circle, that is  $\pi/4$  quite well. (Draw a picture yourselves!)

Of course, the well-known formula for the area of a circle with radius  $r$  is  $\pi r^2$ , where  $\pi = 3.14159\dots$ . It is an interesting question – why should the area of a circle be a constant multiple of the square of its radius? We will be able to prove this later. But experimentally, we can hint at this by the approach as above using squares of different sizes.

Numerical approaches based on such probabilistic principles are called *Monte Carlo methods*.

eight p.m. Once a day in the same time interval another bus departs in the opposite direction. The trip in either direction takes five hours. What is the probability that the buses meet, assuming they use the same route?

**Solution.** The sample space is a square  $12 \times 12$ . If we denote the time of the departure of the buses as  $x$  and  $y$  respectively, then they meet on the trail if and only if  $|x - y| \leq 5$ . This inequality determines the region in the square of “favourable events”. This is a complement to the union of two right-angled isosceles triangles with legs of length 7. Its area in total is 49, so the area of the “favourable part” is  $144 - 49 = 95$ . The probability is  $p = \frac{95}{144} \doteq 0.66$ .

**1.D.18.** A rod of length two meters is randomly divided into three parts. Determine the probability that at least one part is at most 20 cm long.

**Solution.** Random division of a rod into three parts is given by two points of the cut,  $x$  and  $y$  (we first cut the rod in the distance  $x$  from the origin, we do not move it and again cut it in the distance  $y$  from the origin). The sample space is a square  $C$  with side 2 m.

If we place the square  $C$  so that its two sides lie on axes in the plane, then the condition that at least one part is at most 20 cm determines in the square a subregion  $O$ :

$$O = \{(x, y) \in C \mid x \leq 20 \vee x \geq 180 \vee y \leq 20 \vee y \geq 180 \vee |x - y| \leq 20\}.$$

## 5. Plane geometry

So far we have been using elementary notions from the geometry of the real plane in an intuitive way. Now we will investigate in more detail how to deal with the need to describe “position in the plane” and to find some relation between positions of distinct points in the plane.

Our tools will be mappings. We will mainly consider mappings  $F$  which, to (ordered) pairs of values  $(x, y)$ , assign pairs  $(w, z) = F(x, y)$ . Such a mapping will consist of two functions  $w(x, y)$  and  $z(x, y)$ , each depending on two arguments  $x, y$ . This will also serve as a gentle introduction to the part of mathematics called *Linear algebra*, with which we will deal in the subsequent three chapters.

**1.5.1. Vector space  $\mathbb{R}^2$ .** We view the “plane” as a set of pairs of real numbers  $(x, y) \in \mathbb{R}^2$ . We will call these pairs *vectors* in  $\mathbb{R}^2$ . For such vectors we can define addition “coordinate-wise”, that is, for vectors  $u = (x, y)$  and  $v = (x', y')$  we set

$$u + v = (x + x', y + y').$$

Since all the properties of commutative groups hold for individual coordinates, these hold for our new vector addition too. In particular there exists a *zero vector*  $0 = (0, 0)$ , such that  $v + 0 = v$ . We use the same symbol  $0$  for the vector and for the number zero on purpose. The context will always make it clear which “zero” it is.

Next we define scalar multiplication of vectors. For  $a \in \mathbb{R}$  and  $u = (x, y) \in \mathbb{R}^2$ , we set

$$a \cdot u = (ax, ay).$$

Usually we will omit the symbol  $\cdot$  and use the juxtaposition of the symbols  $av$  to denote the scalar multiple of a vector.

We can directly check other properties for scalar multiplication by  $a$  or  $b$  and addition of vectors  $u$  and  $v$ . For instance  $a(u + v) = au + av$ ,  $(a + b)u = au + bu$ ,  $a(bu) = (ab)u$ .

We use the same symbol  $+$  for both vector addition and scalar addition.

Now we take a very important step. Define vectors  $e_1 = (1, 0)$  and  $e_2 = (0, 1)$ . Every vector can then be written uniquely as

$$u = (x, y) = x e_1 + y e_2.$$

As we observe, this subregion has area  $\frac{51}{100}$  times the area of the square.  $\square$

### E. Plane geometry

Let us start with several standard problems related to lines in plane:

**1.E.1.** Write down the general equation of the line  $p : x = 2 - t, y = 1 + 3t, t \in \mathbb{R}$ .

**Solution.** By eliminating  $t$ , the solution is  $3x + y - 7 = 0$ .  $\square$

**1.E.2.** We are given a line

$$p : [2, 0] + t(3, 2), t \in \mathbb{R}.$$

Determine the general equation of this line. Determine its intersection with the line

$$q : [-1, 2] + s(1, 3), s \in \mathbb{R}.$$

**Solution.** The coordinates of the points on the first line are given by the parametric equations as  $x = 2 + 3t$  and  $y = 0 + 2t$ . By eliminating  $t$  from the equations we obtain the equation:

$$2x - 3y - 4 = 0.$$

We obtain the intersection of  $p$  with the line  $q$  by substituting the points of  $q$  in parametric form into the equation for  $p$ :

$$2(-1 + s) - 3(2 + 3s) - 4 = 0.$$

Here we obtain  $s = -12/7$  and from the parametric equation of  $q$  we obtain the coordinates of the intersection  $P$ :

$$P = \left[ -\frac{19}{7}, -\frac{22}{7} \right].$$

$\square$

**1.E.3.** Determine the intersection of the lines

$$p : x + y - 4 = 0, \quad q : x = -1 + 2t, y = 2 + t, t \in \mathbb{R}.$$

**Solution.** Eliminate  $t$  to obtain  $q : x - 2y = -5$ . Then solve for  $x$  and  $y$ . The intersection has coordinates  $x = 1, y = 3$ .

$\square$

The expression on the right is called a *linear combination of vectors*  $e_1$  and  $e_2$  (with coefficients  $x$  and  $y$ ). The pair of vectors  $\underline{e} = (e_1, e_2)$  is called the standard *basis* of the vector space  $\mathbb{R}^2$ .

As shown on the picture, these operations are easy to imagine if we consider the vectors  $v$  to be arrows starting at the origin  $0 = (0, 0)$  and ending at the position  $(x, y)$  in the plane.

The addition of two such arrows is then given by the parallelogram law: Given two arrows starting at the origin, their sum is the arrow given by the diagonal arrow (also starting at the origin) of the parallelogram with the two given arrows as adjacent sides. Multiplication by a scalar  $a$  corresponds to stretching the arrow to its  $a$ -multiple. This includes negative scalars, where the direction of the vector is reversed.

If we choose any two non-zero vectors  $u, v$  such that neither of them is a multiple of the other, then they form a basis of  $\mathbb{R}^2$ , too, i.e. each other vector can be (uniquely) written as a linear combination of these. This seems to be clear from the picture, and we may easily write down the two equations for the coefficients and to solve them (as we shall deduce in a while).

**1.5.2. Points in the plane.** In geometry, we should distinguish between the points in the plane (as for instance the chosen origin  $O$  above), and the vectors as the arrows describing the difference between two such points. We will work in fixed standard coordinates, that is, with pairs of real numbers, but for better usage we will always strictly distinguish vectors written in parentheses and denoted for a moment by bold face letters like  $\mathbf{u}, \mathbf{v}$ , instead of brackets (which we use for coordinates of points in the plane). Points themselves are denoted by capital latin letters.

Even if we view the entire plane as pairs of real numbers in  $\mathbb{R}^2$ , we may understand adding two such couples as follows. The first couple of coordinates describes a point  $P = [x, y]$ , while the other one denotes a vector  $\mathbf{u} = (u_1, u_2)$ . Their sum  $P + \mathbf{u}$  corresponds to adding the (arrow) vector  $\mathbf{u}$  to the point  $P$ . If we fix the vector  $\mathbf{u}$ , we call the resulting mapping

$$P = [x, y] \mapsto P + \mathbf{u} = [x + u_1, y + u_2]$$

the *shift of the plane* (or *translation*) by the vector  $\mathbf{u}$ .

**1.E.4.** Find the equation of the line  $p$ , which goes through the point  $[2, 3]$  and is parallel with the line  $x - 3y + 2 = 0$ . Find a parametric equation of the line  $q$  which goes through the points  $[1, 3]$  and  $[-2, 1]$ .

**Solution.** Every line parallel to the line  $x - 3y + 2 = 0$  is given by the equation

$$x - 3y + c = 0$$

for some  $c \in \mathbb{R}$ . Since the line  $q$  goes through the point  $[2, 3]$ ,  $c = 7$  by putting  $x = 2$  and  $y = 3$ . We can immediately give a parametric equation of the line  $q$

$$q : [1, 3] + t(1 - (-2), 3 - 1) = [1, 3] + t(3, 2), \quad t \in \mathbb{R}.$$

□

**1.E.5.** Consider the following five lines. Determine if any two of the lines are parallel to each other.

$$\begin{aligned} p_1 : 2x + 3y - 4 = 0, & \quad p_2 : x - y + 3 = 0, \\ p_3 : -2x + 2y = -6, & \quad p_4 : -x - \frac{3}{2}y + 2 = 0, \\ p_5 : x = 2 + t, & \quad y = -2 - t, \quad t \in \mathbb{R} \end{aligned}$$

**Solution.** It is clear that

$$-2 \cdot \left(-x - \frac{3}{2}y + 2\right) = 2x + 3y - 4.$$

Thus  $p_1$  and  $p_4$  describe the same line.  $p_2$  can be rewritten as  $-2x + 2y - 6 = 0$ , thus the lines  $p_2$  and  $p_3$  are parallel and distinct. By eliminating  $t$ , the line  $p_5$  has an equation  $x + y = 0$ , which is not parallel to any other line. □

**1.E.6.** Determine the line  $p$  which is perpendicular to the line  $q : 6x - 7y + 13 = 0$  and which goes through the point  $[-6, 7]$ .

**Solution.** Since the direction vector of  $p$  is perpendicular to  $q$ , we can write the result immediately as

$$p : x = -6 + 6t, \quad y = 7 - 7t, \quad t \in \mathbb{R}.$$

□

**1.E.7.** Give an example of numbers  $a, b \in \mathbb{R}$ , such that the vector  $u$  is a normal to  $AB$  where  $A = [1, 2]$ ,  $B = [2b, b]$ ,  $u = (a - b, 3)$ .

**Solution.** The direction of  $AB$  is  $(2b - 1, b - 2)$  (this vector is always nonzero), and therefore the vector  $(2 - b, 2b - 1)$  is normal to  $AB$ . Setting

$$2 - b = a - b, \quad 2b - 1 = 3,$$

we obtain  $a = b = 2$ . □

Thus, the vectors in  $\mathbb{R}^2$  can be understood in more abstract way as the shifts in the plane (sometimes called the *free vectors* in elementary geometry texts).

The standard coordinates on  $\mathbb{R}^2$ , understood as pairs of real numbers are not the only ones. We can put a coordinate system on the plane with our choosing.

### COORDINATES IN THE PLANE $\mathbb{R}^2$

Choose any point in the plane, and call it the origin  $O$ . All other points  $P$  in the plane can be identified with the vectors (arrows)  $\overrightarrow{OP}$  with their tails at the origin.

Choose any point other than  $O$  and call it  $E_1$ . This defines the vector  $\mathbf{e}_1 = \overrightarrow{OE_1} = (1, 0)$ . Choose any other point  $E_2$  so that  $O, E_1, E_2$  are distinct and not collinear. This defines the vector  $\mathbf{e}_2 = \overrightarrow{OE_2} = (0, 1)$ .

Then every point  $P = (a, b)$  in the plane can be described uniquely as  $P = O + a\mathbf{e}_1 + b\mathbf{e}_2$  for real  $a, b$ , or in vector notation,  $\overrightarrow{OP} = a\mathbf{e}_1 + b\mathbf{e}_2$ .

Translation, by adding a fixed vector, can be used either to shift the coordinate system (including the origin), or to shift sets of points in the plane. Notice that the vector corresponding to the shift of the point  $P$  into the point  $Q$  is given as the difference  $Q - P$  (in any coordinates). Thus we shall also use this notation for the vector  $\overrightarrow{PQ} = Q - P$ .

For each choice of coordinates, we have two distinct lines for the two axes. The origin is the point of intersection. Other way round, each choice of two non-parallel lines, together with the scales on each of them defines coordinates in the plane. They are called *affine coordinates*.

Clearly each nontrivial triangle in the plane with vertices  $O, E_1, E_2$  defines coordinates where this triangle is defined by points  $[0, 0], [1, 0], [0, 1]$ . Thus we may say that in the geometry of plane, "all nontrivial triangles are the same, up to a choice of coordinates".

**1.5.3. Lines in the plane.** Every line is parallel to a (unique)

line through the origin. To define a line, we therefore need two ingredients. One is a non-zero vector which describes the direction of the line. Call it  $\mathbf{v} = (v_1, v_2)$ . The other is a point  $P_0 = [x_0, y_0]$  on the line. Every point on the line is then of the form

$$P(t) = P_0 + t\mathbf{v}, \quad t \in \mathbb{R}.$$

### PARAMETRIC DESCRIPTION OF A LINE

We may understand the line  $p$  as the set of all multiples of the vector  $\mathbf{v}$ , shifted by the vector  $(x_0, y_0)$ . This is called the *parametric description* of the line:

$$p = \{P \in \mathbb{R}^2; P = P_0 + t\mathbf{v}, t \in \mathbb{R}\}.$$

The vector  $\mathbf{v}$  is called *direction vector* of the line  $p$ .

In the chosen coordinates, the point  $P(t) = [x(t), y(t)]$  is given as

$$x = x(t) = x_0 + tv_1, \quad y = y(t) = y_0 + tv_2$$

**1.E.8.** Determine the relative position of the lines  $p, q$  in the plane for  $p : 2x - y - 5 = 0, q : x + 2y - 5 = 0$ . If they are not parallel, determine the coordinates of the intersection.

**Solution.** Eliminating  $y$  yields  $(4x - 2y - 10) + (x + 2y - 5) = 0$ , from which  $x = 3$ , and hence  $y = 1$ . Hence  $[3, 1]$  is the (unique) intersection and the lines are not parallel.  $\square$

**1.E.9.** Planar soccer player shoots a ball from the point  $F = [1, 0]$  in the direction  $(3, 4)$  hoping to hit the goal which is a line segment from the point  $A = [23, 36]$  to  $B = [26, 30]$ . Does the ball fly towards the goal?

**Solution.** The ball travels along the line  $[1, 0] + t(3, 4)$ . The line  $\vec{AB}$  has the parametrization  $[23, 36] + u(3, -6)$ , where  $B = [23, 36] + 1 \cdot (3, -6)$ . The intersection of these lines is given by equations  $1 + 3t = 23 + 3u$  and  $4t = 36 - 6u$ , with the solution  $t = 8, u = 2/3$ . As  $0 < 2/3 < 1$  the intersection is in the segment  $AB$ . The ball hits the goal.

**Another solution.** It is sufficient to consider only the slopes of the vectors  $\vec{FA}, (3, 4), \vec{FB}$ . Since  $\frac{36}{22} > \frac{4}{3} > \frac{30}{25}$ , the player scores.  $\square$

**1.E.10.** Consider the plane  $\mathbb{R}^2$  with the standard coordinate system. A laser ray is sent from the origin  $[0, 0]$  in the direction  $(3, 1)$ . It hits the mirror line  $p$  given by the equation

$$p : [4, 3] + t(-2, 1)$$

and then it is reflected (the angle of incidence equals the angle of reflection). At which points does the ray meet the line  $q$ , given by

$$q : [7, -10] + t(-1, 6)?$$

**Solution.** In principle, there could be none, one or two intersections of a ray with a line. First, we inspect possible intersection of the line  $q$  with the ray, before the ray touches the mirror line  $p$ . In the standard way, we find the intersection of the line  $q$  with the line of the initial movement of the ray:  $[0, 0] + t(3, 1)$ . The intersection point is  $[0, 0] + \frac{91}{57}(3, 1) = [\frac{91}{19}, \frac{91}{57}]$ . The ray meets the mirror at the point  $[6, 2]$ , that is  $[0, 0] + 2(3, 1)$ . As  $0 < \frac{91}{57} < 2$  we conclude, that the ray meets the line  $q$  before the reflection point.

Let us concentrate now on the rebound ray. The angle between the line  $p$  and the direction of the ray can be calculated

We can eliminate  $t$  from these two equations to obtain

$$-v_2x + v_1y = -v_2x_0 + v_1y_0.$$

Since the vector  $v = (v_1, v_2)$  is non-zero, at least one of the numbers  $v_1, v_2$  is non-zero. If one of the coordinates  $v_1$  or  $v_2$  is zero, then the line is parallel to one of the coordinate axis.

IMPLICIT DESCRIPTION OF A LINE

The general equation of the line in the plane is

$$(1) \quad ax + by = c,$$

with  $a$  and  $b$  not both zero. The relation between the pair of numbers  $(a, b)$  and the direction vector of the line  $\mathbf{v} = (v_1, v_2)$  is

$$(2) \quad av_1 + bv_2 = 0.$$

We can view the left hand side of the equation (1) as a function  $z = f(x, y)$  mapping each point  $[x, y]$  of the plane to a scalar and the line corresponds to the prescribed constant value of this function. We shall see soon that (2) says the vector  $(a, b)$  is perpendicular to the direction of the line.

GRAPH OF A FUNCTION  $f(x, y)$

Suppose we have two lines  $p$  and  $q$ . We ask about their intersection  $p \cap q$ . That is a point  $[x, y]$  which satisfies the equations of both lines simultaneously. We write them as

$$(3) \quad \begin{aligned} ax + by &= r \\ cx + dy &= s. \end{aligned}$$

Again, we can view the left side as a mapping  $F$ , which to every pair of coordinates  $[x, y]$  of the point  $P$  in the plane assigns a vector of values of two scalar functions  $f_1$  and  $f_2$

using 1.5.7 as

$$\cos \varphi = \frac{(-2, 1) \cdot (3, 1)}{\sqrt{5}\sqrt{10}} = -\frac{\sqrt{2}}{2},$$

therefore  $\varphi = -45^\circ$ . The rebounded ray is thus perpendicular to the entering ray and its direction is  $(1, -3)$ . (Be careful with the orientation! The vector of the direction can also be obtained via reflection (axial symmetry) of the vector perpendicular to the line  $p$ .)

The ray meets the mirror at the point  $[6, 2]$ , thus the reflected ray has the equation

$$[6, 2] + t(1, -3), t \geq 0.$$

The intersection of the line given by the rebounded ray with the line  $q$  is at the point  $[4, 8]$ . This point lies on the opposite side of the line  $p$  to both the incident and reflected rays. ( $t = -2$ ). Thus the rebound ray does not meet the line  $q$ .

All together, there is one intersection of the ray with the line  $q$ , namely  $[\frac{91}{19}, \frac{91}{57}]$ .  $\square$

**Remark.** The reflection of a ray in three-dimensional space is studied in the exercise 3.F.4.

**1.E.11.** A line segment of length 1 started moving at noon with a constant speed of 1 meter per second in the direction  $(3, 2)$  from the point  $[-2, 0]$ . Another line segment of length 1 has started moving also at noon from the point  $[5, -2]$  in the direction  $(-1, 1)$ , but with double speed. Will they collide? (Segments are oriented in direction of their movements.)

**Solution.** Lines along which the segments are moving can be described parametrically:

$$\begin{aligned} p &: [-2, 0] + r(3, 2), \\ q &: [5, -2] + s(-1, 1). \end{aligned}$$

The equation of the line  $p$  is

$$2x - 3y + 4 = 0.$$

Substituting the parametric equation of the line  $q$  yields the intersection point  $P = [1, 2]$ .

Now we choose a single parameter  $t$  for both lines so that the corresponding point on  $p$  and on  $q$  respectively, describes the position of the initial point of the first and second line segment respectively at the time  $t$ . At time 0 the initial point of the the first line segment is at  $[-2, 0]$ , the second is at  $[5, -2]$ . During time  $t$  (measured in seconds) the first segments travels  $t$  units of length in the direction  $(3, 2)$ , the second segments travels  $2t$  units of length in the direction  $(-1, 1)$ . Thus

given by the left sides of the particular equations (3). Hence we can write our two scalar equations as one vector equation  $F(\mathbf{v}) = \mathbf{w}$ , where  $\mathbf{v} = (x, y)$  and  $\mathbf{w} = (r, s)$ .

Notice that the two lines are not parallel if and only if they have a unique point in their intersection.

**1.5.4. Linear mappings and matrices.** Mappings  $F$  with which we have worked with when describing intersection of lines have one very important property in common: they preserve the operations of addition and multiplication with vectors and scalars, that is they preserve linear combinations:

$$F(a \cdot \mathbf{v} + b \cdot \mathbf{w}) = a \cdot F(\mathbf{v}) + b \cdot F(\mathbf{w})$$

for all  $a, b \in \mathbb{R}$ ,  $\mathbf{v}, \mathbf{w} \in \mathbb{R}^2$ . We say that  $F$  is a *linear mapping* from  $\mathbb{R}^2$  to  $\mathbb{R}^2$ , and write  $F: \mathbb{R}^2 \rightarrow \mathbb{R}^2$ . This can be also described with words — linear combination of vectors maps to the same linear combination of their images, that is linear mappings are those mappings which preserve linear combinations.

We have already encountered the same behaviour in the equation 1.5.3(1) for the line, where the linear mapping in question was  $f: \mathbb{R}^2 \rightarrow \mathbb{R}$  and its prescribed value  $c$ . That is also the reason why the values of the mapping  $z = f(x, y)$  are on the image depicted as a plane in  $\mathbb{R}^3$ .

We can write such a mapping using *matrices*. By a matrix we mean a rectangular array of numbers, for instance

$$A = \begin{pmatrix} a & b \\ c & d \end{pmatrix} \quad \text{or} \quad \mathbf{v} = \begin{pmatrix} x \\ y \end{pmatrix}.$$

We speak of a (square  $2 \times 2$ ) matrix  $A$  and (column) vector  $\mathbf{v}$ . Multiplication of matrices, row by column, is defined as follows:

$$A \cdot \mathbf{v} = \begin{pmatrix} a & b \\ c & d \end{pmatrix} \cdot \begin{pmatrix} x \\ y \end{pmatrix} = \begin{pmatrix} ax + by \\ cx + dy \end{pmatrix}.$$

We introduce some more tools for vectors and matrices. Our goal is to compute with matrices in a similar way as we do it with scalars.

We define the product  $C = A \cdot B$  of two square matrices  $A$  and  $B$  applying the above formulas to individual columns of the matrix  $B$  and writing the resulting column vectors again as columns in the matrix  $C$ .

In order to multiply two vectors  $\mathbf{v}$  and  $\mathbf{w}$  in a similar way, we can write the vector  $\mathbf{w}$  as a row of numbers (the transposed vector)  $\mathbf{w}^T$ . Then the product of  $\mathbf{w}^T$  and  $\mathbf{v}$  is

$$\mathbf{w}^T \cdot \mathbf{v} = (r \quad s) \cdot \begin{pmatrix} x \\ y \end{pmatrix} = rx + sy.$$

This is the *scalar product of vectors*  $\mathbf{v}$  and  $\mathbf{w}$  introduced a while ago.

We can easily check the associativity of multiplication (do it for general matrices  $A, B$  and a vector  $\mathbf{v}$  in detail):

$$(A \cdot B) \cdot \mathbf{v} = A \cdot (B \cdot \mathbf{v}).$$

the corresponding parameterisations are:

$$p : [-2, 0] + t \frac{(3, 2)}{\sqrt{3^2 + 2^2}},$$

$$q : [5, -2] + 2t \frac{(-1, 1)}{\sqrt{(-1)^2 + 1^2}}.$$

The initial point of the first segment enters the point  $[1, 2]$  at time  $t_1 = \sqrt{13}$  s, the initial point of the second segment at time  $t_2 = \sqrt{2}$  s – more than a half second sooner. At the time  $t_2 + \frac{1}{2} = \sqrt{2} + \frac{1}{2} < t_1$  the ending point of the second segment moves away from  $P$ . Thus when the initial point of the first segment enters the point  $P$ , the ending point of the second segment is already away and the segments do not collide.  $\square$

We return for a while to complex numbers. The complex plane is basically a “normal” plane, where we have something extra:

**1.E.12.** Interpret multiplication by the imaginary unit  $i$  and complex conjugation as geometrical transformations in the plane.

**Solution.** The imaginary unit  $i$  corresponds to the point  $(0, 1)$ . Notice that multiplying any number  $z = a + ib$  by the imaginary unit  $i$  gives the result

$$i \cdot (a + ib) = -b + ia.$$

Under the interpretation in the plane, this is a rotation around the origin of the segment joining the origin to the point  $z$  through a right angle counterclockwise (cf. 1.1.4).

Taking the complex conjugate is a reflection through the axis of real numbers:

$$z = (a + ib) \mapsto (a - ib) = \bar{z}.$$

$\square$

**1.E.13.** Determine the sum of the three angles, which are between the vectors  $(1, 1)$ ,  $(2, 1)$  and  $(3, 1)$  respectively and the  $x$ -axis in the plane  $\mathbb{R}^2$ .

**Solution.** If we view the plane  $\mathbb{R}^2$  as the Gauss plane (of complex numbers), then the given vectors correspond to complex numbers  $1 + i$ ,  $2 + i$  and  $3 + i$ . We are to find the sum of their arguments. According to de Moivre’s formula this equals the argument of their product. Their product is  $(1 + i)(2 + i)(3 + i) = (1 + 3i)(3 + i) = 10i$ , which is a purely imaginary number with argument  $\pi/2$ . So the sum we are looking for is  $\pi/2$ .  $\square$

Instead of a vector  $\mathbf{v}$  we can write any  $(2 \times 2)$  matrix  $C$ . In a similar way, distributivity also holds:

$$A \cdot (B + C) = A \cdot B + A \cdot C$$

$$(A + B) \cdot C = A \cdot C + B \cdot C.$$

But the commutativity does not hold. For example,

$$\begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix} \cdot \begin{pmatrix} 0 & 0 \\ 0 & 1 \end{pmatrix} = \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix},$$

$$\begin{pmatrix} 0 & 0 \\ 0 & 1 \end{pmatrix} \cdot \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix} = \begin{pmatrix} 0 & 0 \\ 0 & 0 \end{pmatrix}.$$

This last product also shows the existence of divisors of zero.

Notice that the mapping defined by multiplication of vectors with a fixed matrix is a linear mapping, i.e. it respects linear combinations. On the other hand, every linear mapping  $F$  has to be completely given by its values on the two vectors  $\mathbf{e}_1 = (1, 0)$  and  $\mathbf{e}_2 = (0, 1)$  in the standard basis and these values appear in the columns of the matrix  $A$ , which expresses  $F$  as matrix multiplication (check this observation carefully!).

With matrices and vectors we can write the equations for lines and points respectively as

$$\mathbf{u}^T \cdot \mathbf{v} = (a \quad b) \cdot \begin{pmatrix} x \\ y \end{pmatrix} = c$$

$$A \cdot \mathbf{v} = \begin{pmatrix} a & b \\ c & d \end{pmatrix} \cdot \begin{pmatrix} x \\ y \end{pmatrix} = \begin{pmatrix} r \\ s \end{pmatrix} = \mathbf{w}.$$

**1.5.5. Determinant of matrix.** The procedure of finding the intersection of lines described in 1.5.3 fails in some special cases. For instance the intersection of two parallel lines is either empty (when the lines are parallel but distinct) or the line itself (when the lines are identical). This condition occurs when the ratios  $a/c$  and  $b/d$  are the same, that is

$$(1) \quad ad - bc = 0.$$

Note that this expression already takes care of the cases, where either  $c$  or  $d$  is zero.

The expression on the left in (1) is called the *determinant* of the matrix  $A$ . We write it as

$$\det A = \begin{vmatrix} a & b \\ c & d \end{vmatrix} = ad - bc.$$

Our discussion can be now expressed as follows:

**Proposition.** *The determinant is a real valued function  $\det A$  defined for all square  $2 \times 2$  matrices  $A$ . The (vector) equation  $A \cdot \mathbf{v} = \mathbf{u}$  has a unique solution for  $\mathbf{v}$  if and only if  $\det A \neq 0$ .*

So far, we have worked with pairs of real numbers in the plane. Equally well we might pose exactly the same questions for points with integer coordinates and lines with equations with integer coefficients. Notice that the latter requirement is equivalent to considering rational coefficients in the equations. We have to be careful which properties of the scalars we exploit.

Next, we shall exercise the matrix calculus in the plane.

We refer to 1.5.4 for the basic concepts.

First we experience the operations of addition and multiplication on matrices, then we come to geometric tasks.

**1.E.14.** Simplify  $(A - B)^T \cdot 2C \cdot u$ , where

$$A = \begin{pmatrix} 0 & 5 \\ -2 & 2 \end{pmatrix}, B = \begin{pmatrix} 2 & 0 \\ -1 & 1 \end{pmatrix}, \\ C = \begin{pmatrix} 2 & -2 \\ 4 & 5 \end{pmatrix}, u = \begin{pmatrix} 3 \\ 2 \end{pmatrix}.$$

**Solution.** By substituting in

$$A - B = \begin{pmatrix} -2 & 5 \\ -1 & 1 \end{pmatrix}, (A - B)^T = \begin{pmatrix} -2 & -1 \\ 5 & 1 \end{pmatrix}, \\ 2C = \begin{pmatrix} 4 & -4 \\ 8 & 10 \end{pmatrix}$$

and by matrix multiplication we obtain

$$(A - B)^T \cdot 2C \cdot u = \begin{pmatrix} -2 & -1 \\ 5 & 1 \end{pmatrix} \cdot \begin{pmatrix} 4 & -4 \\ 8 & 10 \end{pmatrix} \cdot \begin{pmatrix} 3 \\ 2 \end{pmatrix} \\ = \begin{pmatrix} -52 \\ 64 \end{pmatrix}.$$

□

**1.E.15.** Give an example of matrices  $A$  and  $B$  for which

- (a)  $(A + B) \cdot (A - B) \neq A \cdot A - B \cdot B$ ;
- (b)  $(A + B) \cdot (A + B) \neq A \cdot A + 2A \cdot B + B \cdot B$ .

**Solution.** For any two square matrices  $A$  and  $B$  we have

$$(A + B) \cdot (A - B) = A \cdot A - A \cdot B + B \cdot A - B \cdot B.$$

The identity

$$(A + B) \cdot (A - B) = A \cdot A - B \cdot B$$

is thus obtained if and only if  $-A \cdot B + B \cdot A$  is the zero matrix, that is if and only if the matrices  $A$  and  $B$  commute. An example of such matrices are thus pairs of matrices, which do not commute (the matrix of product is changed when we change the order of multiplied matrices). We can choose for instance

$$A = \begin{pmatrix} 1 & 2 \\ 3 & 4 \end{pmatrix}, B = \begin{pmatrix} 4 & 3 \\ 2 & 1 \end{pmatrix},$$

since with this choice is

$$A \cdot B = \begin{pmatrix} 8 & 5 \\ 20 & 13 \end{pmatrix}, B \cdot A = \begin{pmatrix} 13 & 20 \\ 5 & 8 \end{pmatrix}.$$

Notice that for any pair of square matrices  $A, B$

$$(A + B) \cdot (A + B) = A \cdot A + A \cdot B + B \cdot A + B \cdot B.$$

It follows that

$$(A + B) \cdot (A + B) = A \cdot A + 2A \cdot B + B \cdot B$$

if and only if  $A \cdot B = B \cdot A$ , as in the first case. □

In fact, we needed all the properties of the field of scalars when discussing the solvability of the system of two equations — try to think it through. At least, we can be sure that the intersection of two non-parallel lines with rational coefficients is a point with rational coefficients again. The case of integer coefficients and coordinates is more difficult. We shall come back to this in the next chapter. In particular we shall see that the equation 1.5.3(3) with fixed integer coefficients  $a, b, c, d$  has a unique integer solution for all integer values  $(r, s)$  if and only if the determinant is  $\pm 1$ .

**1.5.6. Affine mappings.** We now investigate how the matrix notation allows us to work with simple mappings in the affine plane. We have seen that matrix multiplication defines a linear mapping. Shifting  $\mathbb{R}^2$  by a fixed vector  $\mathbf{w} = (r, s) \in \mathbb{R}^2$  in the affine plane can be also easily written in matrix notation:

$$P = \begin{pmatrix} x \\ y \end{pmatrix} \mapsto P + \mathbf{w} = \begin{pmatrix} x + r \\ y + s \end{pmatrix}.$$

If we add a fixed vector to the result of a linear mapping then we have the expression

$$\mathbf{v} = \begin{pmatrix} x \\ y \end{pmatrix} \mapsto A \cdot \mathbf{v} + \mathbf{w} = \begin{pmatrix} ax + by + r \\ cx + dy + s \end{pmatrix}.$$

In this way we have described all *affine mappings of the plane* to itself.

Such mappings allow us to recompute coordinates which arise by different choices of origins or bases. We shall come back to this in detail later.

**1.5.7. The distance and angle.** Now we consider distance. We define the *length* of the vector  $\mathbf{v} = (x, y)$  to be

$$\|\mathbf{v}\| = \sqrt{x^2 + y^2}.$$

Immediately we can define notions of distance, angle and rotation in the plane.

#### DISTANCE IN THE PLANE

The distance between the points  $P, Q$  in the plane is given as the length of the vector  $\overrightarrow{PQ}$ , i.e.  $\|Q - P\|$ . Obviously, the distance does not depend on the ordering of  $P$  and  $Q$  and it is invariant under shifts of the plane by any fixed vector  $\mathbf{w}$ .

The *Euclidean plane* is an affine plane with distance defined as given above.

**1.E.16.** Decide whether the mappings  $F, G : \mathbb{R}^2 \rightarrow \mathbb{R}^2$  given by

$$F : \begin{pmatrix} x \\ y \end{pmatrix} \mapsto \begin{pmatrix} 7x - 3y \\ -2x + 5y \end{pmatrix}, \quad x, y \in \mathbb{R},$$

$$G : \begin{pmatrix} x \\ y \end{pmatrix} \mapsto \begin{pmatrix} 2x + 2y - 4 \\ 4x - 9y + 3 \end{pmatrix}, \quad x, y \in \mathbb{R}$$

are linear.

**Solution.** For any vector  $(x, y)^T \in \mathbb{R}^2$  we can express

$$F \left( \begin{pmatrix} x \\ y \end{pmatrix} \right) = \begin{pmatrix} 7 & -3 \\ -2 & 5 \end{pmatrix} \cdot \begin{pmatrix} x \\ y \end{pmatrix},$$

$$G \left( \begin{pmatrix} x \\ y \end{pmatrix} \right) = \begin{pmatrix} 2 & 2 \\ 4 & -9 \end{pmatrix} \cdot \begin{pmatrix} x \\ y \end{pmatrix} + \begin{pmatrix} -4 \\ 3 \end{pmatrix}.$$

This implies that both mappings are affine. Recall that an affine mapping is a linear one if and only if the zero vector maps to zero. Since

$$F \left( \begin{pmatrix} 0 \\ 0 \end{pmatrix} \right) = \begin{pmatrix} 0 \\ 0 \end{pmatrix}, \quad G \left( \begin{pmatrix} 0 \\ 0 \end{pmatrix} \right) = \begin{pmatrix} -4 \\ 3 \end{pmatrix},$$

the mapping  $F$  is linear, the mapping  $G$  is not. Let us mention that  $f(x) = Ax$  and  $g(x) = Ax + b$  respectively, where  $x, b \in \mathbb{R}^n$ ,  $A$  is a square matrix  $n \times n$ , are general forms of a linear and affine mappings respectively.  $\square$

**1.E.17.** Compute the lengths of the sides of the triangle with vertices  $A = [2, 2]$ ,  $B = [3, 0]$ ,  $C = [4, 3]$ .

**Solution.** Using the formula for the length of a vector

$$\|u\| = \sqrt{u_1^2 + u_2^2}, \quad u = (u_1, u_2) \in \mathbb{R}^2$$

we obtain the results

$$|AB| = \|A - B\| = \sqrt{(2 - 3)^2 + (2 - 0)^2} = \sqrt{5},$$

$$|BC| = \|B - C\| = \sqrt{(3 - 4)^2 + (0 - 3)^2} = \sqrt{10},$$

$$|AC| = \|A - C\| = \sqrt{(2 - 4)^2 + (2 - 3)^2} = \sqrt{5}.$$

$\square$

**1.E.18.** Determine the angle between the two vectors

(a)  $u = (-3, -2), v = (-2, 3)$ ;

(b)  $u = (2, 6), v = (-3, -9)$ .

**Solution.** The sought angle  $0 \leq \varphi \leq \pi$  can of course be computed from the formula (1) in 1.5.7. But note that the vector  $(-3, -2)$  can be obtained by changing the coordinates of the vector  $(-2, 3)$  and multiplying one of them by the number  $-1$ . But these operations are used when we want to obtain the vector normal to a vector of direction of a given line (or vice versa). Vectors in the case (a) are thus perpendicular, that is  $\varphi = \pi/2$ . In the case (b), since  $-3 \cdot (2, 6) = 2 \cdot (-3, -9)$ , the vector  $u$  is a multiple of the vector  $v$ . If one vector is a positive multiple of another, the angle between these two is

Angles are a matter of vectors rather than points in Euclidean geometry. Let  $\mathbf{u}$  be a vector of length 1, at angle  $\varphi$  measured counter-clockwise from the vector  $(1, 0)$ . In coordinates,  $\mathbf{u}$  is at the unit circle and has first and second coordinates  $\cos \varphi, \sin \varphi$  respectively (this is one of the elementary definitions of the sine and cosine functions). That is,

$$\mathbf{u} = (\cos \varphi, \sin \varphi).$$

This is compatible with  $-1 \leq \sin \varphi \leq 1$  satisfying

$$(\cos \varphi)^2 + (\sin \varphi)^2 = 1.$$

#### ANGLE BETWEEN VECTORS

The angle  $\varphi$  between two vectors  $\mathbf{v}$  and  $\mathbf{v}'$  can be in general described using their coordinates  $\mathbf{v} = (x, y)$ ,  $\mathbf{v}' = (x', y')$  like this:

$$(1) \quad \cos \varphi = \frac{xx' + yy'}{\|\mathbf{v}\| \|\mathbf{v}'\|}$$

with  $0 \leq \varphi \leq \pi$ .

In our special case  $\mathbf{v} = (1, 0)$ , the more general equation gives

$$\cos \varphi = \frac{x'}{\|\mathbf{v}'\|},$$

which is just the definition of the function  $\cos \varphi$ . The general case can be always reduced to this special one. First we notice that the angle  $\varphi$  between two vectors  $\mathbf{u}, \mathbf{v}$  is always the same as the angle between the *normalized vectors*  $\frac{1}{\|\mathbf{u}\|} \mathbf{u}$  and  $\frac{1}{\|\mathbf{v}\|} \mathbf{v}$ . Thus we can restrict ourselves to two vectors on the unit circle. Then we can rotate our coordinates in such a way that the first of the vectors will become  $(1, 0)$ . This means, it is enough to show that the scalar product  $xx' + yy'$ , as well as the length of vectors are invariant with respect to rotations. We shall come back to this in a moment.

In the special case, when the scalar product is zero, we say that the vectors are *perpendicular* and this corresponds

zero. If it is a negative multiple, as in our case, the angle is  $\pi$ .  $\square$

**1.E.19.** Determine the angle  $\varphi$  between the two diagonals  $A_3A_7$  and  $A_5A_{10}$  of a regular dodecagon (polygon with twelve sides)  $A_0A_1A_2 \dots A_{11}$ .

**Solution.** The angle does not depend neither on the size nor on the position of the given dodecagon. Choose the dodecagon inscribed in a circle with diameter 1.

We can put  $A_0$  to  $[1, 0]$  and then the vertices can be identified with the twelfth roots of 1 in the complex plane. We can write  $A_k = \cos(2k\pi/12) + i \sin(2k\pi/12)$ . Especially  $A_3 = \cos(\pi/2) + i \sin(\pi/2) = i \sim [0, 1]$ ,  $A_5 = \cos(5\pi/6) + i \sin(5\pi/6) = -\frac{\sqrt{3}}{2} + \frac{1}{2}i \sim [-\frac{\sqrt{3}}{2}, \frac{1}{2}]$ ,  $A_7 = \cos(7\pi/6) + i \sin(7\pi/6) = -\frac{\sqrt{3}}{2} - \frac{1}{2}i \sim [-\frac{\sqrt{3}}{2}, -\frac{1}{2}]$ , and  $A_{10} = \cos(5\pi/3) + i \sin(5\pi/3) = 1/2 - i\frac{\sqrt{3}}{2} \sim [1/2, -\frac{\sqrt{3}}{2}]$ .

Using the formula (1) in 1.5.7 we finish the computation:

$$\cos \varphi = \frac{1}{2\sqrt{2 + \sqrt{3}}},$$

that is  $\varphi = 75^\circ$ .

**Alternative solution.** This problem can be solved via method of synthetic geometry only. Denote the centre of the regular dodecagon by  $S$  and the intersection of the diagonals  $A_3A_7$  and  $A_5A_{10}$  by  $T$ . Now  $|\angle A_7A_5A_{10}| = 45^\circ$  (this is the inscribed angle which corresponds to the central angle  $A_7SA_{10}$ , which is a right angle), furthermore  $|\angle A_5A_7A_3| = 30^\circ$  (again the inscribed angle corresponding to the central angle  $A_5SA_3$ , which is  $60^\circ$ ). Thus the angle  $A_5TA_7$  is then equal to a complement of the aforementioned angles to  $180^\circ$ , that is  $105^\circ$ . The deviation we are looking for is then  $180^\circ - 105^\circ = 75^\circ$ .  $\square$

**1.E.20.** Consider a regular hexagon  $ABCDEF$  with vertices labeled in the positive direction, centre at the point  $S = [1, 0]$  and the vertex  $A$  at  $[0, 2]$ . Determine the coordinates of the vertex  $C$ .

**Solution.** The coordinates of the vertex  $C$  can be obtained by rotating the point  $A$  around the centre  $S$  of the hexagon through the angle  $120^\circ$  in the positive direction:

$$\begin{aligned} C &= \begin{pmatrix} \cos 120^\circ & -\sin 120^\circ \\ \sin 120^\circ & \cos 120^\circ \end{pmatrix} (A - S) + S \\ &= \begin{pmatrix} -\frac{1}{2} & -\frac{\sqrt{3}}{2} \\ \frac{\sqrt{3}}{2} & -\frac{1}{2} \end{pmatrix} \begin{pmatrix} -1 \\ 2 \end{pmatrix} + [1, 0] \\ &= \left[ \frac{3}{2} - \sqrt{3}, -1 - \frac{\sqrt{3}}{2} \right]. \end{aligned}$$

to  $\varphi = \pi/2$  as expected. Of course the best example of perpendicular vectors of length 1 are the standard basis vectors  $(1, 0)$  and  $(0, 1)$ .

Notice that our formula for the angle between the vectors is symmetric in the two vector arguments, thus we have to take the smaller of the possible angles between two vectors and  $\varphi$  is always between 0 and  $\pi$ .

We can easily imagine that not all affine coordinates are adequate for expressing the distance and thus for use in the Euclidean plane. Indeed, although we may choose any point  $O$  as the origin again, we want also the basis vectors  $e_1 = \overrightarrow{OE_1}$  and  $e_2 = \overrightarrow{OE_2}$  to be perpendicular and of length one. Such basis will be called *orthonormal*. We shall see that the angles and distances computed in such coordinates will always be the same no matter which coordinates are used.

**1.5.8. Rotation around a point in the plane.** As we saw, the matrix of any given linear mapping  $F : \mathbb{R}^2 \rightarrow \mathbb{R}^2$  is easy to guess. If the mapping works applying the matrix with columns  $(a, c)$  and  $(b, d)$ , then the first column  $(a, c)$  is obtained by multiplying this matrix with the basis vector  $(1, 0)$  and the second is the evaluation at the second basis vector  $(0, 1)$ .

ROTATION AROUND A POINT IN THE PLANE

We can see from the picture that the columns of the matrix corresponding to rotating counter-clockwise through the angle  $\psi$  are computed as follows:

$$\begin{pmatrix} a & b \\ c & d \end{pmatrix} \begin{pmatrix} 1 \\ 0 \end{pmatrix} = \begin{pmatrix} \cos \psi \\ \sin \psi \end{pmatrix}, \quad \begin{pmatrix} a & b \\ c & d \end{pmatrix} \begin{pmatrix} 0 \\ 1 \end{pmatrix} = \begin{pmatrix} -\sin \psi \\ \cos \psi \end{pmatrix}$$

The counter-clockwise direction is called the *positive direction*, the other direction is the negative direction.

ROTATION MATRIX

Rotation through a given angle  $\psi$  in the positive direction about the origin is given by the matrix  $R_\psi$ :

$$\mathbf{v} = \begin{pmatrix} x \\ y \end{pmatrix} \mapsto R_\psi \cdot \mathbf{v} = \begin{pmatrix} \cos \psi & -\sin \psi \\ \sin \psi & \cos \psi \end{pmatrix} \cdot \begin{pmatrix} x \\ y \end{pmatrix}.$$

Now, since we now know how the matrix of the rotation in the plane looks like, we can check that rotation preserves distances and angles (defined by the equation (1) in 1.5.7). Denote the image of a vector  $\mathbf{v}$  as

□

**1.E.21.** An equilateral triangle with vertices  $[1, 0]$  and  $[0, 1]$

lies entirely in the first quadrant. Find the coordinates of its third vertex.

**Solution.** The third coordinate is  $[\frac{1}{2} + \frac{\sqrt{3}}{2}, \frac{1}{2} + \frac{\sqrt{3}}{2}]$  (we are rotating the point  $[1, 0]$  through  $60^\circ$  around  $[0, 1]$  in the positive direction). □

**1.E.22.** An equilateral triangle has vertices at  $A = [1, 1]$  and  $B = [2, 3]$ . Its other vertex lies in the same half-plane as the point  $S = [0, 0]$ . The triangle is rotated by  $60^\circ$  in the positive direction around the point  $S$ , to produce a new triangle. Determine the coordinates of the vertices of the new triangle.

**Solution.** The points we are looking for have coordinates  $[-\frac{3}{2}\sqrt{3}, \sqrt{3} - \frac{1}{2}]$ ,  $[\frac{1}{2} - \frac{1}{2}\sqrt{3}, \frac{1}{2}\sqrt{3} + \frac{1}{2}]$ ,  $[1 - \frac{3}{2}\sqrt{3}, \sqrt{3} + \frac{3}{2}]$ . □

**1.E.23.** Find two matrices  $A$  such that

$$A^2 = \begin{pmatrix} \frac{1}{2} & -\frac{\sqrt{3}}{2} \\ \frac{\sqrt{3}}{2} & \frac{1}{2} \end{pmatrix}.$$

Hint: which geometric transformation in the plane is given by the matrix  $A^2$ ?

**Solution.**  $A^2$  is the matrix of rotation through  $60^\circ$  in the positive direction, thus the matrices we are looking for are

$$A = \pm \begin{pmatrix} \frac{\sqrt{3}}{2} & -\frac{1}{2} \\ \frac{1}{2} & \frac{\sqrt{3}}{2} \end{pmatrix},$$

which are the matrices of rotation through  $30^\circ$  or through  $210^\circ$ . □

**1.E.24. Reflection.** Find the matrix of reflection in the plane through the line  $y = x$  (that is, find the matrix of the axial symmetry).

**Solution.** The given reflection sends  $x$ -axis into  $y$  axis and vice versa. Thus the reflection applied to a vector just transposes its coordinates, therefore the sought matrix is

$$\begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}.$$

A matrix of any linear mapping in  $\mathbb{R}^2$  can be computed also in standard way: it is given by images of the vectors  $(1, 0)$  (first column) and  $(0, 1)$  (second column). In our case the images are  $(0, 1)$  and  $(1, 0)$ . □

$$\mathbf{v}' = \begin{pmatrix} x' \\ y' \end{pmatrix} = R_\psi \cdot \mathbf{v} = \begin{pmatrix} x \cos \psi - y \sin \psi \\ x \sin \psi + y \cos \psi \end{pmatrix},$$

and similarly  $\mathbf{w}' = R_\psi \cdot \mathbf{w}$  for  $\mathbf{w} = (r, s)^T$ , and  $\mathbf{w}' = (r', s')^T$ .

A straightforward expansion (exploiting  $(\cos \psi)^2 + (\sin \psi)^2 = 1$ ) checks the expected equalities  $\|\mathbf{v}'\|^2 = \|\mathbf{v}\|^2$ , and that  $x'r' + y's' = xr + ys$ .

The previous expression can be written using vectors and matrices as follows:

$$(R_\psi \cdot \mathbf{w})^T (R_\psi \cdot \mathbf{v}) = \mathbf{w}^T \mathbf{v}.$$

The transposed vector  $(R_\psi \cdot \mathbf{w})^T$  equals  $\mathbf{w}^T \cdot R_\psi^T$ , where  $R_\psi^T$  is the so-called transpose of the matrix  $R_\psi$ . That is a matrix, whose rows consist of the columns of the original matrix and similarly the columns consist of the rows of the original matrix. Therefore we see that the rotation matrices satisfy the relation  $R_\psi^T \cdot R_\psi = I$ , where the matrix  $I$  (sometimes we denote this matrix just as 1 and mean by this the unit in the ring of matrices) is the *unit matrix*

$$I = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}.$$

This leads us to a remarkable observation — the matrix  $X$  with the property that  $X \cdot R_\psi = I$  (we will call such a matrix the *inverse matrix to the rotation matrix*  $R_\psi$ ) is the transpose of the original matrix. This makes sense, since the inverse mapping to the rotation through the angle  $\psi$  is again a rotation, but through the angle  $-\psi$ . That is, the inverse matrix of  $R_\psi^T$  equals the matrix

$$R_{-\psi} = \begin{pmatrix} \cos(-\psi) & -\sin(-\psi) \\ \sin(-\psi) & \cos(-\psi) \end{pmatrix} = \begin{pmatrix} \cos \psi & \sin \psi \\ -\sin \psi & \cos \psi \end{pmatrix}.$$

It is easy to write the rotation around a point  $P = O + \mathbf{w}$ ,  $P = [r, s]$  again using matrices. One just has to note that instead of rotating around the given point  $P$ , we can first shift  $P$  into the origin, then do the rotation and then do the inverse shift.

**1.E.25.** Determine which linear mappings from  $\mathbb{R}^2$  to  $\mathbb{R}^2$  are given by the following matrices (that is, describe the geometrical meaning of the matrices):

$$A_1 = \begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix}, \quad A_2 = \begin{pmatrix} -1 & 0 \\ 0 & 1 \end{pmatrix},$$

$$A_3 = \begin{pmatrix} \frac{\sqrt{2}}{2} & -\frac{\sqrt{2}}{2} \\ \frac{\sqrt{2}}{2} & \frac{\sqrt{2}}{2} \end{pmatrix}.$$

**Solution.** Let  $(x, y)^T$  stand for an arbitrary real vector. For the matrix  $A_1$  we have

$$\begin{pmatrix} x \\ y \end{pmatrix} \mapsto \begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix} \cdot \begin{pmatrix} x \\ y \end{pmatrix} = \begin{pmatrix} x \\ 0 \end{pmatrix},$$

which means that the linear mapping given by this matrix is the projection on the  $x$  axis. Similarly we can see that the matrix  $A_2$  determines the reflection with the respect to the  $y$  axis, since

$$\begin{pmatrix} x \\ y \end{pmatrix} \mapsto \begin{pmatrix} -1 & 0 \\ 0 & 1 \end{pmatrix} \cdot \begin{pmatrix} x \\ y \end{pmatrix} = \begin{pmatrix} -x \\ y \end{pmatrix}.$$

The matrix  $A_3$  can be expressed in the form

$$\begin{pmatrix} \cos \varphi & -\sin \varphi \\ \sin \varphi & \cos \varphi \end{pmatrix}$$

for  $\varphi = \pi/4$ , thus it gives the rotation of the plane around the origin through the angle  $\pi/4$  (in the positive direction, that is counter-clockwise).  $\square$

**1.E.26.** Show that the composition of an odd number of point reflections in the plane is again a point symmetry.

**Solution.** The point reflection in the plane across the point  $S$  is represented with the formula  $X \mapsto S - (X - S)$ , that is  $X \mapsto 2S - X$ . By repeated application of three point reflections across the points  $S, T$  and  $U$  respectively we obtain  $X \mapsto 2S - X \mapsto 2T - (2S - X) \mapsto 2U - (2T - (2S - X)) = 2(U - T + S) - X$ , that is  $X \mapsto 2(U - T + S) - X$ , which is a point reflection across the point  $U - T + S$ . Composition of any odd number of point reflections can be reduced successively to a point reflection. (In principle, this is done by mathematical induction, try to formulate it by yourself).  $\square$

**1.E.27.** Construct a  $(2n + 1)$ -gon, if the middle points of all its sides are given.

**Solution.** We use the fact that the composition of an odd number of point reflections is again a point reflection (see the previous exercise). Denote the vertices of the  $(2n + 1)$ -gon we are looking for by  $A_1, A_2, \dots, A_{2n+1}$  and the middle points of the sides (starting from the middle point of  $A_1A_2$ ) by  $S_1,$

We calculate:

$$\mathbf{v} = \begin{pmatrix} x \\ y \end{pmatrix} \mapsto \mathbf{v} - \mathbf{w} \mapsto R_\psi \cdot (\mathbf{v} - \mathbf{w})$$

$$\mapsto R_\psi \cdot (\mathbf{v} - \mathbf{w}) + \mathbf{w} =$$

$$\begin{pmatrix} \cos \psi (x - r) - \sin \psi (y - s) + r \\ \sin \psi (x - r) + \cos \psi (y - s) + s \end{pmatrix}.$$

**1.5.9. Reflections.** Another well-known example of a length preserving mapping is *reflection through a line*. It is enough to understand reflection through a line that goes through the origin  $O$ . All other reflections can be derived using shifts. Thus, we look first for a matrix  $Z_\psi$  of reflection with respect to the line through the origin and through the point  $(\cos \psi, \sin \psi)$ .

Notice that

$$Z_0 = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}.$$

Any line going through the origin can be rotated so that it has the direction  $(1, 0)$  and thus we can write general reflection matrix as

$$Z_\psi = R_\psi \cdot Z_0 \cdot R_{-\psi},$$

where we first rotate via the matrix  $R_{-\psi}$  so that the line is in “zero” position, reflect with the matrix  $Z_0$  and return back with the rotation  $R_\psi$ .

Therefore we can calculate (by associativity of matrix multiplication):

$$Z_\psi = \begin{pmatrix} \cos \psi & -\sin \psi \\ \sin \psi & \cos \psi \end{pmatrix} \cdot \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix} \cdot \begin{pmatrix} \cos \psi & \sin \psi \\ -\sin \psi & \cos \psi \end{pmatrix}$$

$$= \begin{pmatrix} \cos \psi & \sin \psi \\ \sin \psi & -\cos \psi \end{pmatrix} \cdot \begin{pmatrix} \cos \psi & \sin \psi \\ -\sin \psi & \cos \psi \end{pmatrix}$$

$$= \begin{pmatrix} \cos^2 \psi - \sin^2 \psi & 2 \sin \psi \cos \psi \\ 2 \sin \psi \cos \psi & -(\cos^2 \psi - \sin^2 \psi) \end{pmatrix}$$

$$= \begin{pmatrix} \cos 2\psi & \sin 2\psi \\ \sin 2\psi & -\cos 2\psi \end{pmatrix}.$$

The last equality follows from the usual formulas for trigonometric functions:

$$(1) \quad \begin{aligned} \sin 2\psi &= 2 \sin \psi \cos \psi \\ \cos 2\psi &= \cos^2 \psi - \sin^2 \psi. \end{aligned}$$

Notice that the product  $Z_\psi \cdot Z_0$  gives:

$$\begin{pmatrix} \cos 2\psi & \sin 2\psi \\ \sin 2\psi & -\cos 2\psi \end{pmatrix} \cdot \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix} = \begin{pmatrix} \cos 2\psi & -\sin 2\psi \\ \sin 2\psi & \cos 2\psi \end{pmatrix}.$$

$S_2, \dots, S_{2n+1}$ . If we carry out the point reflections across the middle points (from  $S_1$  to  $S_{2n+1}$ ), then clearly the point  $A_1$  is a fixed point of the resulting point reflection, thus it is its centre point. In order to find it, it is enough to carry out the given point reflection with any point  $X$  of the plane. The point  $A_1$  then lies in the middle of the line segment  $XX'$  where  $X'$  is the image of  $X$  in that point reflection. The rest of the vertices  $A_2, \dots, A_{2n+1}$  can be obtained by mapping the point  $A_1$  in the point reflections across the points  $S_1, \dots, S_{2n+1}$ .  $\square$

In the next exercises, we exploit the properties of the determinant of a matrix, cf. 1.5.5 and 1.5.7.

**1.E.28.** Determine the area of the triangle  $ABC$ , if  $A = [-8, 1]$ ,  $B = [-2, 0]$ ,  $C = [5, 9]$ .

**Solution.** We know that the area equals to the absolute value of the half of the determinant of the matrix, whose first column is given by the vector  $B - A$  and the second column by the vector  $C - A$ , that is the determinant of the matrix

$$\begin{pmatrix} -2 - (-8) & 5 - (-8) \\ 0 - 1 & 9 - 1 \end{pmatrix}.$$

A simple calculation yields the result

$$\frac{1}{2} |(-2 - (-8)) \cdot (9 - 1) - (5 - (-8)) \cdot (0 - 1)| = \frac{61}{2}.$$

Let us add that the change of the order of the vectors leads to change in the sign of the determinant (but the absolute value is unchanged) and that the value of the determinant would not change at all if we wrote the vertices as rows (preserving the order). Moreover, the determinant formed by vectors  $B - A$  and  $C - A$  is always positive if the vertices  $A, B, C$  are in the anti-clockwise direction.  $\square$

**1.E.29.** Compute the area  $S$  of the quadrilateral given by its vertices  $[1, 1]$ ,  $[6, 1]$ ,  $[11, 4]$ ,  $[2, 4]$ .

**Solution.** First, denote the vertices (in the counter-clockwise direction) as

$$A = [1, 1], \quad B = [6, 1], \quad C = [11, 4], \quad D = [2, 4].$$

If we divide the quadrilateral  $ABCD$  into the triangles  $ABC$  and  $ACD$ , we can obtain its area as the sum of the areas of these two triangles, by evaluating the determinants

$$d_1 = \begin{vmatrix} 6 - 1 & 11 - 1 \\ 1 - 1 & 4 - 1 \end{vmatrix} = \begin{vmatrix} 5 & 10 \\ 0 & 3 \end{vmatrix},$$

$$d_2 = \begin{vmatrix} 11 - 1 & 2 - 1 \\ 4 - 1 & 4 - 1 \end{vmatrix} = \begin{vmatrix} 10 & 1 \\ 3 & 3 \end{vmatrix},$$

This observation can be formulated as follows:

**Proposition.** A rotation through the angle  $\psi$  can be obtained by two subsequent reflections through the lines that have the angle  $\frac{1}{2}\psi$  between them.

In fact we can prove the previous proposition purely by geometrical argumentation, as shown in the above picture (try to be a “synthetic geometer” when reflecting  $A$  to  $A'$  and then  $A'$  to  $A''$ ). If we believe in this proof “by picture”, then the above computational derivation of the proposition provides the proof of the standard double angle formulas (1).

**1.5.10.** The following is a recapitulation of previous ideas.

MAPPINGS THAT PRESERVE LENGTH

**Theorem.** A linear mapping of the Euclidean plane is composed of one or more reflections if and only if it is given by a matrix  $R$  which satisfies

$$R = \begin{pmatrix} a & b \\ c & d \end{pmatrix}, \quad ab + cd = 0, \quad a^2 + c^2 = b^2 + d^2 = 1.$$

This happens if and only if the mapping preserves length. Rotation is such a mapping if and only if the determinant of the matrix  $R$  equals one, which corresponds to an even number of reflections. When there is an odd number of reflections, the determinant equals  $-1$ .

**PROOF.** We calculate how a general matrix  $A$  might look, when the corresponding mapping preserves length. That is, we have a mapping

$$\begin{pmatrix} x \\ y \end{pmatrix} \mapsto \begin{pmatrix} a & b \\ c & d \end{pmatrix} \cdot \begin{pmatrix} x \\ y \end{pmatrix} = \begin{pmatrix} ax + by \\ cx + dy \end{pmatrix}.$$

where in the columns are these vectors  $B - A, C - A$  (for  $d_1$ ) and  $C - A, D - A$  (for  $d_2$ ). Then

$$S = \left| \frac{d_1}{2} \right| + \left| \frac{d_2}{2} \right| = \left| \frac{5 \cdot 3 - 10 \cdot 0}{2} \right| + \left| \frac{10 \cdot 3 - 1 \cdot 3}{2} \right| = \frac{15 + 27}{2} = 21.$$

(thanks to the order of the vectors are all determinants greater than zero). Correctness of the result is easy to confirm, since the quadrilateral  $ABCD$  is a trapezoid with bases of lengths 5, 9 and their distance  $v = 3$ .  $\square$

In the following exercises, we consider non-transparent figures (triangle, quadrangle) in the  $\mathbb{R}^2$  plane.

We will illustrate the power of the concept of determinant and the oriented area on practical visibility issues in the plane.

**1.E.30. Visibility of the sides of a triangle.** Let the triangle with the vertices  $A = [5, 6], B = [7, 8], C = [5, 8]$  be given. Determine, which of its sides are visible from the point  $P = [0, 1]$ .

**Solution.** Order the vertices in the positive direction, that is counter-clockwise:  $[5, 6], [7, 8], [5, 8]$ . Using the corresponding determinants we can determine whether the point  $[0, 1]$  lies to the “left” or to the “right” of the sides of the triangle when we view them as oriented line segments.

$$\begin{aligned} \left| \begin{matrix} B - P \\ C - P \end{matrix} \right| &= \left| \begin{matrix} 7 & 7 \\ 5 & 7 \end{matrix} \right| > 0, & \left| \begin{matrix} C - P \\ A - P \end{matrix} \right| &= \left| \begin{matrix} 5 & 7 \\ 5 & 5 \end{matrix} \right| < 0, \\ \left| \begin{matrix} A - P \\ B - P \end{matrix} \right| &= \left| \begin{matrix} 5 & 5 \\ 7 & 7 \end{matrix} \right| = 0. \end{aligned}$$

Not all the determinants are positive, that means  $P$  is outside the triangle. In that case, if it is left of some oriented segment (a side of the triangle), the segment is not visible from  $P$  (think this over).

Because the last determinant is zero, the points  $[0, 1], [5, 6]$  and  $[7, 8]$  lie on a line, the side  $AB$  is thus not visible. The side  $BC$  is also not visible, unlike the side  $AC$  for which the determinant is negative.  $\square$

**1.E.31.** Which sides of the quadrangle given by the vertices  $[-2, -2], [1, 4], [3, 3]$  and  $[2, 1]$  are “visible” from the position of the point  $X = [3, \pi - 2]$ ?

**Solution.** In the first step we order the vertices such that their order corresponds the counter-clockwise direction. We choose vertex  $A = [-2, -2]$ , the order of the remaining vertices is then  $B = [2, 1], C = [3, 3], D = [1, 4]$  (think, how to

Preserving length thus means that for every  $x$  and  $y$ , we have

$$\begin{aligned} x^2 + y^2 &= (ax + by)^2 + (cx + dy)^2 \\ &= (a^2 + c^2)x^2 + (b^2 + d^2)y^2 + 2(ab + cd)xy. \end{aligned}$$

Since this equation is to hold for every  $x$  and  $y$ , the coefficients of the individual powers  $x^2, y^2$  and  $xy$  on the left and right side of the equation must be equal. Thus we have calculated that the conditions put on the matrix  $R$  in the first part of the theorem we are proving are equivalent to the property that the given mapping preserves length.

Because  $a^2 + c^2 = 1$ , we can assume that  $a = \cos \varphi$  and  $c = \sin \varphi$  for a suitable angle  $\varphi$ . As soon as we choose the first column of the matrix  $R$ , the relation  $ab + cd = 0$  determines the second column up to a multiple. But we also know that the length of the vector in the second column is one, and thus we have only two possibilities for the matrix  $R$ , namely:

$$\begin{pmatrix} \cos \varphi & -\sin \varphi \\ \sin \varphi & \cos \varphi \end{pmatrix}, \quad \begin{pmatrix} \cos \varphi & \sin \varphi \\ \sin \varphi & -\cos \varphi \end{pmatrix}.$$

In the first case, we have a rotation through the angle  $\varphi$ , in the second case we have a rotation composed with the reflection through the first coordinate axis. As we have seen in the previous proposition 1.5.8, every rotation corresponds to two reflections. The determinant of the matrix  $R$  is in these two cases either one or minus one and distinguishes between these two cases by the parity of the number of reflections.  $\square$

Notice, we have now proved our earlier claim on the invariance of formulae for distance and angle in any orthonormal coordinates. Moreover, we have seen that all euclidean affine mappings are generated by translations, and reflections.

**1.5.11. Area of a triangle.** At the end of our little trip to geometry we will focus on the *area* of planar objects. For us, triangles will be sufficient. Every triangle is determined by a pair of vectors  $\mathbf{v}$  and  $\mathbf{w}$ , which, if translated so that they start from one vertex  $P$  of the triangle, determine the remaining two vertices. We would like to find a formula (scalar function area), which assigns the number  $\text{area } \Delta(\mathbf{v}, \mathbf{w})$  equal to the area of the triangle  $\Delta(\mathbf{v}, \mathbf{w})$  defined in the aforementioned way. By translating, we can place  $P$  at the origin since translation should not change the area.

area of  $\Delta = 1/2$  area of  $\square$

order the points without a picture; you can actually use similar procedure to what follows). First consider the side  $AB$ . It along with the point  $X = [3, \pi - 2]$  determines the matrix

$$\begin{pmatrix} -2 - 3 & 2 - 3 \\ -2 - (\pi - 2) & 1 - (\pi - 2) \end{pmatrix}$$

such that its first column is the difference  $A - X$  and the second column is  $B - X$ . Whether it can be “seen” from the point  $[3, \pi - 2]$  (i.e. is left or right of the oriented line  $\overrightarrow{AB}$ , see 1.5.12), is then determined by the sign of the determinant

$$\begin{vmatrix} -2 - 3 & 2 - 3 \\ -2 - (\pi - 2) & 1 - (\pi - 2) \end{vmatrix} = \begin{vmatrix} -5 & -1 \\ -\pi & 3 - \pi \end{vmatrix} = -5 \cdot (3 - \pi) - (-1)(-\pi) < 0.$$

For the side  $BC$  we analogically obtain

$$\begin{vmatrix} 2 - 3 & 3 - 3 \\ 1 - (\pi - 2) & 3 - (\pi - 2) \end{vmatrix} = \begin{vmatrix} -1 & 0 \\ 3 - \pi & 5 - \pi \end{vmatrix} = -1 \cdot (5 - \pi) - 0 < 0.$$

And for the sides  $CD$  and  $DA$  we obtain

$$\begin{vmatrix} 3 - 3 & 1 - 3 \\ 3 - (\pi - 2) & 4 - (\pi - 2) \end{vmatrix} = \begin{vmatrix} 0 & -2 \\ 5 - \pi & 6 - \pi \end{vmatrix} = 0 - (-2) \cdot (5 - \pi) > 0,$$

$$\begin{vmatrix} 1 - 3 & -2 - 3 \\ 4 - (\pi - 2) & -2 - (\pi - 2) \end{vmatrix} = \begin{vmatrix} -2 & -5 \\ 6 - \pi & -\pi \end{vmatrix} = -2 \cdot (-\pi) - (-5) \cdot (6 - \pi) > 0.$$

The determinants differ in signs, thus the point  $X$  is outside the given quadrangle and a side is visible (from  $X$ ), if  $X$  is left of the side. According to our convention of putting vectors  $\overrightarrow{XA}$ ,  $\overrightarrow{XB}$ ,  $\overrightarrow{XC}$ ,  $\overrightarrow{XD}$  into the determinants, the side is visible, if the corresponding determinant is negative (i.e.  $X$  is right of the oriented side). Thus from the point  $X$  are visible exactly the sides determined by the pairs of vertices  $A = [-2, -2]$ ,  $B = [2, 1]$  and  $B = [2, 1]$ ,  $C = [3, 3]$ .  $\square$

**1.E.32.** Give the sides of the pentagon with vertices at points  $[-2, -2]$ ,  $[-2, 2]$ ,  $[1, 4]$ ,  $[3, 1]$  and  $[2, -11/6]$ , which are visible from the point  $[300, 1]$ .

**Solution.** For simplifying the notation, put

$$A = [-2, -2], \quad B = [2, -11/6], \quad C = [3, 1], \\ D = [1, 4], \quad E = [-2, 2].$$

The sides  $BC$  and  $CD$  are clearly visible from the position of the point  $[300, 1]$ . On the other hand,  $DE$  and  $EA$  cannot be seen. For the side  $AB$ , we compute

$$\begin{vmatrix} -2 - 300 & 2 - 300 \\ -2 - 1 & -\frac{11}{6} - 1 \end{vmatrix} = -302 \cdot \left(-\frac{17}{6}\right) - (-298) \cdot (-3) < 0.$$

This implies that the side can be seen from the point  $[300, 1]$ .  $\square$

We can see from the picture that the desired value is half of the area of the parallelogram spanned by the vectors  $\mathbf{v}$  and  $\mathbf{w}$ . It is easy to calculate (using the well-known formula: base times corresponding height), or simply observe from the picture that the following holds

$$\text{area } \Delta(\mathbf{v} + \mathbf{v}', \mathbf{w}) = \text{area } \Delta(\mathbf{v}, \mathbf{w}) + \text{area } \Delta(\mathbf{v}', \mathbf{w}) \\ \text{area } \Delta(a\mathbf{v}, \mathbf{w}) = a \text{ area } \Delta(\mathbf{v}, \mathbf{w}).$$

### LINEARITY IN ARGUMENT

Finally we add to the formulation of our problem a condition

$$\text{area } \Delta(\mathbf{v}, \mathbf{w}) = - \text{area } \Delta(\mathbf{w}, \mathbf{v}),$$

which corresponds to the idea that we give a sign to the area, according to the order in which we are taking the vectors.

If we write the vectors  $\mathbf{v}$  and  $\mathbf{w}$  into the columns of a matrix  $A$ , then the mapping

$$A = (\mathbf{v}, \mathbf{w}) \mapsto \det A$$

satisfies all the three conditions we wanted. How many such mappings could there possibly be? Every vector can be expressed using two basis vectors  $\mathbf{e}_1 = (1, 0)$  and  $\mathbf{e}_2 = (0, 1)$ . By linearity, area  $\Delta$  is uniquely determined by these vectors. We want

$$\text{area } \Delta(\mathbf{e}_1, \mathbf{e}_2) = \frac{1}{2}.$$

In other words, we have chosen the *orientation* and the *scale* through the choice of basis vectors, and we choose the unit square to have area equal to one.

Thus we see that the determinant gives the area of a parallelogram determined by the columns of the matrix  $A$ . The area of the triangle is thus one half of the parallelogram.

**1.5.12. Visibility in the plane.** The previous description of

the value for oriented area gives us an elegant tool for determining the position of a point relative to oriented line segments. By an oriented line segment we mean two points in the plane  $\mathbb{R}^2$  with a selected order. We can imagine it as an arrow from one point to the other. Such an oriented line segment divides the plane into two half-planes. Let us call them “left” and “right”. We want to be able to determine whether a given point is in the left or right half-plane.

Such tasks are often met in computer graphics when dealing with visibility of objects. We can imagine that an oriented line segment can be “seen” from the points to the right of it and cannot be seen from the points to left of it.

**F. Relations and mappings**

We conclude this chapter by considering briefly some aspects of the language of mathematics. We advise the reader to have a quick look at the definitions of the basic concepts of various relations and their properties, beginning in 1.6.1.

**1.F.1.** Determine whether the following relations on the set  $M$  are equivalence relations:

- i)  $M = \{f : \mathbb{R} \rightarrow \mathbb{R}\}$ , where  $f \sim g$  if  $f(0) = g(0)$ .
- ii)  $M = \{f : \mathbb{R} \rightarrow \mathbb{R}\}$ , where  $f \sim g$  if  $f(0) = g(1)$ .
- iii)  $M$  is the set of lines in the plane, where two lines are related if they do not intersect.
- iv)  $M$  is the set of lines in the plane, where two lines are related if they are parallel.
- v)  $M = \mathbb{N}$ , where  $m \sim n$  if  $S(m) + S(n) = 20$ , while  $S(n)$  stands for the sum of the digits of the integer  $n$ .
- vi)  $M = \mathbb{N}$ , where  $m \sim n$  if  $C(m) = C(n)$ , where  $C(n) = S(n)$  if the sum of the digits  $S(n)$  is less than 10, otherwise we define  $C(n) = C(S(n))$ . (Thus always  $C(n) < 10$ .)

**Solution.**

- i) We check the three properties of equivalence:
  - a) Reflexivity: for any real function  $f$ ,  $f(0) = f(0)$ .
  - b) Symmetry: if  $f(0) = g(0)$ , then also  $g(0) = f(0)$ .
  - c) Transitivity: if  $f(0) = g(0)$  and  $g(0) = h(0)$ , then also  $f(0) = h(0)$ . We conclude that the relation is an equivalence relation.
- ii) No. The relation is not reflexive, since for instance for the function  $\sin$  we have  $\sin 0 \neq \sin 1$ . It is not transitive.
- iii) No. The relation is not reflexive (every line intersects itself). It is not transitive.
- iv) Yes. The equivalence classes then correspond to unoriented directions in the plane.
- v) No. The relation is not reflexive.  $S(1) + S(1) = 2$ . It is not transitive.
- vi) Yes.

□

**1.F.2.** Let the relation  $R$  be defined over  $\mathbb{R}^2$  such that  $((a, b), (c, d)) \in R$  for arbitrary  $a, b, c, d \in \mathbb{R}$  if and only if  $b = d$ . Determine whether or not this is an equivalence relation. If it is, describe geometrically the partitioning it determines.

We have the oriented line segment  $AB$  and are given some point  $C$ . We calculate the oriented area of the corresponding triangle determined by the vectors  $A-C$  and  $B-C$ . If the point  $C$  is to the left of the line segment, then with the usual positive orientation (counter-clockwise) we obtain the positive sign of the oriented area, while the negative sign corresponds to the points to the right.

This approach is often used for testing relative positions in 2D graphics.

**6. Relations and mappings**

In the final part of this introductory chapter, we return to the formal description of mathematical structures. We will try to illustrate them on examples we already know. We can consider this part to be an exercise in a formal approach to the objects and concepts of mathematics, i.e. the “language of mathematics”.

**1.6.1. Relations between sets.** First we define the *Cartesian product*  $A \times B$  of two sets  $A$  and  $B$ . It is the set of all ordered pairs  $(a, b)$  such that  $a \in A$  and  $b \in B$ . A *binary relation* between the two sets  $A$  and  $B$  is then a subset  $R$  of the Cartesian product  $A \times B$ .

We write  $a \simeq_R b$  to mean  $(a, b) \in R$ , and say that  $a$  is related to  $b$ . The *domain of the relation* is the subset

$$D = \{a \in A : \exists b \in B, (a, b) \in R\}.$$

Here the symbol  $\exists b$  means that there is at least one such  $b$  satisfying the rest of the claim.

Similarly, the *codomain of the relation* is the subset

$$I = \{b \in B : \exists a \in A, (a, b) \in R\}.$$

A special case of a relation between sets is a *mapping from the set  $A$  to the set  $B$* . This is the case when every element of the domain of the relation is related to exactly one element of the codomain. Examples of mappings known to us are all functions, where the codomain of the mapping is a set of numbers, for instance the set of integers or the set of real numbers, or the linear mappings in the plane given by matrices. We write

$$f : D \subseteq A \rightarrow I \subseteq B, \\ f(a) = b$$

**Solution.** From  $((a, b), (a, b)) \in R$  for all  $a, b \in \mathbb{R}$  it is implied that the relation is reflexive. Equally easy to see is that the relation is symmetric, since in the equality of the second coordinates we can interchange the left and right side. If  $((a, b), (c, d)) \in R$  and  $((c, d), (e, f)) \in R$ , that is,  $b = d$  and  $d = f$ , we easily get that the transitivity condition  $((a, b), (e, f)) \in R$ , that is  $b = f$ . The relation  $R$  is an equivalence relation, where the points in the plane are related if and only if they have the same second coordinate (the line they determine is perpendicular to the  $y$  axis). The corresponding partition then divides the plane into the lines parallel with the  $x$  axis.  $\square$

**1.F.3.** Determine how many distinct binary relations can be defined between the set  $X$  and the set of all subsets of  $X$ , if the set  $X$  has exactly 3 elements.

**Solution.** First, notice that the set of all subsets of  $X$  has exactly  $2^3 = 8$  elements, and thus the Cartesian product with  $X$  has  $8 \cdot 3 = 24$  elements. Possible binary relations then correspond to subsets of this Cartesian product, and of those there are  $2^{24}$ .  $\square$

**1.F.4.** Give the domain  $D$  and the codomain  $I$  of the relations

$$R = \{(a, v), (b, x), (c, x), (c, u), (d, v), (f, y)\}$$

between the sets  $A = \{a, b, c, d, e, f\}$  and  $B = \{x, y, u, v, w\}$ . Is the relation  $R$  a mapping?

**Solution.** Directly from the definition of the domain and the codomain of a relation we obtain

$$D = \{a, b, c, d, f\} \subset A, \quad I = \{x, y, u, v\} \subset B.$$

It is not a mapping since  $(c, x), (c, u) \in R$ , that is  $c \in D$  has two images.  $\square$

**1.F.5.** Determine for each of the following relations over the set  $\{a, b, c, d\}$  whether it is an ordering and whether it is complete:

$$R_1 = \{(a, a), (b, b), (c, c), (d, d), (b, a), (b, c), (b, d)\},$$

$$R_2 = \{(a, a), (b, b), (c, c), (d, d), (d, a), (a, d)\},$$

$$R_3 = \{(a, a), (b, b), (c, c), (d, d), (a, b), (b, c), (b, d)\},$$

$$R_4 = \{(a, a), (b, b), (c, c), (a, b), (a, c), (a, d), (b, c), (b, d), (c, d)\},$$

$$R_5 = \{(a, a), (b, b), (c, c), (d, d), (a, b), (a, c), (a, d), (b, c), (b, d), (c, d)\}.$$

to express the fact that  $(a, b)$  belongs to a relation, and we say that  $b$  is the value of  $f$  at  $a$ . Furthermore we say that

- mapping  $f$  of the set  $A$  to the set  $B$  is *surjective* (or *onto*), if  $D = A$  and  $I = B$ , clarify ?
- mapping  $f$  of the set  $A$  to the set  $B$  is *injective* (or *one-to-one*), if  $D = A$  and for every  $b \in I$  there exist exactly one *preimage*  $a \in A, f(a) = b$ .

Expressing a mapping  $f : A \rightarrow B$  as a relation

$$f \subseteq A \times B, \quad f = \{(a, f(a)); a \in A\}$$

is also known as *the graph of a mapping*  $f$ .

**1.6.2. Composition of relations and functions.** For mappings, the concept of composition is clear. Suppose we have two mappings  $f : A \rightarrow B$  and  $g : B \rightarrow C$ . Then their *composition*  $g \circ f : A \rightarrow C$  is defined as

$$(g \circ f)(a) = g(f(a)).$$

Composition can also be expressed with the notation used for a relation as

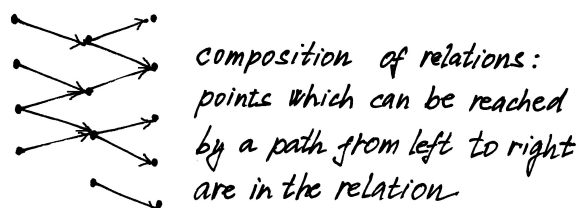

$$f \subseteq A \times B, \quad f = \{(a, f(a)); a \in A\}$$

$$g \subseteq B \times C, \quad g = \{(b, g(b)); b \in B\}$$

$$g \circ f \subseteq A \times C, \quad g \circ f = \{(a, g(f(a))); a \in A\}.$$

The *composition of a relation* is defined in a very similar way. We just add existential quantifiers to the statements, since we have to consider all possible “preimages” and all possible “images”. Let  $R \subseteq A \times B, S \subseteq B \times C$  be relations. Then  $S \circ R \subseteq A \times C$ ,

$$S \circ R = \{(a, c); \exists b \in B, (a, b) \in R, (b, c) \in S\}.$$

A special case of a relation is the *identity relation*

$$\text{id}_A = \{(a, a) \in A \times A; a \in A\}$$

on the set  $A$ . It is a neutral element with respect to composition with any relation that has  $A$  as its codomain or domain.

**Solution.**  $R_1$  is an ordering, which is not complete (for instance neither  $(a, c) \notin R_1$  nor  $(c, a) \notin R_1$ ).

The relation  $R_2$  is not anti-symmetric as it is both  $(a, d) \in R_2$  and  $(d, a) \in R_2$ , therefore it is not an ordering (it is an equivalence).

The relations  $R_3$  and  $R_4$  are also not an ordering, since they are not transitive (for instance  $(a, b), (b, c) \in R_3, R_4$ ,  $(a, c) \notin R_3, R_4$ ) and also  $R_4$  is not reflexive ( $(d, d) \notin R_4$ ).

The relation  $R_5$  is a complete ordering (if we interpret  $(a, b) \in R_5$  as  $a \leq b$ , then  $a \leq b \leq c \leq d$ ).  $\square$

**1.F.6.** Determine whether or not the mapping  $f$  is injective (one-to-one) or surjective (onto), when

- (a)  $f : \mathbb{Z} \times \mathbb{Z} \rightarrow \mathbb{Z}, \quad f((x, y)) = x + y - 10x^2$ ;
- (b)  $f : \mathbb{N} \rightarrow \mathbb{N} \times \mathbb{N}, \quad f(x) = (2x, x^2 + 10)$ .

**Solution.** In the case (a) is given a mapping which is surjective (it is enough to set  $x = 0$ ) but not injective (it is enough to set  $(x, y) = (0, -9)$  and  $(x, y) = (1, 0)$ ). In the case (b) it is an injective mapping (both its coordinates, that is functions  $y = 2x$  and  $y = x^2 + 10$  are clearly increasing over  $\mathbb{N}$ ). The mapping is not surjective (for instance the pair  $(1, 1)$  has no preimage).  $\square$

**1.F.7.** In the following three figures, icons are connected with lines such that people in different parts of the world could have assigned them. Determine whether the connection is a mapping, and whether it is injective, surjective or bijective.

**Solution.** In the first figure the connection is a mapping which is surjective but not injective, because both the snake and the spider are labeled as poisonous. The second figure is not a mapping but only a relation, since the dog is labeled both as a pet and as a meal. The third connection is again a mapping. This time it is neither injective nor surjective.  $\square$

**1.F.8.** Determine the number of mappings from the set  $\{1, 2\}$  to the set  $\{a, b, c\}$ . How many of them are surjective and how many are injective?

**Solution.** To the element 1 we can assign any of the elements  $a, b, c$ . Similarly for the element 2 we can assign any of the

For every relation  $R \subseteq A \times B$ , we define the *inverse relation*

$$R^{-1} = \{(b, a); (a, b) \in R\} \subset B \times A.$$

Beware, the same term is used with mappings in a more specific situation. Of course, for every mapping there is its inverse relation, but this relation is in general not a mapping. Therefore we speak about the existence of an inverse mapping if every element  $b \in B$  is an image of exactly one element in  $A$ . In such a case the inverse mapping is exactly the inverse relation.

Note that the composition of a mapping and its inverse mapping (if it exists) is the identity mapping. In general, this is not so for relations.

**1.6.3. Relation on a set.** In the case when  $A = B$  we speak about a relation on the set  $A$ . We say that the relation  $R$  is:

- *reflexive*, if  $\text{id}_A \subseteq R$ , that is  $(a, a) \in R$  for every  $a \in A$ ,
- *symmetric*, if  $R^{-1} = R$ , that is if  $(a, b) \in R$ , then also  $(b, a) \in R$ ,
- *antisymmetric*, if  $R^{-1} \cap R \subseteq \text{id}_A$ , that is if  $(a, b) \in R$  and if also  $(b, a) \in R$ , then  $a = b$ ,
- *transitive*, if  $R \circ R \subseteq R$ , that is if  $(a, b) \in R$  and  $(b, c) \in R$  implies  $(a, c) \in R$ .

A relation is called an *equivalence relation* if it is reflexive, symmetric and transitive.

A relation is called an *ordering* if it is reflexive, transitive and antisymmetric. Orderings are usually denoted by the symbol  $\leq$ , that is the fact that element  $a$  is in relation with element  $b$  is written as  $a \leq b$ .

Notice that the relation  $<$ , that is “to be strictly smaller than”, is not an ordering on the set of real numbers, since it is not reflexive. The common practice (also used in this book) is to use the sign  $<$  or  $\subset$  for orderings, too.

A good example of an ordering is set inclusion. Consider the set  $2^A$  of all subsets of a finite set  $A$ . We have a relation  $\subseteq$  on the set  $2^A$  given by the property “being a subset”. Thus  $X \subseteq Z$  if  $X$  is a subset of  $Z$ . Clearly all three conditions from the definition of ordering are satisfied: if  $X \subseteq Y$  and  $Y \subseteq X$  then necessarily  $X$  and  $Y$  must be identical. If  $X \subseteq Y \subseteq Z$  then also  $X \subseteq Z$ , and reflexivity is clear from the definition. (As mentioned above, we shall mostly use the symbol  $\subset$  without excluding equality.)

We say that an ordering  $\leq$  on a set  $A$  is *complete*, if every two elements  $a, b \in A$  are *comparable*, that is, either  $a \leq b$  or  $b \leq a$ .

If  $A$  contains more than one element, there exist subsets  $X$  and  $Y$  where neither  $X \subseteq Y$  nor  $Y \subseteq X$ , so the ordering  $\subseteq$  is not complete on the set of all subsets of  $A$ .

The set of real numbers with the usual  $\leq$  is complete. Thus the subdomains  $\mathbb{N}, \mathbb{Z}, \mathbb{Q}$  come equipped with a complete ordering, too. On the other hand, there is no such natural ordering on  $\mathbb{C}$ . The absolute value is only a partial ordering there (comparing the radii of the circles in the complex plane).

elements  $a, b, c$ . Thus there are exactly  $3^2$  mappings of the set  $\{1, 2\}$  to the set  $\{a, b, c\}$ . None of them can be surjective, since the set  $\{a, b, c\}$  has more elements than the set  $\{1, 2\}$ . The mapping is injective if and only if the elements 1 and 2 are mapped to different elements. There are three possibilities for the image of 1, after the image of 1 is given, there remain two possibilities for the image of 2. Thus the number of injective mappings of the set  $\{1, 2\}$  to the set  $\{a, b, c\}$  is 6.  $\square$

**1.F.9.** Determine the number of surjective mappings of the set  $\{1, 2, 3, 4\}$  to the set  $\{1, 2, 3\}$ .

**Solution.** We can determine the number by subtracting the number of non-surjective mappings from the number of all mappings. The number of all mappings is  $V(3, 4) = 3^4$ . Non-surjective mappings have either a one element, or a two element codomain. There are just three mappings with a one element codomain. The number of mappings with a two element codomain is  $\binom{3}{2}(2^4 - 2)$  (there are  $\binom{3}{2}$  ways to choose the codomain and for a fixed two-element codomain there are  $2^4 - 2$  ways how to map four elements onto them). Thus the number of surjective mappings is

$$3^4 - \binom{3}{1}(2^4 - 2) - 3 = 36. \quad \square$$

**1.F.10.** Write down all the relations over a two-element set  $\{1, 2\}$ , which are symmetric but are neither reflexive nor transitive.

**Solution.** The reflexive relations are exactly those which contain both pairs  $(1, 1), (2, 2)$ . This excludes relations

$$\{(1, 1), (2, 2)\}, \quad \{(1, 1), (2, 2), (1, 2)\}, \\ \{(1, 1), (2, 2), (2, 1)\}, \quad \{(1, 1), (2, 2), (1, 2), (2, 1)\}.$$

We claim that the remaining relations, which are symmetric but not transitive, must contain  $(1, 2), (2, 1)$ . If such a relation contains one of these two (ordered) pairs, it must by symmetry contain also the other. If it contains neither of these pairs, then it is clearly transitive. From the total number of 16 relations over a two-element set we have thus selected

$$\{(1, 2), (2, 1)\}, \quad \{(1, 2), (2, 1), (1, 1)\}, \\ \{(1, 2), (2, 1), (2, 2)\}.$$

It is clear that each of these 3 relations is symmetric but neither reflexive nor transitive.  $\square$

**1.6.4. Partitions of an equivalence.** Every equivalence relation  $R$  on a set  $A$  defines also a *partition* of the set  $A$ , consisting of subsets of mutually equivalent elements, namely *equivalence classes*. For any  $a \in A$  we consider the set of elements, which are equivalent with  $a$ , that is

$$[a] = R_a = \{b \in A; (a, b) \in R\}.$$

Clearly  $a \in R_a$  by reflexivity. If  $(a, b) \in R$ , then  $R_a = R_b$  by symmetry and transitivity. Furthermore, if  $R_a \cap R_b \neq \emptyset$  then there is an element  $c$  in both  $R_a$  and  $R_b$  so that  $R_a = R_c = R_b$ . It follows that for every pair  $a, b$ , either  $R_a = R_b$ , or  $R_a$  and  $R_b$  are disjoint. That is, the equivalence classes are pairwise disjoint. Finally,  $A = \cup_{a \in A} R_a$ . That is, the set  $A$  is partitioned into equivalence classes. We write  $[a] = R_a$ , and by the above, we can represent an equivalence class by any one of its elements.

**1.6.5. Existence of scalars.** As before, we assume to know what sets are, and indicate the construction of the natural numbers.

We denote the empty set by  $\emptyset$  (notice the difference between the symbol 0 for the zero and the empty set  $\emptyset$ ) and define

$$(1) \quad 0 := \emptyset, \quad n + 1 := n \cup \{n\},$$

in other words

$$0 := \emptyset, \quad 1 := \{0\}, \quad 2 := \{0, 1\}, \dots, \quad n + 1 := \{0, 1, \dots, n\}.$$

This notation says that if we have already defined the numbers  $0, 1, 2, \dots, n$ , then the number  $n + 1$  is defined as the set of all previous numbers.

We have defined the set of natural numbers  $\mathbb{N}$ .<sup>3</sup> Next, we should construct the operations  $+$  and  $\cdot$  and deduct their required properties. In order to do that in detail, we would have to pay more attention to basic understanding of sets. For example, once we know what a disjoint union of sets is, we may define the natural number  $c = a + b$  as the unique natural number  $c$  having the same number of elements as the disjoint union of  $a$  and  $b$ .

Of course, formally speaking, we need to explain what does it mean for two sets to have the same number of elements. Let us notice that in general, having the two sets  $A$  and  $B$  of the same “size” should mean that there exists a bijection  $A \rightarrow B$ . This is completely in accordance with our intuition for finite sets. However, it is much less intuitive with infinite sets. For example there is the same amount of all natural numbers and those with natural square roots (the bijection  $a \mapsto a^2$ ), although the example 1.G.1 could be read as “most of natural numbers do not have a rational square root”. We say, that each set which is bijective to natural numbers  $\mathbb{N}$  is *countable*. Sets bijective to some natural number  $n$  (as defined above)

<sup>3</sup>The concept of natural numbers based on the principle of “increasing by one” was known to all ancient civilisations, however they always had the smallest natural number one. The set theoretical approach was developed in 19th century and there zero got a logical smallest natural number as the counterpart of the empty set.

**1.F.11.** Consider the set of numbers that have five digits in the binary notation and a relation such that two numbers are related whenever their digit sum has the same parity. Write down the corresponding equivalence classes.

**Solution.** We have two equivalence classes (of eight members):  $[10000] = \{10000, 10011, 10101, 10110, 11001, 11010, 11100, 11111\}$  which corresponds to the set

$$\{16, 19, 21, 22, 25, 26, 28, 31\}$$

and  $[10001] = \{10001, 10010, 10100, 11000, 10111, 11011, 11101, 11110\}$  which corresponds to the set

$$\{17, 18, 20, 24, 23, 27, 29, 30\}.$$

**1.F.12.** Consider the set of numbers that have three digits in the ternary notation and a relation such that two numbers are in the relation whenever they

- i) begin with the same two digits in this notation,
- ii) end with the same two digits in this notation.

Write down the corresponding equivalence classes.

**Solution.**

- i) We obtain six three-element classes

$$\begin{aligned} [100] &= \{100, 101, 102\} \text{ corresponds } \{9, 10, 11\} \\ [110] &= \{110, 111, 112\} \text{ corresponds } \{12, 13, 14\} \\ [120] &= \{120, 121, 122\} \text{ corresponds } \{15, 16, 17\} \\ [200] &= \{200, 201, 202\} \text{ corresponds } \{18, 19, 20\} \\ [210] &= \{210, 211, 212\} \text{ corresponds } \{21, 22, 23\} \\ [220] &= \{220, 221, 222\} \text{ corresponds } \{24, 25, 26\}. \end{aligned}$$

- ii) In this case we have nine two-element classes

$$\begin{aligned} [100] &= \{100, 200\} \text{ corresponds } \{9, 18\} \\ [101] &= \{101, 201\} \text{ corresponds } \{10, 19\} \\ [102] &= \{102, 202\} \text{ corresponds } \{11, 20\} \\ [110] &= \{110, 210\} \text{ corresponds } \{12, 21\} \\ [111] &= \{111, 211\} \text{ corresponds } \{13, 22\} \\ [112] &= \{112, 212\} \text{ corresponds } \{14, 23\} \\ [120] &= \{120, 220\} \text{ corresponds } \{15, 24\} \\ [121] &= \{121, 221\} \text{ corresponds } \{16, 25\} \\ [122] &= \{122, 222\} \text{ corresponds } \{17, 26\}. \end{aligned}$$

are called *finite* (with *number of elements*  $n$ ), while the sets which are neither finite nor countable are called *uncountable*.

We can also define a relation  $\leq$  on  $\mathbb{N}$  as follows:  $m \leq n$ , if either  $m \in n$  or  $m = n$ . Clearly this is a complete ordering. For instance  $2 \leq 4$ , since

$$2 = \{\emptyset, \{\emptyset\}\} \in \{\emptyset, \{\emptyset\}, \{\emptyset, \{\emptyset\}\}, \{\emptyset, \{\emptyset\}, \{\emptyset, \{\emptyset\}\}\} = 4.$$

In other words, the recurrent definition itself gives the relation  $n \leq n+1$ . and transitivity then gives  $n \leq k$  for all  $k$  obtained in this manner later.

This ordering of the positive integers or natural numbers (the number  $a$  is strictly smaller than  $b$  if  $a \in b$ ) has obviously got the following striking property: every subset in  $\mathbb{N}$  or  $\mathbb{Z}^+$  has a smallest element.

**1.6.6. Integers and rational numbers.** With the set  $\mathbb{N}$  of positive integers together with zero, we can always add two numbers together. Also, adding zero to a number does not change it. We can also define subtraction, but the result does not always belong to  $\mathbb{N}$ .

The basic idea of construction of the integers from the natural numbers or positive integers is to add to  $\mathbb{N}$  these missing results. This can be done as follows: instead of subtraction, we will work with ordered pairs of numbers. It just remains to define which such pairs are equivalent (with respect to the result of subtraction). The necessary relation is then:

$$(a, b) \sim (a', b') \iff a - b = a' - b' \iff a + b' = a' + b.$$

Note that the expression in the middle equation may not belong to  $\mathbb{N}$ , but the expression on the right always does. It is easy to check that it really is an equivalence, and we denote its classes as the integers  $\mathbb{Z}$ . We define addition and subtraction on  $\mathbb{Z}$  using representatives. For instance

$$[(a, b)] + [(c, d)] = [(a + c, b + d)],$$

which is clearly independent of the choice of representatives.

It is always possible to choose a representative  $(a, 0)$  for natural numbers  $a$ , and a representative  $(0, a)$  for negative numbers  $-a$ . This is probably the simplest and easiest choice.

If we define multiplication of integers similarly to the addition, we have all the properties (CG1)–(CG4) and (R1)–(R4), see the paragraph 1.1.1. For multiplication, the neutral element is one, but for all numbers  $a$  other than zero and  $\pm 1$  there does not exist an integer  $a^{-1}$  with the property  $a \cdot a^{-1} = 1$ . Thus, for multiplication, we are missing the inverse elements. However, the property of the integral domain (ID) holds. This means that if the product of two integers equals zero, then at least one of them has to be zero.

We can construct the rational numbers  $\mathbb{Q}$  by adding all the missing multiplicative inverses by a method analogous to the construction of  $\mathbb{Z}$  from  $\mathbb{N}$ . On the set of all ordered pairs  $(p, q)$ ,  $q \neq 0$ , of integers, we define a relation  $\sim$  so that it models our expectation of the fractions  $p/q$ :

$$(p, q) \sim (p', q') \iff p/q = p'/q' \iff p \cdot q' = p' \cdot q.$$

Again, we are not able to formulate the expected behaviour in the middle equation when we work in  $\mathbb{Z}$ , but for the equation

□

**1.F.13.** Determine the number of equivalence relations over a set  $\{1, 2, 3, 4\}$ .

**Solution.** We divide the sought equivalences according to the types of corresponding partitions (given by number and cardinality of equivalence classes), and we count the number of partitions of a given type:

The type of partition	number of partitions of this type
1,1,1,1	1
2,1,1	$\binom{4}{2}$
2,2	$\frac{1}{2} \binom{4}{2}$
3,1	$\binom{4}{1}$
4	1

In total we have 15 different equivalences. □

**Remark.** In general, the number of partitions of a given  $n$ -element set is given by the *Bell number*  $B_n$ , satisfying a recurrence formula

$$B_{n+1} = \sum_{k=0}^n \binom{n}{k} B_k.$$

(divide the partitions according to the cardinality of the set, to which one fixed element belongs)

**1.F.14.** Determine the number of orderings of a four-element set.

**Solution.** We will consider all possible Hasse diagrams of orderings over a four-element set  $M$ . We count how many different orderings (recall that an ordering is a subset of a set  $M \times M$ ) the given Hasse diagram has. See the diagram:

In total, there are 219 orderings over a four-element set. □

There are many combinatorics problems which refer to relations. You can find some of them in the additional exercises after this chapter, starting with 1.G.71.

on the right this is indeed possible. This relation is a well-defined equivalence (think it through!). If we formally write  $p/q$  instead of pairs  $(p, q)$ , we can define the operations of multiplication and addition by the well-known formulas

$$p/q \cdot r/s = pr/qs$$

$$p/q + r/s = ps/qs + qr/qs = (ps + qr)/qs.$$

**1.6.7. Remainder classes.** Another example of equivalence classes is the remainder classes of integers. For a fixed natural number  $k$  we define an equivalence  $\sim_k$  so that two numbers  $a, b \in \mathbb{Z}$  are equivalent if they have the same remainder when divided by  $k$ . The resulting set of equivalence classes is denoted as  $\mathbb{Z}_k$ . This procedure is simplest for  $k = 2$ . This yields  $\mathbb{Z}_2 = \{[0], [1]\}$ , where zero stands for even numbers and one for odd numbers. It is easy to see that using representatives we can correctly define addition and multiplication for each  $\mathbb{Z}_k$ .

REMAINDER CLASSES RINGS AND FIELDS

**Theorem.** The remainder class  $\mathbb{Z}_k$  is always a commutative ring of scalars. It is a commutative field of scalars (that is, the property (F) from the paragraph 1.1.1 is also satisfied) if and only if  $k$  is a prime.

If  $k$  is not prime, then  $\mathbb{Z}_k$  contains a divisor of zero, thus it is not an integral domain.

**PROOF.** The second part is easy to see — if  $x \cdot y = k$  for natural numbers  $x, y$ , then the result of multiplying the corresponding classes  $[x] \cdot [y]$  is zero.

On the other hand, if  $x$  and  $k$  are relatively prime, then according to the Bezout equality, (which we derive later, see 11.1.2), there are natural numbers  $a$  and  $b$  satisfying

$$ax + bk = 1,$$

which for corresponding equivalence classes gives

$$[a] \cdot [x] + [0] = [a] \cdot [x] = [1]$$

and thus  $[a]$  is the inverse element to  $[x]$ . □

**G. Additional exercises for the whole chapter**

**1.G.1.** Let  $t$  and  $m$  be positive integers. Show that the number  $\sqrt[m]{t}$  is either integer or is not rational.

**Solution.** We shall exploit the basic divisibility rules of integers which we shall discuss in detail later in chapter 11. Show that if the number is not integer, then it cannot be rational. If  $\sqrt[m]{t}$  is not integer, then there exists a prime  $r$  and integer  $s$  such that  $r^s$  divides  $t$ ,  $r^{s+1}$  does not divide  $t$  (this we write as  $\text{ord}_r t = s$ ) and  $m$  does not divide  $s$ . Assume that  $\sqrt[m]{t} = \frac{p}{q}$ ,  $p, q \in \mathbb{Z}$ , in other words  $t \cdot q^m = p^m$ . Consider  $\text{ord}_r L$  and  $\text{ord}_r R$  and their divisibility by the number  $m$ . ( $L$  and  $R$  denote the left-hand and right hand side of the equation respectively).  $\square$

**1.G.2.** Find the algebraic form of the expressions:

- i)  $\frac{2+i}{5+3i}$ ,
- ii)  $\frac{(1+i)^2}{(\sqrt{2}+\sqrt{2}i)^{30}}$ .

**Solution.** By expanding the fraction by  $5 - 3i$  we get easily the result  $\frac{13}{34} - \frac{1}{34}i$ . The second task is an explicit computation resulting in  $2^{-29}i$ .  $\square$

**1.G.3.** In the complex plane draw the solutions of the equations:

- i)  $z = |z|$ ,
- ii)  $|z^2 + 1| = 1$ ,
- iii)  $\text{Re } z = \text{Re}(z + 1)$ .

**Solution.** Write the solution!!  $\square$

**1.G.4.** Mark the following sets in the complex plane:

- i)  $\{z \in \mathbb{C} \mid |z - 1| = |z + 1|\}$ ,
- ii)  $\{z \in \mathbb{C} \mid 1 \leq |z - i| \leq 2\}$ ,
- iii)  $\{z \in \mathbb{C} \mid \text{Re}(z^2) = 1\}$ ,
- iv)  $\{z \in \mathbb{C} \mid \text{Re}(\frac{1}{z}) < \frac{1}{2}\}$ .

**Solution.** (i) the imaginary axis,

(ii) annulus around  $i$ ,

(iii) hyperbola  $a^2 - b^2 = 1$ ,

(iv) exterior of the unit disc centered at 1.

solution missing

□

**1.G.5.** Consider an “assignment”, which sends every real number  $a$  to a root of  $x^2 + x + a = 0$ . Does it give a function  $\mathbb{R} \rightarrow \mathbb{C}$ ?

**Solution.** No, the prescription is not unique, there is always a choice from two numbers, except for  $a = 1/4$ . □

**1.G.6.** Determine the number of ways of placing the white tower and black tower on the chessboards (of size  $8 \times 8$ ), that are neither in the same column nor in the row.

**Solution.** First, we can place the white tower in any of  $8^2$  positions. Then we have “to our disposal”  $7^2$  positions in which to place the black tower. The total number of ways is  $8^2 \cdot 7^2 = 3\,136$ . □

**1.G.7.** There were six men in the meeting. If all of them shook hands with each other, how many handshakes have happened?

**Solution.** The number of handshakes equals the number of ways of choosing an unordered tuple among 6 elements, thus the result is  $c(6, 2) = \binom{6}{2} = 15$ . □

**1.G.8.** Determine in how many ways a four-member committee can be chosen among 15 deputies, if it is not allowed for two certain deputies to work together.

**Solution.** The result is

$$\binom{15}{4} - \binom{13}{2} = 1\,287.$$

It can be obtained by first calculating the number of all four-member committees and then subtracting the number of those committees where the given two deputies are chosen together (in that case, we only choose two more members among the remaining 13 deputies). □

**1.G.9.** In how many ways can we divide 8 women and 4 men in two six-member groups (which are considered unordered) in such a way that there is at least one man in each group?

**Solution.** If we forget the last condition, division of 12 people in two six-member groups can be done by just choosing 6 people and put them to the first group, which can be done in  $\binom{12}{6}$  ways. The groups are not distinguishable (we do not know which one is the first one), thus the total number is rather  $\frac{1}{2} \cdot \binom{12}{6}$ . In  $\binom{8}{2}$  cases all men are in one group (we choose two women among eight to complete the group). The correct answer is thus

$$\frac{1}{2} \cdot \binom{12}{6} - \binom{8}{2} = 434. \quad \square$$

**1.G.10.** Determine the number of even four-digit numbers composed of exactly two distinct digits.

**Solution.** Analogously to 1.C.6, we ignore first the peculiarities of the digit zero. We obtain  $\binom{5}{2}(2^4 - 2) + 5 \cdot 5(2^3 - 1)$  numbers (In the first summand, we count the numbers that consist only of even digits. In the second summand we count the number of even four-digit numbers with one digit even and one digit odd). Again we have to subtract the numbers that start with zero, of those there are  $(2^3 - 1)4 + (2^2 - 1)5$ . The final number is thus

$$\binom{5}{2}(2^4 - 2) + 5 \cdot 5(2^3 - 1) - (2^3 - 1)4 - (2^2 - 1)5 = 272. \quad \square$$

**1.G.11.** What is the number of 4-digit numbers composed of digits 1, 3, 5, 6, 7 and 9, where no digit occurs more than once?

**Solution.** We have 6 distinct letters at our disposal. We ask: how many distinct ordered 4-tuples can be chosen from them? The result is  $v(6, 4) = 6 \cdot 5 \cdot 4 \cdot 3 = 360$ . □

**1.G.12.** The Greek alphabet consists of 24 letters. How many words of exactly five letters can be composed in it? (Disregarding whether the words have some actual meaning or not.)

**Solution.** For each of the five positions in the word we have 24 possibilities, since the letters can repeat. The result is then  $V(24, 5) = 24^5$ . □

**1.G.13.** In a long-distance race, where the racers start one after another in given time intervals, there were  $k$  racers, among them 3 friends. Determine the number of starting schedules in which no two of the 3 friends start next to each other. For simplicity assume  $k \geq 5$ .

**Solution.** Remaining  $k - 3$  racers can be ordered in  $(k - 3)!$  ways. For the three friends there are then  $k - 2$  places (the start, the end and the  $k - 4$  spaces) where we can put them in  $v(k - 2, 3)$  ways. Using the rule of (combinatorial) product, we obtain

$$(k - 3)! \cdot (k - 2) \cdot (k - 3) \cdot (k - 4) = (k - 2)! \cdot (k - 3) \cdot (k - 4). \quad \square$$

**1.G.14.** There are 32 participants of a tournament. The organisers have stated that the participants must divide arbitrarily into four groups, such that the first one has size 10, the second and the third 8, and the fourth 6. In how many ways can this be done?

**Solution.** We can imagine that from 32 participants we create a row, where first 10 are the first group, next 8 are the second group and so on. There are  $32!$  orderings of all participants. Note that the division into groups is not influenced if we change the order of the people in the same group. Therefore the number of distinct divisions equals

$$P(10, 8, 8, 6) = \frac{32!}{10! \cdot 8! \cdot 8! \cdot 6!}. \quad \square$$

**1.G.15.** We need to accommodate 9 people in one four-bed room, one three-bed room and one two-bed room. In how many ways can this be done?

**Solution.** If we assign to the people in the four-bed room the number 1, in the three-bed room number 2 and in the two-bed room number 3, then we create permutations with repetitions from the elements 1, 2, 3, where 1 occurs four times, 2 three times and 3 two times. Number of such permutations is

$$P(4, 3, 2) = \frac{9!}{4! \cdot 3! \cdot 2!} = 1\,260. \quad \square$$

**1.G.16.** Determine the number of ways how to divide among three people  $A$ ,  $B$  and  $C$  33 distinct coins such that  $A$  and  $B$  together have twice as many coins as  $C$ .

**Solution.** From the problem statement it is clear that  $C$  must receive 11 coins. That can be done in  $\binom{33}{11}$  ways. Each of the remaining 22 coins can be given either to  $A$  or to  $B$ , which gives  $2^{22}$  ways. Using the rule of product we obtain the result  $\binom{33}{11} \cdot 2^{22}$ . □

**1.G.17.** In how many ways can we divide 40 identical balls among 4 boys?

**Solution.** Let us add three matches to the 40 balls. If we order the balls and matches in a row, the matches divide the balls in 4 sections. We order the boys at random, give the first boy all the balls from the first section, give the second boy all the balls from the second section and so on. It is now evident that the result is  $\binom{43}{3} = 12\,341$ . □

**1.G.18.** According to quality, we divide food products into groups  $I, II, III, IV$ . Determine the number of all possible divisions of 9 food products into these groups, such that the numbers of products in groups are all distinct.

**Solution.** If we directly write the considered groups from the elements of  $I, II, III, IV$ , we create combinations of repetitions of the ninth-order from four elements. The number of such combinations is  $\binom{12}{9} = 220$ . □

**1.G.19.** In how many ways could the table of the first soccer league ended, if we know only that at least one of the teams Ostrava, Olomouc is in the table after the team of Brno (there are 16 teams in the league).

**Solution.** Let us first determine the three places where the teams of Brno, Olomouc and Ostrava ended. Those can be chosen in  $c(3, 16) = \binom{16}{3}$  ways. From 6 possible orderings of these three teams on the given three places only four satisfy the given condition. After that, we can independently choose the order of the remaining 13 teams at the remaining places of the table. Using the rule of product, we have the solution

$$\binom{16}{3} \cdot 4 \cdot 13! = 13948526592000. \quad \square$$

**1.G.20.** How many distinct orderings (in a row) at a picture of a volleyball team (6 players), if

- i) Gouald and Bamba want to stand next to each other;
- ii) Gouald and Bamba want to stand next to each other and in the middle;
- iii) Gouald and Kamil do not want to stand next to each other.

**Solution.**

- i) In this case Gouald and Bamba can be considered a single person, we just multiply then by two to determine their relative order. Thus we have  $2 \cdot 5! = 240$  orderings.
- ii) Here it is similar except that the position of Gouald and Bamba is fixed. We have  $2 \cdot 4! = 48$  orderings.
- iii) Probably the simplest approach is to subtract the cases where Kamil and Gouald stand next to each other (see (i)). We get  $6! - 2 \cdot 5! = 720 - 240 = 480$ . □

**1.G.21.** Coin flipping. We flip a coin six times.

- i) How many distinct sequences of heads and tails are there?
- ii) How many sequences with exactly four heads are there?
- iii) How many sequences with at least two heads are there? ○

**1.G.22.** How many distinct anagrams (rearrangements of letters) of the word “krakatit”, such that between the letters “k” there is exactly one other letter.

**Solution.** In the considered anagrams there are exactly six possibilities of placement of the group two “k”, since the first of the two “k” can be placed at any of the positions 1 – 6. If we fix the spots for the two “k”, then the other letters can be placed arbitrarily, that is, in  $P(1, 1, 2, 2)$  ways. Using the rule of product, we have

$$6 \cdot P(1, 1, 2, 2) = \frac{6 \cdot 6!}{2 \cdot 2} = 1080. \quad \square$$

**1.G.23.** How many anagrams of the word BASILICA are there, such that there are no two vowels next to each other and no two consonants next to each other?

**Solution.** Since there are four vowels and four consonants in the word, each such anagram is either of the type *BABABABA* or *ABABABAB*. On the given four places we can permute vowels in  $P_o(2, 2) = \frac{4!}{2!2!}$  ways and independently of that also the consonants ( $4!$  ways). Using the rule of product, the result is then  $2 \cdot 4! \cdot \frac{4!}{2!2!} = 288$ . □

**1.G.24.** In how many ways can we divide 9 girls and 6 boys into two group such that each group contains at least two boys?

**Solution.** We divide the boys and the girls independently:  $2^9(2^5 - 7) = 12800$ . □

**1.G.25.** Material is composed of five layers, each of them has fibres in one of the possible six directions. How many of such materials are there? How many of them have no two neighbouring layers which have fibres in the same direction?

**Solution.**  $6^5$  and  $6 \cdot 5^5$ . □

**1.G.26.** For any fixed  $n \in \mathbb{N}$  determine the number of all solutions to the equation

$$x_1 + x_2 + \dots + x_k = n$$

in the set of positive integers.

**Solution.** If we look for a solution in the domain of positive integers, then we note that the natural numbers  $x_1, \dots, x_k$  are a solution to the equation if and only if the non-negative integers  $y_i = x_i - 1, i = 1, \dots, k$  are a solution to the equation

$$y_1 + y_2 + \dots + y_k = n - k.$$

Using 1.C.13, there are  $\binom{n-1}{k-1}$  of them. □

**1.G.27.** There are  $n$  forts on a circle ( $n \geq 3$ ), numbered in a row with numbers  $1, \dots, n$ . In one moment of time each of the forts shoots at one of its neighbours (fort 1 neighbours also with the fort  $n$ ). Denote by  $P(n)$  the number of all possible results of the shooting (a result of the shooting is a set of numbers of those forts that were hit, regardless of the number of hits taken). Prove that  $P(n)$  and  $P(n + 1)$  are relatively prime.

**Solution.** If we denote the forts that were hit by a black dot and the unhit by a white dot, the task is equivalent to the task to determine the number of all possible colourings of  $n$  dots on a circle with black and white colour, such that no two white dots have “distance” one. For odd  $n$  this number is equal to  $K(n) - 1$  – the number of colourings with black and white, such that no two white dots are adjacent (we reorder the dots such that we start with the dot one and proceed increasingly with odd numbers, and then increasingly with even). For even  $n$  this number equals  $K(n/2)^2$ , the square of the colouring of  $n/2$  dots on a circle such that no two white are adjacent (we colour independently the dots on even positions and on odd positions).

For  $K(n)$  we easily derive a recurrent formula  $K(n) = K(n - 1) + K(n - 2)$ . Furthermore, we can easily compute that  $K(2) = 3$ ,  $K(3) = 4$ ,  $K(4) = 7$ , that is,  $K(2) = F(4) - F(0)$ ,  $K(3) = F(5) - F(1)$ ,  $K(4) = F(6) - F(2)$ , and using induction we can easily prove that  $K(n) = F(n + 2) - F(n - 2)$ , where  $F(n)$  denotes the  $n$ -th member of the Fibonacci sequence ( $F(0) = 0$ ,  $F(1) = F(2) = 1$ ). Since  $(K(2), K(3)) = 1$ , we have for  $n \geq 3$  similarly as in the Fibonacci sequence  $(K(n), K(n - 1)) = (K(n) - K(n - 1), K(n - 1)) = (K(n - 2), K(n - 1)) = \dots = 1$ .

Let us now show that for every even  $n = 2a$  is  $P(n) = K(a)^2$  relatively prime with both  $P(n + 1) = K(2a + 1)$  and  $P(n - 1) = K(2a - 1)$ . For this the following is enough: for  $a \geq 2$  we have

$$\begin{aligned} (K(a), K(2a + 1)) &= (K(a), F(2)K(2a) + F(1)K(2a - 1)) = (K(a), F(3)K(2a - 1) + F(2)K(2a - 2)) = \dots \\ &= (K(a), F(a + 1)K(a + 1) + F(a)K(a)) = (K(a), F(a + 1)) = (F(a + 2) - F(a - 2), F(a + 1)) \\ &= (F(a + 2) - F(a + 1) - F(a - 2), F(a + 1)) = (F(a) - F(a - 2), F(a + 1)) \\ &= (F(a - 1), F(a + 1)) = (F(a - 1), F(a)) = 1, \text{ and} \\ (K(a), K(2a - 1)) &= (K(a), F(2)K(2a - 2) + F(1)K(2a - 3)) = (K(a), F(3)K(2a - 3) + F(2)K(2a - 4)) \\ &= \dots = (K(a), F(a)K(a) + F(a - 1)K(a - 1)) = (K(a), F(a - 1)) = (F(a + 2) - F(a - 2), F(a - 1)) \\ &= (F(a + 2) - F(a), F(a - 1)) = (F(a + 2) - F(a + 1), F(a - 1)) = (F(a), F(a - 1)) = 1. \end{aligned}$$

This proves the claim. □

**1.G.28.** How much money do I save in a building savings in five years, if I invest in it 3000 Kč monthly (at the first day of the month), the yearly interest rate is 3% and once a year I obtain a state donation of 1500 Kč (this donation comes at first of May)?

**Solution.** Let  $x_n$  be the amount of money at the account after  $n$  years. Then (for  $n > 2$ ) we obtain the following recurrent formula (assuming that every month is exactly one twelfth of a year)

$$x_{n+1} = 1.03 x_n + 36000 + 1500 + \underbrace{0.03 \cdot 3000 \left(1 + \frac{11}{12} + \dots + \frac{1}{12}\right)}_{\text{interests from deposits this year}} + \underbrace{0.03 \cdot \frac{2}{3} \cdot 1500}_{\text{interest from the state donation credited at this year}} = 1.03 x_n + 38115.$$

Therefore

$$x_n = 38115 \sum_{i=0}^{n-2} (1.03)^i + (1.03)^{n-1} x_1 + 1500,$$

while  $x_1 = 36000 + 0.03 \cdot 3000 \left(1 + \frac{11}{12} + \dots + \frac{1}{12}\right) = 36585$ , in total

$$x_5 = 38115 \left( \frac{(1.03)^4 - 1}{0.03} \right) + (1.03)^4 \cdot 36585 + 1500 \doteq 202136. \quad \square$$

**Remark.** In reality, interests are computed according to the number of days the money is on the account. You should obtain a real bank statement of a building savings, determine its interest rates and try to compute the credited interests in a year. Compare the result with the sum that was credited in reality. Compute until the numbers agree ...

**1.G.29.** What is the maximum number of areas the plane can be divided into by  $n$  circles?

**Solution.** For the maximum number  $p_n$  of areas we derive a recurrent formula

$$p_{n+1} = p_n + 2n.$$

Note that the  $(n + 1)$ -th circle intersects  $n$  previous circles in at most  $2n$  points (and this can really occur)

ADDING THE THIRD CIRCLE

Clearly  $p_1 = 2$ . Thus for  $p_n$  we obtain

$$\begin{aligned} p_n &= p_{n-1} + 2(n-1) = p_{n-2} + 2(n-2) + 2(n-1) = \dots \\ &= p_1 + \sum_{i=1}^{n-1} 2i = n^2 - n + 2. \end{aligned}$$

□

**1.G.30.** What is the maximum number of areas a 3-dimensional space can be divided into by  $n$  planes?

**Solution.** Let the number be  $r_n$ . We see that  $r_0 = 1$ . Similarly to the exercise (1.B.4) we consider  $n$  planes in the space, we add another plane and we ask what is the maximum number of new areas. Again it is exactly the number of areas the new plane intersects. How many can that be? The number of areas intersected by the  $(n + 1)$ -th plane equals to the number of areas the new  $(n + 1)$ -th plane is divided into by the lines of intersection with the  $n$  planes that were already situated in the space. However, there are at most  $1/2 \cdot (n^2 + n + 2)$  of those (according to the exercise in plane), thus we obtain the recurrent formula

$$r_{n+1} = r_n + \frac{n^2 + n + 2}{2}.$$

This equation can be again solved directly:

$$\begin{aligned} r_n &= r_{n-1} + \frac{(n-1)^2 + (n-1) + 2}{2} = r_{n-1} + \frac{n^2 - n + 2}{2} \\ &= r_{n-2} + \frac{(n-1)^2 - (n-1) + 2}{2} + \frac{n^2 - n + 2}{2} \\ &= r_{n-2} + \frac{n^2}{2} + \frac{(n-1)^2}{2} - \frac{n}{2} - \frac{(n-1)}{2} + 1 + 1 \\ &= r_{n-3} + \frac{n^2}{2} + \frac{(n-1)^2}{2} + \frac{(n-3)^2}{2} - \frac{n}{2} - \frac{(n-1)}{2} - \frac{(n-2)}{2} \\ &\quad + 1 + 1 + 1 \\ &= \dots = r_0 + \frac{1}{2} \sum_{i=1}^n i^2 - \frac{1}{2} \sum_{i=1}^n i + \sum_{i=1}^n 1 \\ &= 1 + \frac{n(n+1)(2n+1)}{12} - \frac{n(n+1)}{4} + n = \end{aligned}$$

$$= \frac{n^3 + 6n + 5}{6},$$

where we have used the known relation

$$\sum_{i=1}^n i^2 = \frac{n(n+1)(2n+1)}{6},$$

which can be easily proved by mathematical induction. □

**1.G.31.** What is the maximum number of areas a 3-dimensional space can be divided into by  $n$  balls? ○

**1.G.32.** What is the number of areas a 3-dimensional space is divided into by  $n$  mutually distinct planes which all intersect a given point?

**Solution.** For the number  $x_n$  of areas we derive a recurrent formula

$$x_n = x_{n-1} + 2(n-1),$$

furthermore  $x_1 = 2$ , that is,

$$x_n = n(n-1) + 2.$$

□

**1.G.33.** From a deck of 52 cards we randomly draw 16 cards. Express the probability that we choose exactly 10 red and 6 black cards.

**Solution.** We first realize that we don't have to care about the order of the cards. (In the resulting fraction we would obtain ordered choices by multiplying by  $16!$  both nominator and denominator.) The number of all possible (unordered) choices of 16 cards from 52 is  $\binom{52}{16}$ . Similarly, the number of all choices of 10 cards from 26 is equal to  $\binom{26}{10}$  and of 6 cards from 26 is  $\binom{26}{6}$ . Since we are choosing independently 10 cards from 26 red and 6 cards from 26 black, using the (combinatorial) rule of product we obtain the result

$$\frac{\binom{26}{10} \cdot \binom{26}{6}}{\binom{52}{16}} \doteq 0.118.$$

□

**1.G.34.** In a box there are 7 white, 6 yellow and 5 blue balls. We draw (without returning) 3 balls randomly. Determine the probability that exactly 2 of them are white.

**Solution.** In total there are  $\binom{7+6+5}{3}$  ways, how to choose 3 balls. Choosing exactly two white allows  $\binom{7}{2}$  choices of two white balls and simultaneously  $\binom{11}{1}$  choices for the third ball. Using the rule of product is the number of ways how to choose exactly two white equal to  $\binom{7}{2} \cdot \binom{11}{1}$ . Thus the result is

$$\frac{\binom{7}{2} \cdot 11}{\binom{18}{3}} \doteq 0.283.$$

□

**1.G.35.** When throwing a dice, eleventh times in a row the result was 4. Determine the probability that the twelfth roll results in 4.

**Solution.** The previous results (according to our assumptions) do not influence the result of further rolls. Thus the probability is  $1/6$ . □

**1.G.36.** From a deck of 32 cards we randomly draw 6 cards. What is the probability that all of them have the same colour?

**Solution.** In order to obtain the result

$$\frac{4 \cdot \binom{8}{6}}{\binom{32}{6}} \doteq 1.234 \cdot 10^{-4},$$

we just first choose one of the 4 colours and realize that there are  $\binom{8}{6}$  ways how to choose 6 cards from 8 cards of this colour. □

**1.G.37.** Three players are given 10 cards each and two remain (from a deck of 32 cards, where 4 of them are aces). Is it more likely, that somebody receives seven, eight and nine of spades; or that two aces remain?

**Solution.** Since the probability that some of the players receives the three mentioned cards equals

$$3 \frac{\binom{29}{7}}{\binom{32}{10}},$$

while the probability that two aces remain equals

$$\frac{\binom{4}{2}}{\binom{32}{2}},$$

it is more likely that some of the players receives the three mentioned cards. Let us note that proving the inequality

$$\frac{3 \cdot \binom{29}{7}}{\binom{32}{10}} > \frac{\binom{4}{2}}{\binom{32}{2}}$$

is possible by transforming both sides, where by repetitive crossing-out (after expanding the binomial coefficients according to their definition) we easily obtain  $6 > 1$ . □

**1.G.38.** We throw  $n$  dice. What is the probability that among the numbers that appeared the values 1, 3 and 6 are not present?

**Solution.** We can reformulate the exercise that we throw the dice  $n$  times. The probability that the first roll does not result into 1, 3 or 6 is  $1/2$ . The probability that neither the first nor the second roll is clearly  $1/4$  (the result of the first roll does not influence the result of the second roll). Since the event determined by the result of a given roll and event determined by the result of another roll are always (stochastically) independent, the probability is  $1/2^n$ . □

**1.G.39.** Two friends are shooting independently of each other at one target – one shoots, then the second shoots, then the first, and so on. The probability that the first hits is 0.4, the second friend has the probability of hitting 0.3. Determine the probability  $P$  of the event that after shooting there will be exactly one hit of the target.

**Solution.** We determine the result by summing the probabilities of two mutually exclusive events – first friend hit the target and the second has not; and second friend hit the target and first has not. Since the events of hitting are independent (note that independence is preserved when taking complements) is the probability given by the product of the probabilities of given elementary elements. That is,

$$P = 0.4 \cdot (1 - 0.3) + (1 - 0.4) \cdot 0.3 = 0.46. \quad \square$$

**1.G.40.** We flip three coins twelve times. What is the probability that at least one flipping results in three tails?

**Solution.** If we realize that when repeating the flipping, the individual results are independent, and denote for  $i \in \{1, \dots, 12\}$  by  $A_i$  the event „the  $i$ -th flipping results in three tails“, we are determining

$$P\left(\bigcup_{i=1}^{12} A_i\right) = 1 - (1 - P(A_1)) \cdot (1 - P(A_2)) \cdots (1 - P(A_{12})).$$

For every  $i \in \{1, \dots, 12\}$  is  $P(A_i) = 1/8$ , since at every coin of the three the tail is with the probability  $1/2$  independently of the results of the other coins. Now we can write the final probability

$$1 - \left(\frac{7}{8}\right)^{12}. \quad \square$$

**1.G.41.** In a particular state there is a parliament with 200 members. Two major political parties in this state flip a coin during an “election” for every seat in the parliament. Each of the parties has associated one side of the coin. What is the probability that each of the parties gains 100 seats? (The coin is “fair”.)

**Solution.** There are  $2^{200}$  of possible results of the elections (considered to be sequences of 200 results of flips). If each party is to obtain 100 seats, then there are exactly 100 tails and 100 heads in the sequence. There are  $\binom{200}{100}$  such sequences (since

the sequence is uniquely determined by choosing 100 members of 200 possible, which will result in, say, tails). The resulting probability is

$$\frac{\binom{200}{100}}{2^{200}} = \frac{200!}{100! \cdot 100!} \doteq 0.056.$$

□

**1.G.42.** Seven Czechs and five English are randomly divided into two (nonempty) groups. What is the probability that one group consists of Czechs only?

**Solution.** There are  $2^{12} - 1$  of possible divisions. If one group consists of Czechs only, it means that all English are in one group (either in the first or in the second). It remains to divide the Czechs into two nonempty groups, that can be done in  $2^7 - 1$  ways. In the end we must add 1 for the division which puts all English in one group and all Czechs in another,

$$\frac{2 \cdot (2^7 - 1) + 1}{2^{12} - 1}$$

□

**1.G.43.** From ten cards, where exactly one is an ace, we randomly draw a card and put it back. How many times must we do this, so that the probability that the ace is drawn at least once, is greater than 0.9?

**Solution.** Let  $A_i$  be the event „at  $i$ -th drawing the ace was drawn“. Since the individual events  $A_i$  are (stochastically) independent, we know that

$$P\left(\bigcup_{i=1}^n A_i\right) = 1 - (1 - P(A_1)) \cdot (1 - P(A_2)) \cdots (1 - P(A_n))$$

for every  $n \in \mathbb{N}$ . We are looking for an  $n \in \mathbb{N}$  such that it holds that

$$P\left(\bigcup_{i=1}^n A_i\right) = 1 - (1 - P(A_1)) \cdot (1 - P(A_2)) \cdots (1 - P(A_n)) > 0.9.$$

Clearly is  $P(A_i) = 1/10$  for any  $i \in \mathbb{N}$ . Thus it is enough to solve the equation

$$1 - \left(\frac{9}{10}\right)^n > 0.9,$$

from which we can express

$$n > \frac{\log_a 0.1}{\log_a 0.9}, \quad \text{kde } a > 1.$$

Evaluating, we obtain that we must do the drawing at least twenty two times.

□

**1.G.44. Texas hold'em.** Let us now solve a couple of simple exercises concerning the popular card game Texas hold'em, whose rules we will not state (if the reader does not know them, she can look them up on the Internet). What is the probability that

- i) the starting combination is a tuple of the same symbols?
- ii) in my starting tuple of cards there is an ace?
- iii) in the end I have one of the six best combinations of cards?
- iv) I win, if I hold in my hand ace and a triple of twos (of any colour), on the flop there is ace and two twos and on the turn there is a third three and all these four cards have distinct colour? (The last card river is not yet turned)

**Solution.**

- i) The number of distinct symbols is 13 and there are always four of them (one of each colour). Thus the number of tuples with the same symbols is  $13 \binom{4}{2} = 78$ . The number of all possible tuples is  $\binom{13 \cdot 4}{2} = 1326$ . The probability of having same symbols is then  $\frac{1}{17} \doteq 0.06$ .
- ii) One card is the ace, that is four choices, and the second is arbitrary, that is 51 choices. But we have counted twice the tuples with two aces, of which there are  $\binom{4}{2} = 6$ . Thus we obtain  $4 \cdot 51 - 6 = 198$  tuples and the probability is  $\frac{198}{1326} \doteq 0.15$ .

iii) Let us compute the probabilities of the individual best combinations:

ROYAL FLUSH: There are exactly only four such combinations – one of each colours. The number of combinations of five cards are  $\binom{52}{5} = 2598960$ . The probability is thus equal to  $1.5 \cdot 10^{-6}$ . Very small :)

STRAIGHT FLUSH: Sequence which ends with the highest card in the range 6 to K, that is eight choices for every colours. We obtain  $\frac{32}{2598960} \doteq 1.2 \cdot 10^{-5}$ .

POKER: Four identical symbols – 13 choices (for every symbol one). The fifth card can be arbitrary, that is 48 choices. That makes  $\frac{624}{2598960} \doteq 2.4 \cdot 10^{-4}$ .

FULL HOUSE: Three identical symbols make  $13\binom{4}{3} = 52$  choices and two identical symbols make  $12\binom{4}{2} = 72$  choices. The probability is  $\frac{3744}{2598960} \doteq 1.4 \cdot 10^{-3}$ .

FLUSH: All five cards of the same colour means  $4\binom{13}{5} = 5148$  choices and the probability is then  $\frac{5148}{2598960} \doteq 2 \cdot 10^{-3}$ .

STRAIGHT: The highest card of the sequence is in the range from 6 to Ace, that is 9 choices. The colour of every card is arbitrary, that makes  $9 \cdot 4^5 = 9216$  choices. But we have counted both straight flush and royal flush which we must subtract.

For determining the probability of one of the six best combinations we don't have to do that, we just do not count the first two combinations. Therefore we obtain the probability approximately  $3.5 \cdot 10^{-3} + 2 \cdot 10^{-3} + 1.4 \cdot 10^{-3} + 2.4 \cdot 10^{-4} = 7.14 \cdot 10^{-3}$ .

iv) The situation is clearly pretty good and therefore it will be better to count bad situation, that is, when the opponent has even better combination. I have at this moment full house of two aces and three two's. The only combination that could beat me at this moment is either full house of three aces and two twos or a poker of twos. That means that the enemy must have either the ace or the last two. If he has the two and any other card, then he clearly wins no matter what card is river. How many ways are there for this other card in his hand?  $3 + 4 + \dots + 4 + 2 = 45$  (one triple and two aces cannot be in his hand since I have them). There are  $\binom{46}{2} = 1035$  remaining combination and the probability of such loss is then 0.043. If he has an ace in his hand, then the following can happen. If he holds two aces, then he again wins if two is not on the river – then I would have split poker. The probability of my (conditional) loss is then  $\frac{1}{1035} \cdot \frac{43}{44} \doteq 10^{-3}$ . If the enemy has in his hand ace and some other card than 2 and A, then it is a draw no matter what is on the river. The total probability of the win is thus almost 96 %.

□

**1.G.45.** A volleyball team (with libero, that is, 7 people) sits after a match in a pub and drinks beer. But there is not enough mugs, and thus the publican keeps using the same seven. What is the probability that

- i) exactly one person does not receive the mug he had last round,
- ii) nobody receives the mug he had last round,
- iii) exactly three receive the mug they had last round.

**Solution.**

- i) If six people receive the mug they had last round, then clearly the seventh person also receives the mug he had last round, the probability is thus zero.
- ii) Let  $M$  is the set of all orderings and event  $A_i$  occurs when the  $i$ -th person receives his mug from last round. We want to calculate  $|M - \cup_i A_i|$ . We obtain  $7! \sum_{k=0}^7 \frac{(-1)^k}{k!} = 1854$ . And the probability is  $\frac{1854}{5040} = \frac{103}{280} \doteq 0.37$ .
- iii) We choose which three receive the mug they had last round –  $\binom{7}{3} = 35$  choices. The remaining four must receive mugs from somebody else. That is again the formula from the previous section, specifically it is  $4! \sum_{k=0}^4 \frac{(-1)^k}{k!} = 9$  choices. In total we have  $9 \cdot 35 = 315$  choices and the probability is  $\frac{315}{5040} = \frac{1}{16}$ .

□

**1.G.46.** In how many ways can we place  $n$  identical rooks on a chessboard  $n \times n$  such that every non-occupied position is threatened by some of the rooks?

**Solution.** Such placements are a union of two sets: the set of placements where in at least one row there is one rook (therefore in every row there is exactly one; this set has  $n^n$  elements – in every row we choose independently one position for the rook), and the set of placements where in every column there is at least one (that is exactly one) rook (as before, this set has  $n^n$  elements). The intersection of these sets has  $n!$  elements (the places for the rooks are chosen sequentially starting in the first row – there we have  $n$  choices, in the second only  $n - 1$  – one column is already occupied. . .). Using the inclusion-exclusion principle, we obtain

$$2n^n - n!.$$

□

**1.G.47.** Determine the probability that when throwing two dice at least one resulted in four, if the sum is 7.

**Solution.** We solve this exercise using the classical probability, where the condition is interpreted as restriction of the probability space. The space has due to the condition 6 elements, and exactly 2 of those are favourable to the given event. The answer is thus  $2/6 = 1/3$ .

□

**1.G.48.** We throw two dice. Determine the conditional probability, that the first die resulted in five under the condition that the sum is 9. Based on this result, decide whether the events “first dice results in five” and “the sum is 9” are independent.

**Solution.** If we denote the event “first dice resulted in five” by  $A$  and the event “the sum is 9” by  $H$ , then it holds

$$P(A|H) = \frac{P(A \cap H)}{P(H)} = \frac{\frac{1}{36}}{\frac{4}{36}} = \frac{1}{4}.$$

Note that the sum 9 occurs when the first die is 3 and the second 6, the first is 4 and the second 6, the first is 5 and the second is 4, or the first is 6 and the second is 3. Of those four results (that have the same probability) only one is favourable to the event  $A$ . Since the probability of  $A$  is clearly  $1/6 \neq 1/4$ , the events are not mutually independent.

□

**1.G.49.** Let us have a deck of 32 cards. If we draw twice one card, what is the probability that the second drawn card is an ace, if we return the first card; and when we don't return the first card (then there are 31 cards in the deck).

**Solution.** If we return the card in the deck, we are just repeating the experiment, which has 32 possible results (which have the same probability), and exactly four of them are favourable. Thus we see that the probability is  $1/8$ . In the second case when we do not return the card, is probability also the same. It is enough to consider that when drawing all the cards one by one is the probability of the ace as the first card identical to the probability that the ace is the second card. We could also use conditional probability, that results into

$$\frac{4}{32} \cdot \frac{3}{31} + \frac{28}{32} \cdot \frac{4}{31} = \frac{1}{8}.$$

□

**1.G.50.** Consider families with two children and for simplicity assume that all choices in the set  $\Omega = \{bb, bg, gb, gg\}$ , where  $b$  stands for „boy“ and  $g$  stands for „girl“ (considering the age of the children) have the same probability. Choose random events

$$H_1 - \text{family has a boy}, \quad A_1 - \text{family has two boys}.$$

Compute  $P(A_1|H_1)$ .

Similarly consider families with three children, where

$$\Omega = \{bbb, bbg, bgb, gbb, bgg, gbg, ggb, ggg\}.$$

If

$$H_2 - \text{the family has both boy and girl}, \quad A_2 - \text{the family has at most one girl},$$

decide whether the events  $A_2$  and  $H_2$  are independent.

**Solution.** Considering which of the four elements of the set  $\Omega$  are (not) favourable to the event  $A_1$  or  $H_1$ , we easily obtain

$$P(A_1|H_1) = \frac{P(A_1 \cap H_1)}{P(H_1)} = \frac{P(A_1)}{P(H_1)} = \frac{\frac{1}{4}}{\frac{3}{4}} = \frac{1}{3}.$$

Further we have to determine whether the following holds:

$$P(A_2 \cap H_2) = P(A_2) \cdot P(H_2).$$

Again we just have to realize that exactly the elements  $bbb, bbg, bgb, gbb$  of the set  $\Omega$ , are favourable to the event  $A_2$ ; to the event  $H_2$  the elements  $bbg, bgb, gbb, bgg, gbg, ggb$  are favourable and to the event  $A_2 \cap H_2$  the elements  $bbg, bgb, gbb$ . Therefore

$$P(A_2 \cap H_2) = \frac{3}{8} = \frac{4}{8} \cdot \frac{6}{8} = P(A_2) \cdot P(H_2),$$

which means that the events  $A_2$  and  $H_2$  are independent. □

**1.G.51.** We flip a coin five times. For every head, we put a white ball in a hat, for every tail we put in the same hat a black ball. Express the probability that in the hat there is more black balls than white balls, if there is at least one black ball in the hat.

**Solution.** Let us have the following two events

$A$  – there are more black balls than white balls in the hat,

$H$  – there is at least one black ball in the hat.

We want to express  $P(A|H)$ . Note that the probability  $P(H^C)$  of the complementary event to the event  $H$  is  $2^{-5}$  and that the probability of the event is the same as the probability  $P(A^C)$  of the complementary event (there are more white balls in the hat). Necessarily,  $P(H) = 1 - 2^{-5}$ ,  $P(A) = 1/2$ . Furthermore  $P(A \cap H) = P(A)$ , since the event  $H$  contains the event  $A$  (the event  $A$  has  $H$  as a consequence). Thus we have obtained

$$P(A|H) = \frac{P(A \cap H)}{P(H)} = \frac{\frac{1}{2}}{1 - (\frac{1}{2})^5} = \frac{16}{31}. \quad \square$$

**1.G.52.** In a box there are 9 red and 7 white balls. Sequentially we draw three balls (without returning). Determine the probability that the first two are red and the third is white.

**Solution.** We solve this exercise using the theorem about multiplication of probabilities. First we require a red ball, that happens with the probability  $9/16$ . If a red ball was drawn, then in the second round we draw a red ball with the probability  $8/15$  (there are 15 balls in the box, 8 of them are red). Finally, if two red balls were drawn, the probability that a white ball is drawn is  $7/14$  (there are 7 white balls and 7 red balls in the box). Thus we obtain

$$\frac{9}{16} \cdot \frac{8}{15} \cdot \frac{7}{14} = 0.15. \quad \square$$

**1.G.53.** In the box there are 10 balls, 5 of them are black and 5 are white. We will sequentially draw the balls, and we do not return them back. Determine the probability that first we draw a white ball, then a black, then a white and in the last, fourth turn again a white.

**Solution.** We use the theorem about multiplication of probabilities. In the first round we draw a white ball with the probability  $5/10$ , then a black ball with probability  $5/9$ , then a white ball with probability  $4/8$  and in the end a white ball with probability  $3/7$ . That gives

$$\frac{5}{10} \cdot \frac{5}{9} \cdot \frac{4}{8} \cdot \frac{3}{7} = \frac{5}{84}. \quad \square$$

**1.G.54.** From a deck of 32 cards we randomly draw six cards. Compute the probability that the first king will be chosen as the sixth card (that is, the previous five cards do not contain any king).

**Solution.** Using the theorem about multiplication of probabilities we have

$$\frac{28}{32} \cdot \frac{27}{31} \cdot \frac{26}{30} \cdot \frac{25}{29} \cdot \frac{24}{28} \cdot \frac{4}{27} \doteq 0.0723. \quad \square$$

**1.G.55.** What is the probability that a sum of two randomly chosen positive numbers smaller than 1 is smaller than  $3/7$ ?

**Solution.** It is clear that it is a simple exercise on geometrical probability where the basic space  $\Omega$  is a square with vertices at  $[0, 0]$ ,  $[1, 0]$ ,  $[1, 1]$ ,  $[0, 1]$  (we are choosing two numbers in  $[0, 1]$ ). We are interested in the probability of the event that a randomly chosen point  $[x, y]$  in this square satisfies  $x + y < 3/7$ , that is, the probability that the point lies in the triangle  $A$  with vertices at  $[0, 0]$ ,  $[3/7, 0]$ ,  $[0, 3/7]$ . Now we can easily compute

$$P(A) = \frac{\text{vol } A}{\text{vol } \Omega} = \frac{(\frac{3}{7})^2/2}{1} = \frac{9}{98}. \quad \square$$

**1.G.56.** Let a pole be randomly broken into three parts. Determine the probability that the length of the second (middle) part is greater than two thirds of the length of the pole before the breaking.

**Solution.** Let  $d$  stand for the length of the pole. The breaking of the pole at two points is given by the choice of the points where we split the pole. Let  $x$  be the point which is the first (closer to left end of the pole), and  $x + y$  be the point where the second splitting occurs. That says that the basic space is the set  $\{[x, y]; x \in (0, d), y \in (0, d - x)\}$ , that is, a triangle with vertices at  $[0, 0]$ ,  $[d, 0]$ ,  $[0, d]$ . The length of the middle part is given by the value of  $y$ . The condition from the exercise statement can be now restated as  $y > 2d/3$ , which corresponds to the triangle with vertices at  $[0, 2d/3]$ ,  $[d/3, 2d/3]$ ,  $[0, d]$ . Areas of the considered triangles are  $d^2/2$  a  $(d/3)^2/2$ , therefore the probability is

$$\frac{\frac{d^2}{3^2 \cdot 2}}{\frac{d^2}{2}} = \frac{1}{9}. \quad \square$$

**1.G.57.** A pole of length 2 m is randomly divided into three parts. Determine the probability of the event that the third part is shorter than 1, 5 m.

**Solution.** This exercise is for using the geometrical probability, where we are looking for the probability that the sum of the lengths of the first two parts is greater than one fourth of the length of the pole. We determine the probability of the complementary event, that is, the probability that if we randomly choose two points on the pole, both of them are in the first quarter of the pole. The probability of this event is  $1/4^2$ , since the probability of picking a point in the first quarter of the pole is clearly  $1/4$  and this choice is independently repeated (once). Thus the probability of the complementary event is  $15/16$ .  $\square$

**1.G.58.** Mirek and Marek have a lunch at the school canteen. The canteens opens from 11 to 14. Each of them eats the lunch for 30 minutes, and the arrival time is random. What is the probability that they meet at a given day, if they always sit at the same table?

**Solution.** The space of all possible events is a square  $3 \times 3$ . Denote by  $x$  the arrival time of Mirek and by  $y$  the arrival time of Marek, these two meet if and only if  $|x - y| \leq 1/2$ . This inequality determines in the square of possible events the area whose volume is  $11/36$  of the volume of the whole square. Thus that is also the probability of the event.  $\square$

**1.G.59.** From Brno Honza rides a car to Prague randomly between 12 and 16, and in the same time interval Martin rides a car to Brno from Prague. Both stop in a motorest in the middle of the trip for thirty minutes. What is the probability that they meet there, if Honza's speed is 150 km/h and Martin's is 100 km/h? (The distance Praha-Brno is 200 km).

**Solution.** If we denote the departure time of Martin by  $x$  and the departure time of Honza by  $y$ , and in order to have fewer fractions in the following calculations choose a time unit to be ten minutes, then the base space is a square  $24 \times 24$ . The arrival time of Martin to the motorest is  $x + 6$ , arrival time of Honza is  $y + 4$ . As in the previous exercise, the event that they meet in the motorest is equivalent to the event that their arrival times do not differ by more than thirty minutes, that is,  $|(x + 6) - (y + 4)| \leq 3$ . This condition determines an area with volume  $24^2 - \frac{1}{2}(23^2 + 19^2)$  (see the figure)

and the probability

$$p = \frac{24^2 - \frac{1}{2}(23^2 + 19^2)}{24^2} = \frac{131}{576} \doteq 0.227.$$

□

**1.G.60.** Mirek departs randomly between 10 and 20 o'clock from Brno to Prague. Marek departs randomly in the same interval from Prague to Brno. The trip takes 2 hours. What is the probability that they meet on the road (they use the same road)?

**Solution.** We are solving analogously to the previous exercise. The space of all events is a square  $10 \times 10$ , Mirek, departing at the time  $x$ , meets Marek, departing at the time  $y$  if and only if  $|x - y| \leq 2$ . The probability is  $p = \frac{36}{100} = \frac{9}{25} = 0.36$ .

□

**1.G.61.** Two meter-long pole is randomly divided into three pieces. Determine the probability that a triangle can be built of the pieces.

**Solution.** Division of the pole is given as in the previous exercises by the points of cutting  $x$  and  $y$  and the probability space is again a square  $2 \times 2$ . In order to be able to build a triangle of the pieces, the lengths of the parts must satisfy the triangle inequalities, that is, sum of lengths of any two parts must be greater than the length of the third part. Since the sum of the lengths is 2 meters, this condition is equivalent to the condition that each part must be smaller than 1 meter. Using the cut-points  $x$  and  $y$ , we can express this that it cannot simultaneously hold  $x \leq 1$  and  $y \leq 1$  or simultaneously  $x \geq 1$  and  $y \geq 1$  (this corresponds to the conditions that the border parts of the pole are smaller than 1), and also  $|x - y| \leq 1$  (the middle part is smaller than one). These conditions are satisfied by the shaded area in the picture, whose volume is  $1/4$ .

□

**1.G.62.** Do the equations

- (a)  $4x_1 - \sqrt{3}x_2 = 3,$   
 $x_1 - 2\sqrt{7}x_2 = -2;$
- (b)  $4x_1 - \sqrt{3}x_2 = 16,$   
 $x_1 - 2\sqrt{7}x_2 = -7;$
- (c)  $4x_1 + 2x_2 = 7,$   
 $-2x_1 - x_2 = -3$

have a unique solution (that is, exactly one)?

**Solution.** The set of equation is uniquely solvable if and only if the determinant of the matrix given by the left-hand side coefficients is nonzero. Therefore, the coefficients on the right-hand side do not influence the uniqueness of the solution. Thus we have to have the same answer in (a) and (b). Since

$$\begin{vmatrix} 4 & -\sqrt{3} \\ 1 & -2\sqrt{7} \end{vmatrix} = 4 \cdot (-2\sqrt{7}) - (-\sqrt{3} \cdot 1) \neq 0,$$

$$\begin{vmatrix} 4 & 2 \\ -2 & -1 \end{vmatrix} = 4 \cdot (-1) - (2 \cdot (-2)) = 0,$$

for (a) and (b) there is a unique solution and in (c) there is not. If we multiply the second equation in (c) by  $-2$ , we see that it has no solution at all. □

**1.G.63.** Determine  $A \cdot A$  for

$$A = \begin{pmatrix} \cos \varphi & -\sin \varphi \\ \sin \varphi & \cos \varphi \end{pmatrix}, \quad \text{where } \varphi \in \mathbb{R}.$$

**Solution.** We know that the mapping

$$\begin{pmatrix} x \\ y \end{pmatrix} \mapsto \begin{pmatrix} \cos \varphi & -\sin \varphi \\ \sin \varphi & \cos \varphi \end{pmatrix} \cdot \begin{pmatrix} x \\ y \end{pmatrix}, \quad x, y \in \mathbb{R}$$

is the rotation of the plane  $\mathbb{R}^2$  around the origin through the angle  $\varphi$  in the positive direction. Since matrix multiplication is associative, we obtain that the mapping

$$\begin{pmatrix} x \\ y \end{pmatrix} \mapsto \begin{pmatrix} \cos \varphi & -\sin \varphi \\ \sin \varphi & \cos \varphi \end{pmatrix} \cdot \begin{pmatrix} \cos \varphi & -\sin \varphi \\ \sin \varphi & \cos \varphi \end{pmatrix} \cdot \begin{pmatrix} x \\ y \end{pmatrix}, \quad x, y \in \mathbb{R}$$

is a rotation through the angle  $2\varphi$ . That means that

$$A \cdot A = \begin{pmatrix} \cos 2\varphi & -\sin 2\varphi \\ \sin 2\varphi & \cos 2\varphi \end{pmatrix}.$$

Note that we could have directly multiplied  $A \cdot A$  (and apply the formulas for sine and cosine of double angle). But repeating the aforementioned method (or using the mathematical induction) yields

$$A^n = \begin{pmatrix} \cos n\varphi & -\sin n\varphi \\ \sin n\varphi & \cos n\varphi \end{pmatrix}, \quad n = 2, 3, \dots,$$

easier (we set  $A^2 = A \cdot A$ ,  $A^3 = A \cdot A \cdot A$ , etc.). □

**1.G.64. The parallelogram identity.** The calculation in coordinates can be useful in plane geometry. Let us demonstrate this on the proof “parallelogram identity”: if  $u, v \in \mathbb{R}^2$ , then:

$$2(\|u\|^2 + \|v\|^2) = \|u + v\|^2 + \|u - v\|^2.$$

Thus the sum of the squares of the diagonals of a parallelogram is the sum of the squares of the lengths of the four sides of the parallelogram.

**Solution.** Writing both sides of the equation into the coordinates  $u = (u_1, u_2)$ ,  $v = (v_1, v_2)$  yields:

$$\begin{aligned} & \|u + v\|^2 + \|u - v\|^2 \\ &= (u_1 + v_1)^2 + (u_2 + v_2)^2 + (u_1 - v_1)^2 + (u_2 - v_2)^2 \\ &= u_1^2 + 2u_1v_1 + v_1^2 + u_2^2 + 2u_2v_2 + v_2^2 + \\ & \quad + u_1^2 - 2u_1v_1 + v_1^2 + u_2^2 - 2u_2v_2 + v_2^2 \\ &= 2(u_1^2 + u_2^2 + v_1^2 + v_2^2) \\ &= 2(\|u\|^2 + \|v\|^2). \end{aligned}$$

□

**1.G.65.** Compute the area  $S$  of a quadrilateral given by the vertices

$$[0, -2], \quad [-1, 1], \quad [1, 5], \quad [1, -1].$$

**Solution.** In the usual notation

$$A = [0, -2], \quad B = [1, -1], \quad C = [1, 5], \quad D = [-1, 1]$$

and the usual division of the quadrilateral into triangles  $ABC$  and  $ACD$  with areas  $S_1$  and  $S_2$  we obtain

$$S = S_1 + S_2 = \frac{1}{2} \begin{vmatrix} 1-0 & 1-0 \\ -1+2 & 5+2 \end{vmatrix} + \frac{1}{2} \begin{vmatrix} 1-0 & -1-0 \\ 5+2 & 1+2 \end{vmatrix} = \frac{1}{2}(7-1) + \frac{1}{2}(3+7) = 8.$$

□

**1.G.66.** Determine the area of the quadrilateral  $ABCD$  with vertices  $A = [1, 0]$ ,  $B = [11, 13]$ ,  $C = [2, 5]$  and  $D = [-2, -5]$ .

**Solution.** We divide the quadrilateral into two triangles  $ABC$  and  $ACD$ . We compute their areas by computing absolute values of the determinants, see 1.5.11,

$$S = \left| \frac{1}{2} \cdot \begin{vmatrix} 1 & 5 \\ 10 & 13 \end{vmatrix} \right| + \left| \frac{1}{2} \cdot \begin{vmatrix} 1 & 5 \\ -3 & -5 \end{vmatrix} \right| = \frac{47}{2}.$$

□

**1.G.67.** Compute the area of parallelogram with vertices at  $[5, 5]$ ,  $[6, 8]$  and  $[6, 9]$ .

**Solution.** Although such parallelogram is not uniquely determined (the fourth vertex is not given), the triangle with vertices at  $[5, 5]$ ,  $[6, 8]$  and  $[6, 9]$  must be necessarily a half of every parallelogram with these three vertices (one of the sides of the triangle becomes the diagonal of the parallelogram). Therefore the area equals the determinant

$$\begin{vmatrix} 6-5 & 6-5 \\ 8-5 & 9-5 \end{vmatrix} = \begin{vmatrix} 1 & 1 \\ 3 & 4 \end{vmatrix} = 1 \cdot 4 - 1 \cdot 3 = 1.$$

□

**1.G.68.** Give the area of a meadow, which is determined on the area map by the points at positions  $[-7, 1]$ ,  $[-1, 0]$ ,  $[29, 0]$ ,  $[25, 1]$ ,  $[24, 2]$  and  $[17, 5]$ . (Ignore the measurement units. They are determined by the ratio of the area map to the reality.)

**Solution.** The given hexagon can be divided into four triangles with vertices at

$$\begin{aligned} & [-7, 1], [-1, 0], [17, 5]; & [-1, 0], [24, 2], [17, 5]; \\ & [-1, 0], [25, 1], [24, 2]; & [-1, 0], [29, 0], [25, 1]. \end{aligned}$$

The areas are 24,  $89/2$ ,  $27/2$  and 15 respectively, which gives the total area as

$$24 + 44 \frac{1}{2} + 13 \frac{1}{2} + 15 = 97.$$

□

**1.G.69.** Determine the area of a triangle  $A_2A_3A_{11}$ , where  $A_0A_1 \dots A_{11}$  are the vertices of a regular dodecagon inscribed in a circle of radius 1.

**Solution.** The vertices of the dodecagon can be identified with the twelfth roots of 1 in the complex plane. As in ?? we find out  $A_2 = \cos(\pi/3) + i \sin(\pi/3) = 1/2 + i\sqrt{3}/2$ ,  $A_3 = \cos(\pi/2) + i \sin(\pi/2) = i$ ,  $A_{11} = \cos(-\pi/6) + i \sin(-\pi/6) = \sqrt{3}/2 - i/2$ , that means the that the coordinates of these points in the complex plane are  $A_2 = [1/2, \sqrt{3}/2]$ ,  $A_3 = [0, 1]$ ,  $A_{11} = [\sqrt{3}/2, -\frac{1}{2}]$ . According to the formula for the area of a triangle, the area of the triangle  $S$  is

$$S = \frac{1}{2} \begin{vmatrix} A_2 - A_{11} \\ A_3 - A_{11} \end{vmatrix} = \frac{1}{2} \begin{vmatrix} \frac{1}{2} - \frac{\sqrt{3}}{2} & \frac{1}{2} + \frac{\sqrt{3}}{2} \\ -\frac{\sqrt{3}}{2} & \frac{3}{2} \end{vmatrix} = \frac{3 - \sqrt{3}}{4}.$$

□

**1.G.70.** Determine which sides of the quadrilateral with vertices  $A = [95, 99]$ ,  $B = [130, 106]$ ,  $C = [40, 60]$ ,  $D = [130, 120]$ , are visible from the point  $[2, 0]$ . ○

**1.G.71.** Determine the number of relations over the set  $\{1, 2, 3, 4\}$ , which are both symmetric and transitive.

**Solution.** Relations of the given properties is an equivalence over some subset of the set  $\{1, 2, 3, 4\}$ . In total,  $1 + 4 \cdot 1 + \binom{4}{2} \cdot 2 + \binom{4}{3} \cdot 5 + 15 = 52$ . □

**1.G.72.** Determine the number of ordering relations over a three-element set. ○

**1.G.73.** Determine the number of ordering relations over the set  $\{1, 2, 3, 4\}$  such that the elements 1 and 2 are not comparable (that is, neither  $1 \prec 2$  nor  $2 \prec 1$ , where  $\prec$  stands for the ordering relation). ○

**1.G.74.** Determine the number of surjective mappings  $f$  from the set  $\{1, 2, 3, 4, 5\}$  to the set  $\{1, 2, 3\}$  such that  $f(1) = f(2)$ .

**Solution.** Every such mappings is uniquely given by the images of the elements  $\{1, 3, 4, 5\}$ , there are exactly that many mappings as there are surjective mappings of the set  $\{1, 3, 4, 5\}$  to the set  $\{1, 2, 3\}$ , that is, 36, as we know from the previous exercise. □

**1.G.75.** Give all the elements in  $S \circ R$ , if

$$R = \{(2, 4), (4, 4), (4, 5)\} \subset \mathbb{N} \times \mathbb{N},$$

$$S = \{(3, 1), (3, 2), (3, 5), (4, 1), (4, 4)\} \subset \mathbb{N} \times \mathbb{N}.$$

**Solution.** Considering all choices of two ordered tuple

$$(2, 4), (4, 1); \quad (2, 4), (4, 4); \quad (4, 4), (4, 1); \quad (4, 4), (4, 4)$$

satisfying that the second element of the first ordered tuple—which is a member of  $R$ —equals the first element of the second ordered tuple—which is a member of  $S$ —we obtain

$$S \circ R = \{(2, 1), (2, 4), (4, 1), (4, 4)\}.$$

□

**1.G.76.** Let a binary relation be given

$$R = \{(0, 4), (-3, 0), (5, \pi), (5, 2), (0, 2)\}$$

between sets  $A = \mathbb{Z}$  a  $B = \mathbb{R}$ . Express  $R^{-1}$  and  $R \circ R^{-1}$ .

**Solution.** We can immediately see that

$$R^{-1} = \{(4, 0), (0, -3), (\pi, 5), (2, 5), (2, 0)\}.$$

Furthermore,

$$R \circ R^{-1} = \{(4, 4), (0, 0), (\pi, \pi), (2, 2), (4, 2), (\pi, 2), (2, \pi), (2, 4)\}.$$

□

**1.G.77.** Decide whether the relation  $R$  determined by the condition:

(a)  $(a, b) \in R \iff |a| < |b|$ ;

(b)  $(a, b) \in R \iff |a| = |2b|$

over the set of integers  $\mathbb{Z}$  is transitive.

**Solution.** In the first case  $R$  is transitive, because

$$|a| < |b|, |b| < |c| \implies |a| < |c|.$$

In the second case  $R$  is not transitive. For instance, consider

$$(4, 2), (2, 1) \in R, \quad (4, 1) \notin R.$$

□

**1.G.78.** Find all relations over  $M = \{1, 2\}$ , which are not antisymmetric. Which of them are transitive?

**Solution.** There are four relations that are not antisymmetric. They are exactly subsets of the set  $\{1, 2\} \times \{1, 2\}$ , which contain the elements  $(1, 2), (2, 1)$  (otherwise the condition of antisymmetry is satisfied). Of these four only the relation

$$\{(1, 1), (1, 2), (2, 1), (2, 2)\} = M \times M,$$

is transitive, because not containing tuples  $(1, 1)$  and  $(2, 2)$  in a transitive relation means that the relation cannot contain both  $(1, 2)$  and  $(2, 1)$ . □

**1.G.79.** We have a set  $\{3, 4, 5, 6, 7\}$ . Write explicitly the relations

i)  $a$  divides  $b$ ,

ii) Either  $a$  divides  $b$  or  $b$  divides  $a$ ,

iii)  $a$  and  $b$  have a common divisor greater than one,

and examine their properties. ○

**1.G.80.** Is there an equivalence relation, which is also an ordering, over the set of all lines in the plane?

**Solution.** An equivalence relation (or ordering relation) must be reflexive, therefore every line must be in relation with itself. Furthermore we require that the relation is both symmetric (equivalence) and antisymmetric (ordering). That means that a line can be in relation only with itself. If we define the relation such that two lines are in relation if and only if they are identical, we obtain “very natural” relation which is both equivalence relation and ordering. We just need to check that it is transitive, which it trivially is. Thus the only relation satisfying the problem statement is the identity over the set of all lines in the plane. □

**1.G.81.** Determine whether the relation

$$R = \{(k, l) \in \mathbb{Z} \times \mathbb{Z}; |k| \geq |l|\}$$

over the set  $\mathbb{Z}$  is an equivalence and/or an ordering.

**Solution.** The relation  $R$  is not an equivalence: it is not symmetric (take  $(6, 2) \in R, (2, 6) \notin R$ ); it is not an ordering: it is not antisymmetric (take  $(2, -2) \in R, (-2, 2) \in R$ ). □

**1.G.82.** Show that the intersection of any equivalence relation over a set  $X$  is again an equivalence relation, and that the union of two ordering relations over a set  $X$  does not have to be an ordering.

**Solution.** We see that the intersection of equivalence relations is reflexive, symmetric and transitive: all the equivalence relations must contain the tuple  $(x, x)$  for every  $x \in X$ , therefore the intersection contains that tuple too. If the element  $(x, y)$  is in the intersection, then the element  $(y, x)$  is also in the intersection (just use the fact that every equivalence is symmetric). If tuples  $(x, y)$  and  $(y, z)$  are in the intersection, then both are in the equivalences also. Since the equivalences are transitive, they all contain the element  $(x, z)$  and thus that element is also in the intersection.

If we chose  $X = \{1, 2\}$  and the ordering relation

$$R_1 = \{(1, 1), (2, 2), (1, 2)\}, \quad R_2 = \{(1, 1), (2, 2), (2, 1)\}$$

over  $X$ , we obtain the relation

$$R_1 \cup R_2 = \{(1, 1), (2, 2), (1, 2), (2, 1)\},$$

which is not antisymmetric, thus not an ordering. □

**1.G.83.** Over the set  $M = \{1, 2, \dots, 19, 20\}$  there is an equivalence relation  $\sim$  such that  $a \sim b$  for any  $a, b \in M$  if and only if the first digits of the numbers  $a, b$  are the same. Construct the partition given by this equivalence.

**Solution.** Two numbers from the set  $M$  are in the same equivalence class if and only if they are in the relation (first digit is the same). Therefore the partition consists of the sets

$$\{1, 10, 11, \dots, 18, 19\}, \{2, 20\}, \{3\}, \{4\}, \{5\}, \{6\}, \{7\}, \{8\}, \{9\}.$$
□

**1.G.84.** We are given partition of two classes  $\{b, c\}, \{a, d, e\}$  of the set  $X = \{a, b, c, d, e\}$ . Write down the equivalence relation  $R$  over the set  $X$  which gives this partition.

**Solution.** Equivalence  $R$  is determined by the fact that the two elements are in relation if and only if they are in the same partition class (note also that  $R$  must be symmetric), and every element is in relation with itself ( $R$  must be reflexive). Therefore  $R$  contains exactly

$$(a, a), (b, b), (c, c), (d, d), (e, e), \\ (b, c), (c, b), (a, d), (a, e), (d, a), (d, e), (e, a), (e, d).$$
□

**1.G.85.** Let  $\{a, b, c, d\}$  be a set with a relation

$$\{(a, a), (b, b), (a, b), (b, c), (c, b)\}.$$

What is the minimal number of elements we have to add to the relation in order to make it an equivalence?

**Solution.** Let us successively ensure the three properties that define an equivalence. First it is the reflexivity. We must add the tuples  $\{(c, c), (d, d)\}$ . Second is the symmetry – we must add  $(b, a)$  and for the third step we must do the so-called transitive closure. Since  $a$  is in relation with  $b$  and  $b$  is in relation with  $c$ , we must add  $(a, c)$  and  $(c, a)$ . □

**1.G.86.** What is the maximal domain  $D \subseteq \mathbb{R}$  and codomain  $H \subseteq \mathbb{R}$  such that the following mappings are bijective, and what is then the inverse function?

i)  $x \mapsto x^4$

ii)  $x \mapsto x^3$

iii)  $x \mapsto \frac{1}{x+1}$

**Solution.**

i)  $D = [0, \infty)$  and  $H = [0, \infty)$  or also  $D = (-\infty, 0]$  a  $H = [0, \infty)$ . The inverse function is then  $x \mapsto \sqrt[4]{x}$ .

ii)  $D = H = \mathbb{R}$  and the inverse function is  $x \mapsto \sqrt[3]{x}$ .

iii)  $D = \mathbb{R} \setminus \{-1\}$  and  $H = \mathbb{R} \setminus \{0\}$ . The inverse function is  $x \mapsto \frac{1}{x} - 1$ . □

**1.G.87.** Consider a relation  $\mathbb{R} \times \mathbb{R}$ . A point is in the relation whenever it holds that

$$(x - 1)^2 + (y + 1)^2 = 1.$$

Can we describe the points using the function  $y = f(x)$ ? Depict the points in the relation.

**Solution.** We cannot, because for instance  $y = -1$  has two preimages:  $x = 0$  and  $x = 2$ . The points lie on a circle with the centre at the point  $(1, -1)$  and radius 1. □

**1.G.88.** Let for any two integers  $k, l$  hold that  $(k, l) \in R$  whenever the number  $4k - 4l$  is an integral multiple of 7. Is such a relation over  $R$  an equivalence? Is it an ordering?

**Solution.** Note that two integers are in the relation  $R$  if and only if they have the same remainder under the division by 7. Therefore it is an example of the so-called remainder class of integers. Therefore we know that the relation  $R$  is an equivalence relation. Its symmetry (for instance,  $(3, 10), (10, 3) \in R, 3 \neq 10$ ) implies that it is not an ordering.  $\square$

**1.G.89.** Let a relation  $R$  be defined over the set  $N = \{3, 4, 5, \dots, n, n + 1, \dots\}$ , such that two numbers are in the relation whenever they are relatively prime (that is, the prime decompositions of the numbers do not contain any common number). Determine whether this relation is reflexive, symmetric, antisymmetric, transitive.

**Solution.** For a tuple of the same numbers it holds that  $(n, n) \notin R$ . Therefore the relation is not reflexive. It is clear that when two numbers are relatively prime or not, it does not matter how they are ordered – it is a property of unordered tuples. Therefore,  $R$  is symmetric. From the symmetry we have that it is not antisymmetric (for instance,  $(3, 5) \in R, 3 \neq 5$ ). Since  $R$  is symmetric and  $(n, n) \notin R$  for any number  $n \in N$ , a choice of two distinct numbers which are in the relation gives that  $R$  is not transitive.  $\square$

**1.G.90.** Determine the number of injective mappings of the set  $\{1, 2, 3\}$  to the set  $\{1, 2, 3, 4\}$ .

**Solution.** Any injective mapping among the given sets is given by choosing an (ordered) triple from the set  $\{1, 2, 3, 4\}$  (the elements in the chosen triple will correspond in order to images of the numbers 1, 2, 3) and vice versa. Every injective mapping gives such a triple. Thus the number of injective mappings equals the number of ordered triples among four elements, that is  $v(3, 4) = 4 \cdot 3 \cdot 2 = 24$ .  $\square$

**1.G.91.** How many relations are there over an  $n$ -element set?

**Solution.** A relation is an arbitrary subset of the cartesian product of the set with itself. This cartesian product has  $n^2$  elements, thus the number of all relations over an  $n$ -element set is  $2^{n^2}$ .  $\square$

**1.G.92.** How many reflexive relations are there over an  $n$ -element set?

**Solution.** The relation over the set  $M$  is reflexive if and only if it has the diagonal relation  $\Delta_M = \{(a, a), \text{ all } a \in M\}$  as a subset. As for the rest of the  $n^2 - n$  ordered pairs in the cartesian product  $M \times M$ , we have independent choice, whether or not the pair belongs to the relation. In total we have  $2^{n^2 - n}$  different reflexive relations over an  $n$ -element set.  $\square$

**1.G.93.** How many symmetric relations are there over an  $n$ -element set?

**Solution.** A relation  $R$  over the set  $M$  is symmetric if and only if the intersection of  $R$  with each  $\{(a, b), (b, a), \text{ where } a \neq b, a, b \in M\}$  is either the whole two-element set or is empty. There are  $\binom{n}{2}$  two-element subsets of the set  $M$ . If we also declare what the intersection of  $R$  and the diagonal relation  $\Delta_M = \{(a, a), \text{ where } a \in M\}$  should be, then  $R$  is completely determined. In total we are to do  $\binom{n}{2} + n$  independent choices between two alternatives: each set of the type  $\{(a, b), (b, a) \mid \text{where } a, b \in M, a \neq b\}$  is either the subset of  $R$  or it is disjoint with  $R$ . Every pair  $(a, a), a \in M$  is either in  $R$  or not. In total we have  $2^{\binom{n}{2} + n}$  symmetric relations over an  $n$ -element set.  $\square$

**1.G.94.** How many anti-symmetric relations over an  $n$ -element set are there?

**Solution.** A relation  $R$  over the set  $M$  is anti-symmetric if and only if the intersection of  $R$  with each set  $\{(a, b), (b, a)\}, a \neq b, a, b \in M$  is either empty or one-element (which means that it is either  $\{(a, b)\}$  or  $\{(b, a)\}$  but not both). The intersection of  $R$  with the diagonal relation is arbitrary. By declaring what these intersections are, the relation  $R$  is completely determined. In total we have  $3^{\binom{n}{2}} 2^n$  anti-symmetric relations over an  $n$ -element set.  $\square$

**1.G.95.** Determine the number of ordering relations of the set  $\{1, 2, 3, 4, 5\}$  such that exactly two pairs of element are incomparable.  $\circ$

**Solution to the exercises**

**1.B.3.**  $y_n = 2\left(\frac{3}{2}\right)^n - 2$ .

**1.G.21.**

i)  $2^6 = 64$

ii)  $\binom{6}{4} = 15$

iii) No head is one possibility  $\binom{6}{0} = 1$ , one head is  $\binom{6}{1} = 6$ . Thus there are 7 sequences with at most one head and the result is  $64 - 7 = 57$ .

**1.G.31.** The maximum number  $y_n$  of areas a plane can be divided into by  $n$  circles is  $y_n = y_{n-1} + 2(n-1)$ ,  $y_1 = 2$ , that is,  $y_n = n^2 - n + 2$ .

For the maximum number  $p_n$  of areas a space can be divided into by  $n$  balls we obtain the recurrent formula  $p_{n+1} = p_n + y_n$ ,  $p_1 = 2$ , that is,  $p_n = \frac{n}{3}(n^2 - 3n + 8)$ .

**1.G.70.** First, we orient the vertices of the given quadrangle in the counter-clockwise order:  $ABCD$ . After computing the corresponding determinants as in the previous exercises we see that only the side  $CB$  is visible.

**1.G.72.** 19.

**1.G.73.** 87.

**1.G.79.**

i)  $(3, 3), (4, 4), (5, 5), (6, 6), (7, 7), (3, 6)$ , check that it is an ordering relation.

ii) again  $(i, i)$  for  $i = 1, \dots, 7$  and additionally  $(3, 6), (6, 3)$ , check that it is an equivalence relation.

iii)  $(i, i)$  for  $i = 1, \dots, 7$  and also  $(3, 6), (6, 3), (4, 6), (6, 4)$ . Check that it is not an equivalence, since transitivity does not hold.

**1.G.95.** Three different Hasse diagrams which satisfy the given condition. In total  $5! + 5! + 5!/4 = 270$ .

## Elementary linear algebra

*Can't you count with scalars yet?*

*– no worry, let us go straight to matrices...*

### A. Vectors and matrices

Before we approach vector spaces in a systematic way, we begin with something we know – systems of linear equations. Step by step we shall see that the vector spaces are hidden behind them and we get used to the matrix calculus on the

way.

**2.A.1. A colourful example.** A company of painters orders 810 litres of paint, to contain 270 litres each of red, green and blue coloured paint. The provider can satisfy this order

In the previous chapter we warmed up by considering relatively simple problems which did not require any sophisticated tools. It was enough to use addition and multiplication of scalars. In this and subsequent chapters we shall add more sophisticated thoughts and tools.

First we restrict ourselves to concepts and operations consisting of a finite number of multiplications and additions to a finite number of scalars. This will take us three chapters and only then will we move on to infinitesimal concepts and tools. Typically we deal with finite collections of scalars of a given size. We speak about “linear objects” and “linear algebra”. Although it might seem to be a very special tool, we shall see later that even more complicated objects are studied mostly using their “linear approximations”.

In this chapter we will work with finite sequences of scalars. Such sequences arise in real-world problems whenever we deal with objects described by several parameters, which we shall call coordinates. Do not try much to imagine the space with more than three coordinates. You have to live with the fact that we are able to depict only one, two or three dimensions. However, we will deal with an arbitrary number of dimensions. For example, observing any parameter in a group of 500 students (for instance, their study results), our data will have 500 elements and we would like to work with them. Our goal is to develop tools which will work well even if the number of elements is large.

Do not be afraid of terms like field or ring of scalars  $\mathbb{K}$ . Simply, imagine any specific domain of numbers. Rings of scalars are for instance integers  $\mathbb{Z}$  and all residue classes  $\mathbb{Z}_k$ . Among fields we have seen only  $\mathbb{R}$ ,  $\mathbb{Q}$ ,  $\mathbb{C}$  and residue classes  $\mathbb{Z}_k$  for  $k$  prime.  $\mathbb{Z}_2$  is very specific among them, because the equation  $x = -x$  does not imply  $x = 0$  here, whereas in every other field it does.

### 1. Vectors and matrices

In the first two parts of this chapter, we will work with vectors and matrices in the simple context of finite sequences of scalars. We can imagine working with integers or residue classes as well as real or complex numbers. We hope to illustrate how easily a concise and formal reasoning can lead to strong results valid in a much broader context than just for real numbers.

by mixing the colours he usually sells (he has enough in his warehouse). He has

- reddish colour – it contains 50 % of red, 25 % of green and 25 % of blue colour;
- greenish colour – it contains 12,5 % of red, 75 % of green and 12,5 % of blue colour;
- bluish colour – it contains 20 % of red, 20 % of green and 60 % of blue colour.

How many litres of each of the colours at the warehouse have to be mixed in order to satisfy the order?

**Solution.** Denote by

- $x$  – the number of litres of reddish colour to be used;
- $y$  – the number of litres of bluish colour to be used;
- $z$  – the number of litres greenish colour to be used;

By mixing the colours we want a colour that contains 270 litres of red. Note that reddish contains 50 % red, greenish contains 12,5 % red and bluish 20 % red. Thus the following has to be satisfied:

$$0,5x + 0,125y + 0,2z = 270.$$

Similarly, we require (for blue and green colours respectively) that

$$\begin{aligned} 0,25x + 0,75y + 0,2z &= 270, \\ 0,25x + 0,125y + 0,6z &= 270. \end{aligned}$$

From the first equation  $x = 540 - 0,25y - 0,4z$ . Substitute for  $x$  into the second and third equations to obtain two linear equations of two variables  $2,75y + 0,4z = 540$  and  $0,25y + 2z = 540$ . From the second of these we express  $z = 270 - 0,125y$  and substitute into the first one we obtain  $2,7y = 432$ , that is,  $y = 160$ . Therefore  $z = 270 - 0,125 \cdot 160 = 250$  and hence  $x = 540 - 0,25 \cdot 160 + 0,4 \cdot 250 = 400$ .

An alternative approach is to deduce consequences from the given equations by a sequence of adding them or multiplying them by non-zero scalars. This is easily handled in the matrix notation (which we met when solving equations with two variables in the previous chapter already). The first row of the matrix consists of coefficients of the variables in the first equation, second of the coefficients in the second equation and third of the coefficients in the third. Therefore the *matrix of the system* is

$$\begin{pmatrix} 0,5 & 0,125 & 0,2 \\ 0,25 & 0,75 & 0,2 \\ 0,25 & 0,125 & 0,6 \end{pmatrix},$$

The *extended matrix of the system* is obtained from the matrix of the system by inserting the column of the right-hand sides

Later, we follow the general terminology where the notion of vectors is related to fields of scalars only.

**2.1.1. Vectors over scalars.** For now, a *vector* is for us an ordered  $n$ -tuple of scalars from  $\mathbb{K}$ , where the fixed  $n \in \mathbb{N}$  is called *dimension*.

We can add and multiply scalars. We will be able to add vectors, but multiplying a vector will be possible only by a scalar. This corresponds to the idea we have already seen in the plane  $\mathbb{R}^2$ . There, addition is realized as vector composition (as composition of arrows having their direction and size and compared when emanating from the origin). Multiplication by scalar is realized as stretching the vectors.

A vector  $u = (a_1, \dots, a_n)$  is multiplied by a scalar  $c$  by multiplying every element of the  $n$ -tuple  $u$  by  $c$ . Addition is defined coordinate-wise.

BASIC VECTOR OPERATIONS

$$\begin{aligned} u + v &= (a_1, \dots, a_n) + (b_1, \dots, b_n) \\ &= (a_1 + b_1, \dots, a_n + b_n) \\ c \cdot u &= c \cdot (a_1, \dots, a_n) = (c \cdot a_1, \dots, c \cdot a_n). \end{aligned}$$

For vector addition and multiplication by scalars we shall use the same symbols as for scalars, that is, respectively, plus and either dot or juxtaposition, i.e.,  $cu = c(a_1, \dots, a_n) = (ca_1, \dots, ca_n)$ .

**The vector notation convention.** We shall not, unlike many other textbooks, use any special notations for vectors and leave it to the reader to pay attention to the context. For scalars, we shall mostly use letters from the beginning of the alphabet, for the vectors from the end of the alphabet. The middle part of the alphabet can be used for indices of variables or components and also for summation indices.

In the general theory in the end of this chapter and later, we will work exclusively with fields of scalars when talking about vectors. Now we will work with the more relaxed properties of scalars as listed in 1.1.1.

For vector addition in  $\mathbb{K}^n$ , the properties (CG1)–(CG4) (see 1.1.1) clearly hold with the zero element being (notice we define the addition coordinate-wise)  $0 = (0, \dots, 0) \in \mathbb{K}^n$ . We are purposely using the same symbol for both the zero vector element and the zero scalar element. Next, let us notice the following basic properties of vectors:

VECTOR PROPERTIES

For all vectors  $v, w \in \mathbb{K}^n$  and scalars  $a, b \in \mathbb{K}$  we have

- (V1)  $a \cdot (v + w) = a \cdot v + a \cdot w$
- (V2)  $(a + b) \cdot v = a \cdot v + b \cdot v$
- (V3)  $a \cdot (b \cdot v) = (a \cdot b) \cdot v$
- (V4)  $1 \cdot v = v$

of the individual equations in the system:

$$\left( \begin{array}{ccc|c} 0,5 & 0,125 & 0,2 & 270 \\ 0,25 & 0,75 & 0,2 & 270 \\ 0,25 & 0,125 & 0,6 & 270 \end{array} \right)$$

By doing elementary row transformations sequentially (they all correspond to adding rows and multiplication by scalars with the equations, see 2.1.7) we can eliminate the variables in the equations, one by one:

$$\left( \begin{array}{ccc|c} 0,5 & 0,125 & 0,2 & 270 \\ 0,25 & 0,75 & 0,2 & 270 \\ 0,25 & 0,125 & 0,6 & 270 \end{array} \right) \sim \left( \begin{array}{ccc|c} 1 & 0,25 & 0,4 & 540 \\ 1 & 3 & 0,8 & 1080 \\ 1 & 0,5 & 2,4 & 1080 \end{array} \right) \sim$$

$$\left( \begin{array}{ccc|c} 1 & 0,25 & 0,4 & 540 \\ 0 & 2,75 & 0,4 & 540 \\ 0 & 0,25 & 2 & 540 \end{array} \right) \sim \left( \begin{array}{ccc|c} 1 & 0,25 & 0,4 & 540 \\ 0 & 11 & 1,6 & 2160 \\ 0 & 1 & 8 & 2160 \end{array} \right) \sim$$

$$\left( \begin{array}{ccc|c} 1 & 0,25 & 0,4 & 540 \\ 0 & 1 & 8 & 2160 \\ 0 & 11 & 1,6 & 2160 \end{array} \right) \sim \left( \begin{array}{ccc|c} 1 & 0,25 & 0,4 & 540 \\ 0 & 1 & 8 & 2160 \\ 0 & 0 & -86,4 & -21600 \end{array} \right).$$

By back substitution, we compute successively

$$z = \frac{-21600}{-86,4} = 250,$$

$$y = 2160 - 8 \cdot 250 = 160,$$

$$x = 540 - 0,4 \cdot 250 - 0,25 \cdot 160 = 400.$$

Thus it is necessary to mix 400 litres of reddish, 160 litres of bluish and 250 litres of greenish colour.  $\square$

**2.A.2.** Solve the system of simultaneous linear equations

$$\begin{aligned} x_1 + 2x_2 + 3x_3 &= 2, \\ 2x_1 - 3x_2 - x_3 &= -3, \\ -3x_1 + x_2 + 2x_3 &= -3. \end{aligned}$$

**Solution.** We write the system of equations in the form of the extended matrix of the system

$$\left( \begin{array}{ccc|c} 1 & 2 & 3 & 2 \\ 2 & -3 & -1 & -3 \\ -3 & 1 & 2 & -3 \end{array} \right).$$

Every row of the matrix corresponds to one equation. As in the previous example, equivalent transformation of the equations correspond to the elementary row operations on the matrix and we use them to transform it into the row echelon form

$$\begin{aligned} \left( \begin{array}{ccc|c} 1 & 2 & 3 & 2 \\ 2 & -3 & -1 & -3 \\ -3 & 1 & 2 & -3 \end{array} \right) &\sim \left( \begin{array}{ccc|c} 1 & 2 & 3 & 2 \\ 0 & -7 & -7 & -7 \\ 0 & 7 & 11 & 3 \end{array} \right) \sim \\ &\sim \left( \begin{array}{ccc|c} 1 & 2 & 3 & 2 \\ 0 & 1 & 1 & 1 \\ 0 & 0 & 4 & -4 \end{array} \right) \sim \left( \begin{array}{ccc|c} 1 & 2 & 3 & 2 \\ 0 & 1 & 1 & 1 \\ 0 & 0 & 1 & -1 \end{array} \right). \end{aligned}$$

First we subtracted from the second row twice the first row, and to the third row we added three times the first row. Then

The properties (V1)–(V4) of our vectors are easily checked for any specific ring of scalars  $\mathbb{K}$ , since we need just the corresponding properties of scalars as listed in 1.1.1 and 1.1.5, applied to individual components of the vectors. In this way we shall work with, for instance,  $\mathbb{R}^n$ ,  $\mathbb{Q}^n$ ,  $\mathbb{C}^n$ , but also with  $\mathbb{Z}^n$ ,  $(\mathbb{Z}_k)^n$ ,  $n = 1, 2, 3, \dots$

**2.1.2. Matrices over scalars.** Matrices are slightly more complicated objects, useful when working with vectors.

MATRICES OF TYPE  $m/n$

A matrix of the type  $m/n$  over scalars  $\mathbb{K}$  is a rectangular schema  $A$  with  $m$  rows and  $n$  columns

$$A = \begin{pmatrix} a_{11} & a_{12} & \dots & a_{1n} \\ a_{21} & a_{22} & \dots & a_{2n} \\ \vdots & & & \vdots \\ a_{m1} & a_{m2} & \dots & a_{mn} \end{pmatrix}$$

where  $a_{ij} \in \mathbb{K}$  for all  $1 \leq i \leq m$ ,  $1 \leq j \leq n$ . For a matrix  $A$  with elements  $a_{ij}$  we also use the notation  $A = (a_{ij})$ .

The vector  $(a_{i1}, a_{i2}, \dots, a_{in}) \in \mathbb{K}^n$  is called the ( $i$ -th) row of the matrix  $A$ ,  $i = 1, \dots, m$ . The vector  $(a_{1j}, a_{2j}, \dots, a_{mj}) \in \mathbb{K}^m$  is called the ( $j$ -th) column of the matrix  $A$ ,  $j = 1, \dots, n$ .

Matrices of the type  $1/n$  or  $n/1$  are actually just vectors in  $\mathbb{K}^n$ .

All general matrices can be understood as vectors in  $\mathbb{K}^{mn}$ , we just consider all the columns. In particular, matrix addition and matrix multiplication by scalars is defined:

$$A + B = (a_{ij} + b_{ij}), \quad a \cdot A = (a \cdot a_{ij})$$

where  $A = (a_{ij})$ ,  $B = (b_{ij})$ ,  $a \in \mathbb{K}$ .

The matrix  $-A = (-a_{ij})$  is called the *additive inverse* to the matrix  $A$  and the matrix

$$0 = \begin{pmatrix} 0 & \dots & 0 \\ \vdots & & \vdots \\ 0 & \dots & 0 \end{pmatrix}$$

is called the *zero matrix*. By considering matrices as  $mn$ -dimensional vectors, we obtain the following:

**Proposition.** The formulas for  $A+B$ ,  $a \cdot A$ ,  $-A$ ,  $0$  define the operations of addition and multiplication by scalars for the set of all matrices of the type  $m/n$ , which satisfy properties (V1)–(V4).

**2.1.3. Matrices and equations.** Many mathematical models are based on systems of linear equations. Matrices are useful for the description of such systems. In order to see this, let us introduce the notion of *scalar product* of two vectors, assigning to the vectors  $(a_1, \dots, a_n)$  and  $(x_1, \dots, x_n)$  their product

$$(a_1, \dots, a_n) \cdot (x_1, \dots, x_n) = a_1x_1 + \dots + a_nx_n.$$

This means, we multiply the corresponding coordinates of the vectors and sum the results.

we added the second row to the third row and multiplied the second row by  $-1/4$ . Now we restore the system of equations

$$\begin{aligned} x_1 + 2x_2 + 3x_3 &= 2, \\ x_2 + x_3 &= 1, \\ x_3 &= -1. \end{aligned}$$

We see immediately that  $x_3 = -1$ . If we substitute  $x_3 = -1$  into the equation  $x_2 + x_3 = 1$ , we obtain  $x_2 = 2$ . Then by substituting  $x_3 = -1$ ,  $x_2 = 2$  into the first equation, we obtain  $x_1 = 1$ .  $\square$

Systems of linear equations can be written in matrix notation. But is it an advantage, when we can solve the systems even without speaking about matrices? Yes it is, we can handle the equations more conceptually. We can easily decide how many solutions a system has. It is much more efficient in computer assisted computations. Thus we shall get familiar with various operations which can be done with matrices. As we have seen in previous examples, equivalent operations with linear equations correspond to elementary row (column) transformations. Further we have seen that transforming a matrix into a row echelon form, a process called Gaussian elimination, see 2.1.7), solves the system very easily. We demonstrate this on some examples, where we will see that a system can have infinitely many solutions or no solution at all.

**2.A.3.** Solve a system of linear equations

$$\begin{aligned} 2x_1 - x_2 + 3x_3 &= 0, \\ 3x_1 + 16x_2 + 7x_3 &= 0, \\ 3x_1 - 5x_2 + 4x_3 &= 0, \\ -7x_1 + 7x_2 + -10x_3 &= 0. \end{aligned}$$

**Solution.** Because the right-hand side of all equations is zero (such a case is called a homogeneous system) we work with the matrix of the system only. We find the solution by transforming the matrix into the row echelon form using elementary row transformations. These correspond to changing the order of equations, multiplying an equation by a non-zero number and addition of multiples of equations. Furthermore, we can always go back and forth between the matrix notation and the original system notation with variables  $x_i$ . We obtain:

$$\begin{pmatrix} 2 & -1 & 3 \\ 3 & 16 & 7 \\ 3 & -5 & 4 \\ -7 & 7 & -10 \end{pmatrix} \sim \begin{pmatrix} 2 & -1 & 3 \\ 0 & 35/2 & 5/2 \\ 0 & -7/2 & -1/2 \\ 0 & 7/2 & 1/2 \end{pmatrix}.$$

Every system of  $m$  linear equations in  $n$  variables

$$\begin{aligned} a_{11}x_1 + a_{12}x_2 + \cdots + a_{1n}x_n &= b_1 \\ a_{21}x_1 + a_{22}x_2 + \cdots + a_{2n}x_n &= b_2 \\ &\vdots \\ a_{m1}x_1 + a_{m2}x_2 + \cdots + a_{mn}x_n &= b_m \end{aligned}$$

can be seen as a constraint on values of  $m$  scalar products with one unknown vector  $(x_1, \dots, x_n)$  (called the *vector of variables*, or *vector variable*) and the known vectors of coordinates  $(a_{i1}, \dots, a_{in})$ .

The vector of variables can be also seen as a column in a matrix of the type  $n/1$ , and similarly the values  $b_1, \dots, b_m$  can be seen as a vector  $u$ , and that is again a single column of the matrix of the type  $m/1$ . Our system of equations can then be formally written as  $A \cdot x = u$  as follows:

$$\begin{pmatrix} a_{11} & \cdots & a_{1n} \\ \vdots & & \vdots \\ a_{m1} & \cdots & a_{mn} \end{pmatrix} \cdot \begin{pmatrix} x_1 \\ \vdots \\ x_n \end{pmatrix} = \begin{pmatrix} b_1 \\ \vdots \\ b_m \end{pmatrix}$$

where the left-hand side is interpreted as  $m$  scalar products of the individual rows of the matrix (giving rise to a column vector) with the vector variable  $x$ , whose values are prescribed by the equations. That means that the identity of the  $i$ -th coordinates corresponds to the original  $i$ -th equation

$$a_{i1}x_1 + \cdots + a_{in}x_n = b_i$$

and the notation  $A \cdot x = u$  gives the original system of equations.

**2.1.4. Matrix product.** In the plane, that is, for vectors of

dimension two, we developed a matrix calculus. We noticed that it is effective to work with (see 1.5.4). Now we generalize such a calculus and we develop all the tools we know already from the plane case to deal with higher dimensions  $n$ .

It is possible to define matrix multiplication only when the dimensions of the rows and columns allow it, that is, when the scalar product is defined for them as before:

MATRIX PRODUCT

For any matrix  $A = (a_{ij})$  of the type  $m/n$  and any matrix  $B = (b_{jk})$  of the type  $n/q$  over the ring of scalars  $\mathbb{K}$  we define their product  $C = A \cdot B = (c_{ik})$  as a matrix of the type  $m/q$  with the elements

$$c_{ik} = \sum_{j=1}^n a_{ij}b_{jk}, \text{ for arbitrary } 1 \leq i \leq m, 1 \leq k \leq q.$$

That is, the element  $c_{ik}$  of the product is exactly the scalar product of the  $i$ -th row of the matrix on the left and of the  $k$ -th column of the matrix on the right. For instance we have

$$\begin{pmatrix} 2 & 1 \\ 1 & -1 \end{pmatrix} \cdot \begin{pmatrix} 2 & 1 & 1 \\ -1 & 0 & 1 \end{pmatrix} = \begin{pmatrix} 3 & 2 & 3 \\ 3 & 1 & 0 \end{pmatrix}.$$

From there we see that the second, third and fourth equations are multiples of the equation  $7x_2 + x_3 = 0$ . We continue:

$$\begin{pmatrix} 2 & -1 & 3 \\ 0 & 35/2 & 5/2 \\ 0 & -7/2 & -1/2 \\ 0 & 7/2 & 1/2 \end{pmatrix} \sim \begin{pmatrix} 2 & -1 & 3 \\ 0 & 35/2 & 5/2 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix} \\ \sim \begin{pmatrix} 2 & -1 & 3 \\ 0 & 7 & 1 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix},$$

Considered as equations, the last two are redundant, and we are left with just

$$\begin{aligned} 2x_1 - x_2 + 3x_3 &= 0, \\ 7x_2 + x_3 &= 0 \end{aligned}$$

We substitute for the variable  $x_3$  a parameter  $t \in \mathbb{R}$  and express

$$x_2 = -\frac{1}{7}x_3 = -\frac{1}{7}t \quad \text{a} \quad x_1 = \frac{1}{2}(x_2 - 3x_3) = -\frac{11}{7}t.$$

If we now substitute  $t = -7s$ , we obtain the result in a simple form

$$(x_1, x_2, x_3) = (11s, s, -7s), \quad s \in \mathbb{R}.$$

The whole system has infinitely many solutions.  $\square$

**2.A.4.** Find all solutions of the system of linear equations

$$\begin{aligned} 3x_1 &+ 3x_3 - 5x_4 = -8, \\ x_1 - x_2 + x_3 - x_4 &= -2, \\ -2x_1 - x_2 + 4x_3 - 2x_4 &= 0, \\ 2x_1 + x_2 - x_3 - x_4 &= -3. \end{aligned}$$

**Solution.** The corresponding extended matrix of the system is

$$\left( \begin{array}{cccc|c} 3 & 0 & 3 & -5 & -8 \\ 1 & -1 & 1 & -1 & -2 \\ -2 & -1 & 4 & -2 & 0 \\ 2 & 1 & -1 & -1 & -3 \end{array} \right).$$

By changing the order of rows (equations) we obtain

$$\left( \begin{array}{cccc|c} 1 & -1 & 1 & -1 & -2 \\ 2 & 1 & -1 & -1 & -3 \\ -2 & -1 & 4 & -2 & 0 \\ 3 & 0 & 3 & -5 & -8 \end{array} \right),$$

which we transform into the row echelon form:

$$\left( \begin{array}{cccc|c} 1 & -1 & 1 & -1 & -2 \\ 2 & 1 & -1 & -1 & -3 \\ -2 & -1 & 4 & -2 & 0 \\ 3 & 0 & 3 & -5 & -8 \end{array} \right) \sim \left( \begin{array}{cccc|c} 1 & -1 & 1 & -1 & -2 \\ 0 & 3 & -3 & 1 & 1 \\ 0 & -3 & 6 & -4 & -4 \\ 0 & 3 & 0 & -2 & -2 \end{array} \right) \\ \left( \begin{array}{cccc|c} 1 & -1 & 1 & -1 & -2 \\ 0 & 3 & -3 & 1 & 1 \\ 0 & 0 & 3 & -3 & -3 \\ 0 & 0 & 3 & -3 & -3 \end{array} \right) \sim \left( \begin{array}{cccc|c} 1 & -1 & 1 & -1 & -2 \\ 0 & 3 & -3 & 1 & 1 \\ 0 & 0 & 3 & -3 & -3 \\ 0 & 0 & 0 & 0 & 0 \end{array} \right).$$

The system has thus infinitely many solutions, because we have three equations in four variables. These three equations have exactly one solution for any choice for the variable

**2.1.5. Square matrices.** If there is the same number of rows and columns in the matrix, we speak of a *square matrix*. The number of rows or columns is then called the *dimension of the matrix*. The matrix

$$E = (\delta_{ij}) = \begin{pmatrix} 1 & \dots & 0 \\ \vdots & \ddots & \vdots \\ 0 & \dots & 1 \end{pmatrix}$$

is called the *unit matrix*, or alternatively, the *identity matrix*. The numbers  $\delta_{ij}$  defined in such a way are also called the *Kronecker delta*. When we restrict ourselves to square matrices over  $\mathbb{K}$  of fixed dimension  $n$ , the matrix product is defined for any two matrices. That is, there is the well defined multiplication operation there. Its properties are similar to that of scalars:

**Proposition.** *On the set of all square matrices of dimension  $n$  over an arbitrary ring of scalars  $\mathbb{K}$ , the multiplication operation is defined with the following properties of rings (see 1.1.1):*

- (R1) Multiplication is associative.
- (R3) The unit matrix  $E = (\delta_{ij})$  is the unit element for multiplication.
- (R4) Multiplication and addition is distributive.

*In general, neither the property (R2) nor (ID) are true. Therefore, the square matrices for  $n > 1$  do not form an integral domain, and consequently they cannot be a (commutative or non-commutative) field.*

**PROOF.** Associativity of multiplication – (R1): Since scalars are associative, distributive and commutative, we can compute for any three matrices  $A = (a_{ij})$  of type  $m/n$ ,  $B = (b_{jk})$  of type  $n/p$  and  $C = (c_{kl})$  of type  $p/q$ :

$$\begin{aligned} A \cdot B &= \left( \sum_j a_{ij} \cdot b_{jk} \right), \quad B \cdot C = \left( \sum_k b_{jk} \cdot c_{kl} \right), \\ (A \cdot B) \cdot C &= \left( \sum_k \left( \sum_j a_{ij} b_{jk} \right) c_{kl} \right) = \left( \sum_{j,k} a_{ij} b_{jk} c_{kl} \right), \\ A \cdot (B \cdot C) &= \left( \sum_j a_{ij} \left( \sum_k b_{jk} c_{kl} \right) \right) = \left( \sum_{j,k} a_{ij} b_{jk} c_{kl} \right). \end{aligned}$$

Note that while computing, we relied on the fact that it does not matter in which order are we performing the sums and products, that is, we were relying on the properties of scalars.

We can easily see that multiplication by a unit matrix has the property of a unit element:

$$A \cdot E = \begin{pmatrix} a_{11} & \dots & a_{1m} \\ \vdots & & \\ a_{m1} & \dots & a_{mm} \end{pmatrix} \cdot \begin{pmatrix} 1 & 0 & \dots & 0 \\ 0 & 1 & \dots & 0 \\ \vdots & \vdots & & \vdots \\ 0 & 0 & \dots & 1 \end{pmatrix} = A$$

and similarly from the left,

$$E \cdot A = A.$$

It remains to prove the distributivity of multiplication and addition. Again using the distributivity of scalars we can

$x_4 \in \mathbb{R}$ . Thus for  $x_4$  we substitute the parameter  $t \in \mathbb{R}$  and go back from the matrix notation to the system of equations

$$\begin{array}{rccccrcr} x_1 & - & x_2 & + & x_3 & - & t & = & -2, \\ & & 3x_2 & - & 3x_3 & + & t & = & 1, \\ & & & & 3x_3 & - & 3t & = & -3. \end{array}$$

From the last equation we have  $x_3 = t - 1$ . Substituting for  $x_3$  into the second equation gives

$$3x_2 - 3t + 3 + t = 1, \quad \text{that is,} \quad x_2 = \frac{1}{3}(2t - 2).$$

Finally, using the first equation, we have

$$x_1 - \frac{1}{3}(2t - 2) + t - 1 - t = -2, \quad \text{tj.} \quad x_1 = \frac{1}{3}(2t - 5).$$

The set of solutions can be written (for  $t = 3s$ ) in the form  $\{(x_1, x_2, x_3, x_4) = (2s - \frac{5}{3}, 2s - \frac{2}{3}, 3s - 1, 3s), s \in \mathbb{R}\}$ .

We return to the extended matrix of the system and transform it further by using the row transformations in order to have (still in the row echelon form) the first non-zero number of every row (the so-called *pivot*) equal to one and that all the other numbers in the column of the pivot are zero. We have

$$\begin{aligned} & \left( \begin{array}{cccc|c} 1 & -1 & 1 & -1 & -2 \\ 0 & 3 & -3 & 1 & 1 \\ 0 & 0 & 3 & -3 & -3 \\ 0 & 0 & 0 & 0 & 0 \end{array} \right) \\ & \sim \left( \begin{array}{cccc|c} 1 & -1 & 1 & -1 & -2 \\ 0 & 1 & -1 & 1/3 & 1/3 \\ 0 & 0 & 1 & -1 & -1 \\ 0 & 0 & 0 & 0 & 0 \end{array} \right) \\ & \sim \left( \begin{array}{cccc|c} 1 & -1 & 0 & 0 & -1 \\ 0 & 1 & 0 & -2/3 & -2/3 \\ 0 & 0 & 1 & -1 & -1 \\ 0 & 0 & 0 & 0 & 0 \end{array} \right) \\ & \sim \left( \begin{array}{cccc|c} 1 & 0 & 0 & -2/3 & -5/3 \\ 0 & 1 & 0 & -2/3 & -2/3 \\ 0 & 0 & 1 & -1 & -1 \\ 0 & 0 & 0 & 0 & 0 \end{array} \right), \end{aligned}$$

because first we have multiplied the second and the third row by 1/3, then we have added the third row to the second and its  $(-1)$ -multiple to the first. Finally we have added the second row to the first. From the last matrix we easily obtain the result

$$\begin{pmatrix} x_1 \\ x_2 \\ x_3 \\ x_4 \end{pmatrix} = \begin{pmatrix} -5/3 \\ -2/3 \\ -1 \\ 0 \end{pmatrix} + t \begin{pmatrix} 2/3 \\ 2/3 \\ 1 \\ 1 \end{pmatrix}, \quad t \in \mathbb{R}.$$

Free variables are those whose columns do not contain any pivot (in our case there is no pivot in the fourth column, that is, the fourth variable is free and we use it as a parameter).  $\square$

easily calculate for matrices  $A = (a_{ij})$  of the type  $m/n$ ,  $B = (b_{jk})$  of the type  $n/p$ ,  $C = (c_{jk})$  of the type  $n/p$ ,  $D = (d_{kl})$  of the type  $p/q$

$$\begin{aligned} A \cdot (B + C) &= \left( \sum_j a_{ij}(b_{jk} + c_{jk}) \right) \\ &= \left( \left( \sum_j a_{ij}b_{jk} \right) + \left( \sum_j a_{ij}c_{jk} \right) \right) = A \cdot B + A \cdot C \\ (B + C) \cdot D &= \left( \sum_k (b_{jk} + c_{jk})d_{kl} \right) \\ &= \left( \left( \sum_k b_{jk}d_{kl} \right) + \left( \sum_k c_{jk}d_{kl} \right) \right) = B \cdot D + C \cdot D. \end{aligned}$$

As we have seen in 1.5.4, two matrices of dimension two do not necessarily commute: for example

$$\begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix} \cdot \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix} = \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix}$$

$$\begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix} \cdot \begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix} = \begin{pmatrix} 0 & 0 \\ 0 & 0 \end{pmatrix}.$$

This gives us immediately a counterexample to the validity of (R2) and (ID). For matrices of type 1/1 both axioms clearly hold, because the scalars itself have them. For matrices of greater dimension the counterexamples can be obtained similarly. Simply place the counterexamples for dimension 2 in their left upper corner, and select the rest to be zero. (Verify this on your own!)  $\square$

In the proof we have actually worked with matrices of more general types, thus we have proved the properties in greater generality:

ASSOCIATIVITY AND DISTRIBUTIVITY

Matrix multiplication is associative and distributive, that is,

$$A \cdot (B \cdot C) = (A \cdot B) \cdot C$$

$$A \cdot (B + C) = A \cdot B + A \cdot C,$$

whenever are all the given operations defined. The unit matrix is a unit element for multiplication (both from the right and from the left).

**2.1.6. Inverse matrices.** With scalars we can do the following: from the equation  $a \cdot x = b$  with a fixed invertible  $a$  we can express  $x = a^{-1} \cdot b$  for any  $b$ . We would like to be able to do this for matrices too. So we need to solve the problem – how to tell that such a matrix exists, and if so, how to compute it?

We say that  $B$  is the *inverse* of  $A$  if

$$A \cdot B = B \cdot A = E.$$

Then we write  $B = A^{-1}$ . From the definition it is clear that both matrices must be square and of the same dimension  $n$ . A matrix which has an inverse is called an *invertible matrix* or a *regular square matrix*.

**2.A.5.** Determine the solutions of the system of equations

$$\begin{aligned} 3x_1 &+ 3x_3 - 5x_4 = 8, \\ x_1 - x_2 + x_3 - x_4 &= -2, \\ -2x_1 - x_2 + 4x_3 - 2x_4 &= 0, \\ 2x_1 + x_2 - x_3 - x_4 &= -3. \end{aligned}$$

**Solution.** Note that the system of equations in this exercise differs from the system of equations in the previous exercise only in the value 8 (instead of  $-8$ ) on the right-hand side. If we do the same row transformations as in the previous exercise, we obtain

$$\begin{aligned} \left( \begin{array}{cccc|c} 3 & 0 & 3 & -5 & 8 \\ 1 & -1 & 1 & -1 & -2 \\ -2 & -1 & 4 & -2 & 0 \\ 2 & 1 & -1 & -1 & -3 \end{array} \right) &\sim \left( \begin{array}{cccc|c} 1 & -1 & 1 & -1 & -2 \\ 2 & 1 & -1 & -1 & -3 \\ -2 & -1 & 4 & -2 & 0 \\ 3 & 0 & 3 & -5 & 8 \end{array} \right) \\ &\sim \left( \begin{array}{cccc|c} 1 & -1 & 1 & -1 & -2 \\ 0 & 3 & -3 & 1 & 1 \\ 0 & 0 & 3 & -3 & -3 \\ 0 & 0 & 3 & -3 & 13 \end{array} \right) \sim \left( \begin{array}{cccc|c} 1 & -1 & 1 & -1 & -2 \\ 0 & 3 & -3 & 1 & 1 \\ 0 & 0 & 3 & -3 & -3 \\ 0 & 0 & 0 & 0 & 16 \end{array} \right), \end{aligned}$$

where the last operation was subtracting the third row from the fourth. From the fourth equation  $0 = 16$  follows that the system has no solutions. Let us emphasize that whenever we obtain an equation of the form  $0 = a$  for some  $a \neq 0$  (that is, zero row on the left side and non-zero number after the vertical bar) when doing the row transformation, the system has no solutions.  $\square$

You can find more exercises for systems of systems of linear equations on the page [124](#)

Now we are going to manipulate with matrices to get more familiar with their properties.

**2.A.6. Matrix multiplication.** Note that, in order to be able

to multiply two matrices, the necessary and sufficient condition is that the first matrix has the same number of columns as the number of rows of the second matrix. The number of rows of the resulting matrix is then given by the number of rows of the first matrix, the number of columns then equals the number of columns of the second matrix.

$$\begin{aligned} \text{i)} & \begin{pmatrix} 1 & 2 \\ -1 & 3 \end{pmatrix} \cdot \begin{pmatrix} 1 & -1 \\ 2 & 1 \end{pmatrix} = \begin{pmatrix} 5 & 1 \\ 5 & 4 \end{pmatrix}, \\ \text{ii)} & \begin{pmatrix} 1 & -1 \\ 2 & 1 \end{pmatrix} \cdot \begin{pmatrix} 1 & 2 \\ -1 & 3 \end{pmatrix} = \begin{pmatrix} 2 & -1 \\ 1 & 7 \end{pmatrix}, \\ \text{iii)} & \begin{pmatrix} 1 & 2 & 3 \\ 1 & -1 & 1 \end{pmatrix} \cdot \begin{pmatrix} 1 & -1 & 2 & 1 \\ 1 & 1 & -2 & -3 \\ 3 & 2 & 1 & 0 \end{pmatrix} \\ & = \begin{pmatrix} 12 & 7 & 1 & -5 \\ 3 & 0 & 5 & 4 \end{pmatrix}, \end{aligned}$$

In the subsequent paragraphs we derive (among other things) that  $B$  is actually the inverse of  $A$  whenever just one of the above required equations holds. The other is then a consequence.

We easily check that if  $A^{-1}$  and  $B^{-1}$  exist, then there also is the inverse of the product  $A \cdot B$

$$(1) \quad (A \cdot B)^{-1} = B^{-1} \cdot A^{-1}.$$

Indeed, because of the associativity of matrix multiplication proved a while ago, we have

$$(B^{-1} \cdot A^{-1}) \cdot (A \cdot B) = B^{-1} \cdot (A^{-1} \cdot A) \cdot B = E$$

$$(A \cdot B) \cdot (B^{-1} \cdot A^{-1}) = A \cdot (B \cdot B^{-1}) \cdot A^{-1} = E.$$

Because we can calculate with matrices similarly as with scalars (they are just a little more complicated), the existence of an inverse matrix can really help us with the solution of systems of linear equations: if we express a system of  $n$  equations for  $n$  unknowns as a matrix product

$$A \cdot x = \begin{pmatrix} a_{11} & \cdots & a_{1m} \\ \vdots & & \vdots \\ a_{m1} & \cdots & a_{mm} \end{pmatrix} \cdot \begin{pmatrix} x_1 \\ \vdots \\ x_m \end{pmatrix} = \begin{pmatrix} b_1 \\ \vdots \\ b_m \end{pmatrix} = u$$

and when the inverse of the matrix  $A$  exists, then we can multiply from the left by  $A^{-1}$  to obtain

$$A^{-1} \cdot u = A^{-1} \cdot A \cdot x = E \cdot x = x,$$

that is,  $A^{-1} \cdot u$  is the desired solution.

On the other hand, expanding the condition  $A \cdot A^{-1} = E$  for unknown scalars in the matrix  $A^{-1}$  gives us  $n$  systems of linear equations for the same matrix on the left and different vectors on the right. Thus we should think about methods for solutions of the systems of linear equations.

**2.1.7. Equivalent operations with matrices.** Let us gain some practical insight into the relation between systems of equations and their matrices. Clearly, searching for the inverse can be more complicated than finding the direct solution to the system of equations. But note that whenever we have to solve more systems of equations with the same matrix  $A$  but with different right sides  $u$ , then yielding  $A^{-1}$  can be really beneficial for us.

From the point of view of solving systems of equations  $A \cdot x = u$ , it is natural to consider the matrices  $A$  and vectors  $u$  equivalent whenever they give a system of equations with the same solution set. Let us think about possible operations which would simplify the matrix  $A$  such that obtaining the solution is easier.

We begin with simple manipulations of rows of equations which do not influence the solution, and similar modifications of the right-hand side vector. If we are able to change a square matrix into the unit matrix, then the right-hand side vector is a solution of the original system. If some of the rows of the system vanish during the course of manipulations (that is,

$$\text{iv) } \begin{pmatrix} 1 & 3 & 1 \\ -2 & 2 & -1 \\ 3 & 1 & -4 \end{pmatrix} \cdot \begin{pmatrix} 1 \\ 3 \\ -3 \end{pmatrix} = \begin{pmatrix} 7 \\ 7 \\ 18 \end{pmatrix},$$

$$\text{v) } (1 \ 3 \ -3) \cdot \begin{pmatrix} 1 & -2 & 3 \\ 3 & 2 & 1 \\ 1 & -1 & -4 \end{pmatrix} = (7 \ 7 \ 18),$$

$$\text{vi) } (1 \ 2 \ -2) \cdot \begin{pmatrix} 2 \\ 1 \\ 3 \end{pmatrix} = (-2).$$

**Remark.** Parts i) and ii) in the previous exercise show that multiplication of square matrices is not commutative in general. In part iii) we see that if we can multiply two rectangular matrices, then it is possible only in one of the orders. In parts iv) and v) note that  $(A \cdot B)^T = B^T \cdot A^T$ .

**2.A.7.** Let

$$A = \begin{pmatrix} 4 & 0 & -5 \\ 2 & 7 & 15 \\ 2 & 7 & 13 \end{pmatrix}, \quad B = \begin{pmatrix} 7 & 2 & 0 \\ 0 & 0 & 3 \\ 0 & -19 & \sqrt{13} \end{pmatrix}.$$

Can the matrix  $A$  be transformed into  $B$  using only elementary row transformations (we say then that such matrices are row equivalent)?

**Solution.** Both matrices are row equivalent with the three-dimensional identity matrix. It is easy to see that row equivalence on the set of all matrices of given type is indeed an equivalence relation. Thus the matrices  $A$  and  $B$  are row equivalent.  $\square$

**2.A.8.** Find a matrix  $B$  for which the matrix  $C = B \cdot A$  is

in row echelon form, where

$$A = \begin{pmatrix} 3 & -1 & 3 & 2 \\ 5 & -3 & 2 & 3 \\ 1 & -3 & -5 & 0 \\ 7 & -5 & 1 & 4 \end{pmatrix}.$$

**Solution.** If we multiply the matrix  $A$  successively from the left by elementary matrices (consider what elementary row transformations does it correspond to)

$$E_1 = \begin{pmatrix} 0 & 0 & 1 & 0 \\ 0 & 1 & 0 & 0 \\ 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix}, \quad E_2 = \begin{pmatrix} 1 & 0 & 0 & 0 \\ -5 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix},$$

$$E_3 = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ -3 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix}, \quad E_4 = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ -7 & 0 & 0 & 1 \end{pmatrix},$$

$$E_5 = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 1/3 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix}, \quad E_6 = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & -2 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix},$$

they become zero), then we get some direct information about the solution. Our simple operations are:

ELEMENTARY ROW TRANSFORMATIONS

- interchanging two rows,
- multiplication of any given row by a non-zero scalar,
- adding another row to any given row.

These operations are called *elementary row transformations*. It is clear that the corresponding operations at the level of the equations in the system do not change the set of the solutions whenever our ring of coordinates is an integral domain.

Analogously, *elementary column transformations* of matrices are

- interchanging two columns
- multiplication of any given column by a non-zero scalar,
- adding another column to any given column.

These do not preserve the solution set, since they change the variables themselves.

Systematically we can use elementary row transformations for subsequent elimination of variables. This gives an algorithm which is usually called the *Gaussian elimination method*. Henceforth, we shall assume that our scalars come from a integral domain (e.g. integers are allowed, but not say  $\mathbb{Z}_4$ ).

GAUSSIAN ELIMINATION OF VARIABLES

**Proposition.** Any non-zero matrix over an arbitrary integral domain of scalars  $\mathbb{K}$  can be transformed, using finitely many elementary row transformations, into row echelon form:

- For each  $j$ , if  $a_{ik} = 0$  for all columns  $k = 1, \dots, j$ , then  $a_{kj} = 0$  for all  $k \geq i$ ,
- if  $a_{(i-1)j}$  is the first non-zero element at the  $(i-1)$ -st row, then  $a_{ij} = 0$ .

**PROOF.** The matrix in row echelon form looks like

$$\begin{pmatrix} 0 & \dots & 0 & a_{1j} & \dots & \dots & \dots & a_{1m} \\ 0 & \dots & 0 & 0 & \dots & a_{2k} & \dots & a_{2m} \\ \vdots & & & & & & & \\ 0 & \dots & \dots & \dots & \dots & 0 & a_{lp} & \dots \\ \vdots & & & & & & & \end{pmatrix}.$$

The matrix can (but does not have to) end with some zero rows. In order to transform an arbitrary matrix, we can use a simple algorithm, which will bring us, row by row, to the resulting echelon form:

$$E_7 = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & -4 & 0 & 1 \end{pmatrix}, \quad E_8 = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 1/4 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix},$$

we obtain

$$B = E_8 E_7 E_6 E_5 E_4 E_3 E_2 E_1 = \begin{pmatrix} 0 & 0 & 1 & 0 \\ 0 & 1/12 & -5/12 & 0 \\ 1 & -2/3 & 1/3 & 0 \\ 0 & -4/3 & -1/3 & 1 \end{pmatrix},$$

$$C = \begin{pmatrix} 1 & -3 & -5 & 0 \\ 0 & 1 & 9/4 & 1/4 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix}.$$

**2.A.9. Complex numbers as matrices.** Consider the set of

matrices  $C = \left\{ \begin{pmatrix} a & b \\ -b & a \end{pmatrix}, a, b \in \mathbb{R} \right\}$ . Note that

$C$  is closed under addition and matrix multiplication, and further show that the mapping  $f: C \rightarrow \mathbb{C}, \begin{pmatrix} a & b \\ -b & a \end{pmatrix} \mapsto a + bi$  satisfies  $f(M + N) = f(M) + f(N)$  and  $f(M \cdot N) = f(M) \cdot f(N)$  (on the left-hand sides of the equations we have addition and multiplication of matrices, on the right-hand sides we have addition and multiplication of complex numbers). Thus the set  $C$  along with multiplication and addition can be seen as the field  $\mathbb{C}$  of complex numbers. The mapping  $f$  is called an isomorphism (of fields). Thus for instance we have

$$\begin{pmatrix} 3 & 5 \\ -5 & 3 \end{pmatrix} \cdot \begin{pmatrix} 8 & -9 \\ 9 & 8 \end{pmatrix} = \begin{pmatrix} 69 & 13 \\ -13 & 69 \end{pmatrix},$$

which corresponds to  $(3 + 5i) \cdot (8 - 9i) = 69 - 13i$ .

**2.A.10.** Solve the equations for matrices

$$\begin{pmatrix} 1 & 3 \\ 3 & 8 \end{pmatrix} \cdot X_1 = \begin{pmatrix} 1 & 2 \\ 3 & 4 \end{pmatrix}, \quad X_2 \cdot \begin{pmatrix} 1 & 3 \\ 3 & 8 \end{pmatrix} = \begin{pmatrix} 1 & 2 \\ 3 & 4 \end{pmatrix}.$$

**Solution.** Clearly the unknowns  $X_1$  and  $X_2$  must be matrices of the type  $2 \times 2$  (in order for the products to be defined and that the result is a matrix of the type  $2 \times 2$ ). Set

$$X_1 = \begin{pmatrix} a_1 & b_1 \\ c_1 & d_1 \end{pmatrix}, \quad X_2 = \begin{pmatrix} a_2 & b_2 \\ c_2 & d_2 \end{pmatrix}$$

and multiply out the matrices in the first given equation. We obtain

$$\begin{pmatrix} a_1 + 3c_1 & b_1 + 3d_1 \\ 3a_1 + 8c_1 & 3b_1 + 8d_1 \end{pmatrix} = \begin{pmatrix} 1 & 2 \\ 3 & 4 \end{pmatrix},$$

GAUSSIAN ELIMINATION ALGORITHM

- (1) By a possible interchange of rows we can obtain a matrix where the first row has a non-zero element in the first non-zero column. Let that column be column  $j$ . In other words,  $a_{1j} \neq 0$ , but  $a_{iq} = 0$  for all  $i$ , and all  $q$ ,  $1 \leq q < j$ .
- (2) For each  $i = 2, \dots$ , multiply the first row by the element  $a_{ij}$ , multiply  $i$ -th row by the element  $a_{1j}$  and subtract, to obtain  $a_{ij} = 0$  on the  $i$ -th row.
- (3) By repeated application of the steps (1) and (2), always for the not-yet-echelon part of rows and columns in the matrix we reach, after a finite number of steps, the final form of the matrix.

□ This algorithm clearly stops after a finite number of steps and provides the proof of the proposition. □

The given algorithm is really the usual elimination of variables used in the systems of linear equations.

In a completely analogous manner we define the column echelon form of matrices and considering column elementary transformations instead the row ones, we obtain an algorithm for transforming matrices into the column echelon form.

**Remark.** Although we could formulate the Gaussian elimination for general scalars from any ring, this does not make much sense in view of solving equations. Clearly having divisors of zero among the scalars, we might get zeros during the procedure and lose information this way. Think carefully about the differences between the choices  $\mathbb{K} = \mathbb{Z}$ ,  $\mathbb{K} = \mathbb{R}$  and possibly  $\mathbb{Z}_2$  or  $\mathbb{Z}_4$ .

On the other hand, if we are dealing with fields of scalars, we can always arrive at a row echelon form where the non-zero entries on the “diagonal” are ones. This is done by applying the appropriate scalar multiplication to each individual row. However, this is not possible in general – think for instance of the integers  $\mathbb{Z}$ .

**2.1.8. Matrix of elementary row transformations.** Let us

now restrict ourselves to fields of scalars  $\mathbb{K}$ , that is, every non-zero scalar has an inverse.

Note that elementary row or column transformations correspond respectively to multiplication from the left or right by the following matrices (only the differences from the unit matrix are indicated):

- (1) Interchanging the  $i$ -th and  $j$ -th row (column)

$$\begin{pmatrix} \ddots & & & & \\ & 0 & \dots & 1 & \\ & \vdots & \ddots & \vdots & \\ & 1 & \dots & 0 & \\ & & & & \ddots \end{pmatrix} \begin{array}{l} \leftarrow i\text{-th row} \\ \leftarrow j\text{-th row} \end{array}$$

that is,

$$\begin{aligned} a_1 &+ 3c_1 &= 1, \\ &b_1 + 3d_1 &= 2, \\ 3a_1 &+ 8c_1 &= 3, \\ &3b_1 + 8d_1 &= 4. \end{aligned}$$

By adding a  $(-3)$ -multiple of the first equation with the third equation we obtain  $c_1 = 0$  and then  $a_1 = 1$ . Analogously, by adding a  $(-3)$ -multiple of the second equation to the fourth equation we obtain  $d_1 = 2$  and then  $b_1 = -4$ . Thus we have

$$X_1 = \begin{pmatrix} 1 & -4 \\ 0 & 2 \end{pmatrix}.$$

We can find the values  $a_2, b_2, c_2, d_2$  by a different approach. If  $A$  is a square matrix, we write  $A^{-1}$  to denote its inverse, so that  $A \cdot A^{-1} = A^{-1} \cdot A = E$ , the unit matrix) It is easy to check that

$$\begin{pmatrix} a & b \\ c & d \end{pmatrix}^{-1} = \frac{1}{ad - bc} \begin{pmatrix} d & -b \\ -c & a \end{pmatrix},$$

which holds for any numbers  $a, b, c, d \in \mathbb{R}$  provided  $ad - bc \neq 0$ . (This is easy to derive; it also directly follows from formula 1 in 2.2.11). We calculate

$$\begin{pmatrix} 1 & 3 \\ 3 & 8 \end{pmatrix}^{-1} = \begin{pmatrix} -8 & 3 \\ 3 & -1 \end{pmatrix}.$$

Multiplying the given equations by this matrix from the right gives

$$X_2 = \begin{pmatrix} 1 & 2 \\ 3 & 4 \end{pmatrix} \cdot \begin{pmatrix} -8 & 3 \\ 3 & -1 \end{pmatrix},$$

and thus

$$X_2 = \begin{pmatrix} -2 & 1 \\ -12 & 5 \end{pmatrix}.$$

2.A.II. Solve the matrix equation

$$X \cdot \begin{pmatrix} 2 & 5 \\ 1 & 3 \end{pmatrix} = \begin{pmatrix} 4 & -6 \\ 2 & 1 \end{pmatrix}.$$

2.A.12. **Computing the inverse matrix.** Compute

the inverse of the matrices

$$A = \begin{pmatrix} 4 & 3 & 2 \\ 5 & 6 & 3 \\ 3 & 5 & 2 \end{pmatrix}, \quad B = \begin{pmatrix} 1 & 0 & 1 \\ 3 & 3 & 4 \\ 2 & 2 & 3 \end{pmatrix}.$$

Then determine the matrix  $(A^T \cdot B)^{-1}$ .

**Solution.** We find the inverse by the following method: write next to each other the matrix  $A$  and the unit matrix. Then use elementary row transformations so that the sub-matrix  $A$  changes into the unit matrix. This will change the original unit sub-matrix to  $A^{-1}$ . We obtain

(2) Multiplication of the  $i$ -th row (column) by the scalar  $a$ :

$$\begin{pmatrix} \ddots & & & & \\ & 1 & & & \\ & & a & & \\ & & & 1 & \\ & & & & \ddots \end{pmatrix} \leftarrow i\text{-th row}$$

(3) To row  $i$ , add row  $j$  (columns):

$$i\text{-th row and } j\text{-th column} \rightarrow \begin{pmatrix} \ddots & & & & \\ & 1 & & & \\ & & \ddots & & \\ & & & 1 & \\ & & & & \ddots \end{pmatrix}$$

This trivial observation is actually very important, since the product of invertible matrices is invertible (recall 2.1.6(1)) and all elementary transformations over a field of scalars are invertible (the definition of the elementary transformation itself ensures that inverse transformations are of the same type and it is easy to determine the corresponding matrix).

Thus, the Gaussian elimination algorithm tells us, that for an arbitrary matrix  $A$ , we can obtain its equivalent row echelon form  $A' = P \cdot A$  by multiplying with a suitable invertible matrix  $P = P_k \cdots P_1$  from the left (that is, sequential multiplication with  $k$  matrices of the elementary row transformations).

If we apply the same elimination procedure for the columns, we can transform any matrix  $B$  into its column echelon form  $B'$  by multiplying it from the right by a suitable invertible matrix  $Q = Q_1 \cdots Q_\ell$ . If we start with the matrix  $B = A'$  in row echelon form, this procedure eliminates only the still non-zero elements out of the diagonal of the matrix and in the end we can transform the remaining elements to be units. Thus we have verified a very important result which we will use many times in the future:

**2.1.9. Theorem.** For every matrix  $A$  of the type  $m/n$  over a field of scalars  $\mathbb{K}$ , there exist square invertible matrices  $P$  and  $Q$  of dimensions  $m$  and  $n$ , respectively, such that the matrix  $P \cdot A$  is in row echelon form and

$$P \cdot A \cdot Q = \begin{pmatrix} 1 & \dots & 0 & 0 & \dots & 0 \\ \vdots & \ddots & & & & \\ 0 & \dots & 1 & 0 & \dots & 0 \\ 0 & \dots & 0 & 0 & \dots & 0 \\ \vdots & & & & & \end{pmatrix}.$$

The number of the ones in the diagonal is independent of the particular choice of  $P$  and  $Q$ .

**PROOF.** We already have proved everything but the last sentence. We shall see this last claim below in 2.1.11.  $\square$

$$\begin{aligned}
 & \left( \begin{array}{ccc|ccc} 4 & 3 & 2 & 1 & 0 & 0 \\ 5 & 6 & 3 & 0 & 1 & 0 \\ 3 & 5 & 2 & 0 & 0 & 1 \end{array} \right) \\
 & \sim \left( \begin{array}{ccc|ccc} 1 & -2 & 0 & 1 & 0 & -1 \\ 5 & 6 & 3 & 0 & 1 & 0 \\ 3 & 5 & 2 & 0 & 0 & 1 \end{array} \right) \\
 & \sim \left( \begin{array}{ccc|ccc} 1 & -2 & 0 & 1 & 0 & -1 \\ 0 & 16 & 3 & -5 & 1 & 5 \\ 0 & 11 & 2 & -3 & 0 & 4 \end{array} \right) \\
 & \sim \left( \begin{array}{ccc|ccc} 1 & -2 & 0 & 1 & 0 & -1 \\ 0 & 5 & 1 & -2 & 1 & 1 \\ 0 & 11 & 2 & -3 & 0 & 4 \end{array} \right) \\
 & \sim \left( \begin{array}{ccc|ccc} 1 & -2 & 0 & 1 & 0 & -1 \\ 0 & 5 & 1 & -2 & 1 & 1 \\ 0 & 1 & 0 & 1 & -2 & 2 \end{array} \right) \\
 & \sim \left( \begin{array}{ccc|ccc} 1 & 0 & 0 & 3 & -4 & 3 \\ 0 & 0 & 1 & -7 & 11 & -9 \\ 0 & 1 & 0 & 1 & -2 & 2 \end{array} \right) \\
 & \sim \left( \begin{array}{ccc|ccc} 1 & 0 & 0 & 3 & -4 & 3 \\ 0 & 1 & 0 & 1 & -2 & 2 \\ 0 & 0 & 1 & -7 & 11 & -9 \end{array} \right).
 \end{aligned}$$

In the first step we subtracted from the first row the third row, in the second step we added a  $(-5)$ -multiple of the first to the second row and added a  $(-3)$ -multiple of the first row to the third row, in the third step we subtracted from the second row the third row, in the fourth step we added a  $(-2)$ -multiple of the second row to the third row, in the fifth step we added a  $(-5)$ -multiple of the third row to the second row and added a 2-multiple of the third row to the first row, and in the last step we changed the second and the third row. We have obtained the result

$$A^{-1} = \begin{pmatrix} 3 & -4 & 3 \\ 1 & -2 & 2 \\ -7 & 11 & -9 \end{pmatrix}.$$

Note that when calculating the matrix  $A^{-1}$  we did not have to cope with fractions thanks to the suitably chosen row transformations. Although we could carry on similarly when doing the next exercise, that is,  $B^{-1}$ , we will rather do the more obvious row transformations. We have

$$\begin{aligned}
 & \left( \begin{array}{ccc|ccc} 1 & 0 & 1 & 1 & 0 & 0 \\ 3 & 3 & 4 & 0 & 1 & 0 \\ 2 & 2 & 3 & 0 & 0 & 1 \end{array} \right) \sim \\
 & \left( \begin{array}{ccc|ccc} 1 & 0 & 1 & 1 & 0 & 0 \\ 0 & 3 & 1 & -3 & 1 & 0 \\ 0 & 2 & 1 & -2 & 0 & 1 \end{array} \right) \sim
 \end{aligned}$$

**2.1.10. Algorithm for computing inverse matrices.** In the previous paragraphs we almost obtained the complete algorithm for computing the inverse matrix. Using the simple modification below, we find either that the inverse does not exist, or we compute the inverse. Keep in mind that we are still working over a field of scalars.

Equivalent row transformations of a square matrix  $A$  of dimension  $n$  leads to an invertible matrix  $P'$  such that  $P' \cdot A$  is in row echelon form. If  $A$  has an inverse, then there exists also the inverse of  $P' \cdot A$ . But if the last row of  $P' \cdot A$  is zero, then the last row of  $P' \cdot A \cdot B$  is also zero for any matrix  $B$  of dimension  $n$ . Thus, the existence of a zero row in the result of (row) Gaussian elimination excludes the existence of  $A^{-1}$ .

Assume now that  $A^{-1}$  exists. As we have just seen, the row echelon form of  $A$  will have exclusively non-zero rows only. In particular, all diagonal elements of  $P' \cdot A$  are non-zero. But now, we can employ row elimination by the elementary row transformation from the bottom-right corner backwards and also transform the diagonal elements to be units. In this way, we obtain the unit matrix  $E$ . Summarizing, we find another invertible matrix  $P''$  such that for  $P = P'' \cdot P'$  we have  $P \cdot A = E$ .

Now observe that we could clearly work with columns instead of row transformation and thus, under the assumption of the existence of  $A^{-1}$ , we would find a matrix  $Q$  such that  $A \cdot Q = E$ . From this we see immediately that

$$P = P \cdot E = P \cdot (A \cdot Q) = (P \cdot A) \cdot Q = E \cdot Q = Q.$$

That is, we have found the inverse matrix

$$A^{-1} = P = Q$$

for the matrix  $A$ . Notice that at the point of finding the matrix  $P$  with the property  $P \cdot A = E$ , we do not have to do any further computation, since we have already obtained the inverse matrix.

In practice, we can work as follows:

#### COMPUTING THE INVERSE MATRIX

Write the unit matrix  $E$  to the right of the matrix  $A$ , producing an augmented matrix  $(A, E)$ . Transform the augmented matrix using the elementary row transformations to row echelon form. This produces an augmented matrix  $(PA, PE)$ , where  $P$  is invertible, and  $PA$  is in row echelon form. By the above, either we may achieve  $PA = E$ , in which case  $A$  is invertible and  $P = PE = A^{-1}$ , or  $PA$  has a row of zeros, in which case we conclude that the inverse matrix for  $A$  does not exist.

**2.1.11. Linear dependence and rank.** In the previous practical algorithms dealing with matrices we worked all the time with row and column additions and scalar multiplications, seeing them as vectors.

Such operations are called *linear combinations*. We shall return to such operations in an abstract sense later on in 2.3.1.

$$\begin{pmatrix} 1 & 0 & 1 & | & 1 & 0 & 0 \\ 0 & 3 & 1 & | & -3 & 1 & 0 \\ 0 & 0 & 1/3 & | & 0 & -2/3 & 1 \end{pmatrix} \sim \begin{pmatrix} 1 & 0 & 1 & | & 1 & 0 & 0 \\ 0 & 1 & 2/3 & | & -1 & 1/3 & 0 \\ 0 & 0 & 1/3 & | & 0 & -2/3 & 1 \end{pmatrix} \sim \begin{pmatrix} 1 & 0 & 0 & | & 1 & 2 & -3 \\ 0 & 1 & 0 & | & -1 & 1 & -1 \\ 0 & 0 & 1/3 & | & 0 & -2/3 & 1 \end{pmatrix} \sim \begin{pmatrix} 1 & 0 & 0 & | & 1 & 2 & -3 \\ 0 & 1 & 0 & | & -1 & 1 & -1 \\ 0 & 0 & 1 & | & 0 & -2 & 3 \end{pmatrix},$$

that is,

$$B^{-1} = \begin{pmatrix} 1 & 2 & -3 \\ -1 & 1 & -1 \\ 0 & -2 & 3 \end{pmatrix}.$$

Using the identity

$$(A^T \cdot B)^{-1} = B^{-1} \cdot (A^T)^{-1} = B^{-1} \cdot (A^{-1})^T$$

and the knowledge of the inverse matrices computed before, we obtain

$$\begin{aligned} (A^T \cdot B)^{-1} &= \begin{pmatrix} 1 & 2 & -3 \\ -1 & 1 & -1 \\ 0 & -2 & 3 \end{pmatrix} \cdot \begin{pmatrix} 3 & 1 & -7 \\ -4 & -2 & 11 \\ 3 & 2 & -9 \end{pmatrix} \\ &= \begin{pmatrix} -14 & -9 & 42 \\ -10 & -5 & 27 \\ 17 & 10 & -49 \end{pmatrix}. \end{aligned}$$

**2.A.13.** Compute the inverse of the matrix

$$A = \begin{pmatrix} 1 & 0 & -2 \\ 2 & -2 & 1 \\ 5 & -5 & 2 \end{pmatrix}.$$

**2.A.14.** Calculate  $A^5$  and  $A^{-3}$ , if

$$A = \begin{pmatrix} 2 & -1 & 1 \\ -1 & 2 & -1 \\ 0 & 0 & 1 \end{pmatrix}.$$

**2.A.15.** Compute the inverse of the matrix

$$\begin{pmatrix} 8 & 3 & 0 & 0 & 0 \\ 5 & 2 & 0 & 0 & 0 \\ 0 & 0 & -1 & 0 & 0 \\ 0 & 0 & 0 & 1 & 2 \\ 0 & 0 & 0 & 3 & 5 \end{pmatrix}.$$

**2.A.16.** Determine whether there exists an inverse of the matrix

$$C = \begin{pmatrix} 1 & 1 & 1 & 1 \\ 1 & 1 & -1 & 1 \\ 1 & -1 & 1 & -1 \\ 1 & -1 & -1 & 1 \end{pmatrix}.$$

If yes, then compute  $C^{-1}$ .

But it will be useful to understand their core meaning right now. A linear combination of rows of a matrix  $A = (a_{ij})$  of type  $m/n$  is understood as an expression of the form

$$c_1 u_{i_1} + \dots + c_k u_{i_k},$$

where  $c_i$  are scalars,  $u_j = (a_{j1}, \dots, a_{jn})$  are rows of the matrix  $A$ . Similarly, we can consider linear combinations of columns by replacing the above rows  $u_j$  by the columns  $u_j = (a_{1j}, \dots, a_{mj})$ .

If the zero row can be written as a linear combination of some given rows with at least one non-zero scalar coefficient, we say that these rows are *linearly dependent*. In the alternative case, that is, when the only possibility of obtaining the zero row is to select all the scalars  $c_j$  equal to zero, the rows are called *linearly independent*.

Analogously, we define linearly dependent and linearly independent columns.

The previous results about the Gaussian elimination can be now interpreted as follows: the number of non-zero “steps” in the row (column) echelon form is always equal to the number of linearly independent rows (columns) of the matrix. Let  $E_h$  be the matrix from the theorem 2.1.9 with  $h$  ones on the diagonals and assume that by two different row transformation procedures into the echelon form we obtain two different  $h' < h$ . But then according to our algorithm there are invertible matrices  $P'$ ,  $P''$ ,  $Q'$ , and  $Q''$  such that

$$E_h = P' \cdot A \cdot Q', \quad E_{h'} = P'' \cdot A \cdot Q''.$$

In particular,  $E_h = P' \cdot P''^{-1} \cdot E_{h'} \cdot Q''^{-1} \cdot Q'$  and so there are invertible matrices  $P$  and  $Q$  such that

$$E_{h'} \cdot Q = P \cdot E_h.$$

Now, on the left hand side, there are the first  $h'$  rows of  $Q$ , complemented by zero rows. At the same time, on the right hand side, there are  $h$  first columns of  $P$ , complemented by zero columns. Thus, the equality implies that taking the first  $h$  rows and columns in  $P$ , the last row in this part of  $P$  must be zero. But this shows, that our Gaussian elimination algorithm applied to  $P$  would show  $P$  is not invertible. Therefore  $h' = h$  and we have proved that the number of ones in the matrix  $P \cdot A \cdot Q$  in theorem 2.1.9 is independent of the choice of our elimination procedure and it is always equal to the number of linearly independent rows in  $A$ , which must be the same as the number of linearly independent columns in  $A$ . This number is called the *rank of the matrix* and we denote it by  $h(A)$ . We have the following theorem:

**Theorem.** Let  $A$  be a matrix of type  $m/n$  over a field of scalars  $\mathbb{K}$ . The matrix  $A$  has the same number  $h(A)$  of linearly independent rows as linearly independent columns. In particular, the rank is always at most the minimum of the dimensions of the matrix  $A$ .

The algorithm for computing the inverse matrix also says that a square matrix  $A$  of dimension  $m$  has an inverse if and only if its rank equals  $m$ .

2.A.17. Compute  $A^{-1}$ , if

(a)  $A = \begin{pmatrix} 1 & i \\ -i & 3 \end{pmatrix}$ , while  $i$  is the imaginary unit

(b)  $A = \begin{pmatrix} 1 & -5 & -3 \\ -1 & 5 & 4 \\ -1 & 6 & 2 \end{pmatrix}$ .

2.A.18. Find the inverse to the  $n \times n$  matrix ( $n > 1$ )

$$A = \begin{pmatrix} 2-n & 1 & \cdots & 1 & 1 \\ 1 & 2-n & \ddots & \ddots & 1 \\ \vdots & \ddots & \ddots & \ddots & \vdots \\ 1 & \ddots & \ddots & 2-n & 1 \\ 1 & 1 & \cdots & 1 & 2-n \end{pmatrix}.$$

**Solution.** You can try for small  $n$  ( $n = 2, 3, 4$ ), which is easy to compute with the known algorithm, and then guess the general form.

$$A^{-1} = \frac{1}{n-1} \begin{pmatrix} 0 & 1 & 1 & \cdots & 1 \\ 1 & 0 & 1 & \cdots & 1 \\ 1 & 1 & 0 & \ddots & \vdots \\ \vdots & \vdots & \ddots & \ddots & 1 \\ 1 & 1 & \cdots & 1 & 0 \end{pmatrix}.$$

We have already encountered systems of linear equations at the beginning of the chapter. Now we will deal with them in more detail. We use the inverse matrix to assist in computing the solution to the system of linear equations. Note that we do the same computation as before. To express the variables is the same as to bring the matrix of the system with equivalent transformation to the identity matrix and that is the same as to multiply the matrix of the system with the inverse matrix.

**2.A.19. Participants of a trip.** There were 45 participants of a two-day bus trip. On the first day, the fee for a watchtower visit was €30 for an adult, €16 for a child and €24 for a senior. The total fee for the first day was €1 116. On the second day, the fee for a bus with a palace and botanical garden tour was €40 for an adult, €24 for a child and €34 for a senior. The total fee for the second day was €1 542. How many adults, children and seniors were there among the participants?

**Solution.** Introduce the variables

- $x$  for the „number of adults“;
- $y$  for the „number of children“;

○ **2.1.12. Matrices as mappings.** Similarly to the way we worked with matrices in the geometry of the plane (see 1.5.7), we can interpret every matrix  $A$  of the type  $m/n$  as a mapping

$$A : \mathbb{K}^n \rightarrow \mathbb{K}^m, \quad x \mapsto A \cdot x.$$

○ By the distributivity of matrix multiplication, it is clear how the linear combinations of vectors are mapped using such mappings:

$$A \cdot (ax + by) = a(A \cdot x) + b(A \cdot y).$$

Straight from the definition we see, by the associativity of multiplication, that composition of mappings corresponds to matrix multiplication in given order. Thus invertible matrices of dimension  $n$  correspond to bijective mappings  $A : \mathbb{K}^n \rightarrow \mathbb{K}^n$ .

**Remark.** From this point of view, the theorem 2.1.9 is very interesting. We can see it as follows: the rank of the matrix determines how large is the image of the whole  $\mathbb{K}^n$  under this mapping. In fact, if  $A = P \cdot E_k \cdot Q$  where the matrix  $E_k$  has  $k$  ones as in 2.1.9, then the invertible  $Q$  first bijectively “shuffles” the  $n$ -dimensional vectors in  $\mathbb{K}^n$ , the matrix  $E_k$  then “copies” the first  $k$  coordinates and completes them with the remaining  $m - k$  zeros.

This “ $k$ -dimensional” image then cannot be enlarged by multiplying with  $P$ . Multiplying by  $P$  can only bijectively reshuffle the coordinates in the image.

□ **2.1.13. Back to linear equations.** We shall return to the notions of dimension, linear independence and so on in the third part of this chapter. But we should notice now what our results say about the solutions of the systems of linear equations.

If we consider the matrix of the system of equations and add to it the column of the required results, we speak about the *extended matrix of the system*. The above Gaussian elimination approach corresponds to the sequential variable elimination in the equations and the deletion of the linearly dependent equations (these are simply consequences of other equations).

Thus we have derived complete information about the size of the set of solutions of the system of linear equations, based on the rank of the matrix of the system. If we are left with more non-zero rows in the row echelon form of the extended matrix than in the original matrix of the system, then there cannot be a solution (simply, we cannot obtain the given vector value with the corresponding linear mapping). If the rank of both matrices is the same, then the backwards elimination provides exactly as many free parameters as the difference between the number of variables  $n$  and the rank  $h(A)$ . In particular, there will be exactly one solution if and only if the matrix is invertible.

All this will be stated explicitly in terms of abstract vector spaces in the important Kronecker-Capelli theorem, see 2.3.5.

$z$  for the „number of seniors“;

There were 45 participants, therefore

$$x + y + z = 45.$$

The fees for the first and second days respectively imply that

$$\begin{aligned} 30x + 16y + 24z &= 1116, \\ 40x + 24y + 34z &= 1542. \end{aligned}$$

We write the system of three linear equations in the matrix notation as

$$\begin{pmatrix} 1 & 1 & 1 \\ 30 & 16 & 24 \\ 40 & 24 & 34 \end{pmatrix} \cdot \begin{pmatrix} x \\ y \\ z \end{pmatrix} = \begin{pmatrix} 45 \\ 1116 \\ 1542 \end{pmatrix}.$$

We compute

$$\begin{pmatrix} 1 & 1 & 1 \\ 30 & 16 & 24 \\ 40 & 24 & 34 \end{pmatrix}^{-1} = \frac{1}{6} \begin{pmatrix} 16 & 5 & -4 \\ 30 & 3 & -3 \\ -40 & -8 & 7 \end{pmatrix}.$$

Hence the solution is

$$\begin{aligned} \begin{pmatrix} x \\ y \\ z \end{pmatrix} &= \frac{1}{6} \begin{pmatrix} 16 & 5 & -4 \\ 30 & 3 & -3 \\ -40 & -8 & 7 \end{pmatrix} \cdot \begin{pmatrix} 45 \\ 1116 \\ 1542 \end{pmatrix} \\ &= \frac{1}{6} \begin{pmatrix} 132 \\ 72 \\ 66 \end{pmatrix} = \begin{pmatrix} 22 \\ 12 \\ 11 \end{pmatrix}, \end{aligned}$$

expressed in words, there were 22 adults, 12 children and 11 seniors.  $\square$

The latter approach is particularly efficient if we have to solve several systems with the same matrix on the left hand side but different values on the right hand side.

But what if the matrix of the system is not invertible? Then we cannot use the inverse matrix for solving the system. Such a system cannot have a single solution. As the reader may have noticed above, a system of linear equations either has no solution, has one solution or has infinitely many solutions, depending on one or more free parameters (for instance, it cannot have exactly two solutions). We should have also noticed when dealing with equations with two variables in the previous section, that the space of the solutions is either a vector space (in the case when the right-hand side of the system is zero, we speak of a *homogeneous system* of linear equations) or an affine space, see 4.1.1 (in the case when the right-hand side of at least one of the equations is non-zero, we speak of a *non-homogeneous system* of linear equations).

We can recognize all the possibilities from the rank of the matrices, i.e. the number of nonzero rows left in the row-echelon form.

## 2. Determinants

In the fifth part of the first chapter, we introduced the scalar function  $\det$  on square matrices of dimension 2 over the real numbers, called determinant, see 1.5.5. We saw that the determinant assigned a non-zero number to a matrix if and only if the matrix was invertible. We did not say it in exactly this way, but you can check for yourself in previous paragraphs starting with 1.5.4 and formula 1.5.5(1).

We saw also that determinants were useful in another way, see the paragraphs 1.5.10 and 1.5.11. There we showed that the volume of the parallelepiped should be linearly dependent on every two of the vectors defining it. It was useful to require the change of the sign when changing the order of these vectors. Because determinants (and only determinants) have these properties, up to a constant scalar multiple, we concluded that it was determining the volume. Now we will see that we can proceed similarly for every finite dimension.

We work again with arbitrary scalars  $\mathbb{K}$  and matrices over these scalars. Our results about determinants will thus hold for all commutative rings, notably also for integer matrices or matrices over any residue classes.

**2.2.1. Definition of the determinant.** Each bijective mapping from a set  $X$  to itself is called a *permutation of the set*  $X$ , cf. 1.3.1. If  $X = \{1, 2, \dots, n\}$ , the permutation can be written by putting the resulting ordering into a table:

$$\begin{pmatrix} 1 & 2 & \dots & n \\ \sigma(1) & \sigma(2) & \dots & \sigma(n) \end{pmatrix}.$$

In this way, we shall view a permutation as a bijection or an ordering.

The element  $x \in X$  is called a fixed point of the permutation  $\sigma$  if  $\sigma(x) = x$ . If there exist exactly two distinct elements  $x, y \in X$  such that  $\sigma(x) = y$  while all other elements  $z \in X$  are fixed points, then the permutation  $\sigma$  is called a *transposition*, and we denote it by  $(x, y)$ . Of course, then  $\sigma(y) = x$  holds for such a transformation.

For dimension 2, the formula for a determinant was simple – take all possible products of two elements, one from every column and every row of the matrix, give them a sign such that interchanging two columns leads to the change of the sign of the whole result, and sum all of them (that is, both):

$$A = \begin{pmatrix} a & b \\ c & d \end{pmatrix}, \det A = ad - bc.$$

Consider now square matrices  $A = (a_{ij})$  of dimension  $n$  over  $\mathbb{K}$ . The formula for the determinant of the matrix  $A$  is also composed of all possible products from elements from individual rows and columns, with properly chosen signs.

In dimension 3 we can guess the correct signs easily. The product of the elements on the diagonal should be with positive sign and we want anti-symmetry when interchanging two columns or rows. This gives the so called *Sarrus rule*:

**2.A.20.** Determine the rank of the matrix

$$A = \begin{pmatrix} 1 & -3 & 0 & 1 \\ 1 & -2 & 2 & -4 \\ 1 & -1 & 0 & 1 \\ -2 & -1 & 1 & -2 \end{pmatrix}.$$

Then determine the number of solutions of the system of linear equations

$$\begin{aligned} x_1 + x_2 + x_3 - 2x_4 &= 4, \\ -3x_1 - 2x_2 - x_3 - x_4 &= 5, \\ + 2x_2 &+ x_4 = 1, \\ x_1 - 4x_2 + x_3 - 2x_4 &= 3 \end{aligned}$$

Determine also all solutions of the system

$$\begin{aligned} x_1 + x_2 + x_3 - 2x_4 &= 0, \\ -3x_1 - 2x_2 - x_3 - x_4 &= 0, \\ + 2x_2 &+ x_4 = 0, \\ x_1 - 4x_2 + x_3 - 2x_4 &= 0 \end{aligned}$$

and of the system

$$\begin{aligned} x_1 - 3x_2 &= 1, \\ x_1 - 2x_2 + 2x_3 &= -4, \\ x_1 - x_2 &= 1, \\ -2x_1 - x_2 + x_3 &= -2. \end{aligned}$$

**Solution.** Transforming the matrix to the row-echelon form, we check that the rank is four. (The rank cannot exceed the number of rows or columns). The first of the three given systems is given by the extended matrix

$$\left( \begin{array}{cccc|c} 1 & 1 & 1 & -2 & 4 \\ -3 & -2 & -1 & -1 & 5 \\ 0 & 2 & 0 & 1 & 1 \\ 1 & -4 & 1 & -2 & 3 \end{array} \right).$$

But the left-hand side is exactly  $A^T$  and thus we can get the column-echelon form the same way as before. In particular, the columns of the matrix are linearly independent and the rank is maximal, i.e. four again. Therefore there exists a matrix  $(A^T)^{-1}$  and the system has a unique solution

$$(x_1, x_2, x_3, x_4)^T = (A^T)^{-1} \cdot (4, 5, 1, 3)^T.$$

The second of the systems has the same left-hand side (given by the matrix  $A^T$ ) as the first. Because the numbers on the right-hand side of the equations in the system do not influence the number of solutions and because every homogeneous system has a zero solution, the only solution of the second system is given by

$$(x_1, x_2, x_3, x_4) = (0, 0, 0, 0).$$

SARRUS RULE

$$\begin{vmatrix} a_{11} & a_{12} & a_{13} \\ a_{21} & a_{22} & a_{23} \\ a_{31} & a_{32} & a_{33} \end{vmatrix} = a_{11}a_{22}a_{33} + a_{13}a_{21}a_{32} + a_{12}a_{23}a_{31} - a_{13}a_{22}a_{31} - a_{11}a_{23}a_{32} - a_{12}a_{21}a_{33}$$

The general definition can be formulated via a sum over all permutations:

DEFINITION OF DETERMINANT

The determinant of the matrix  $A$  is a scalar  $\det A = |A|$  defined by the relation

$$|A| = \sum_{\sigma \in \Sigma_n} \text{sgn}(\sigma) a_{1\sigma(1)} \cdot a_{2\sigma(2)} \cdots a_{n\sigma(n)}$$

where  $\Sigma_n$  is the set of all possible permutations over  $\{1, \dots, n\}$  and the symbol  $\text{sgn}$  for a permutation  $\sigma$ , called the parity of  $\sigma$ , will be described below. Each of the expressions

$$\text{sgn}(\sigma) a_{1\sigma(1)} \cdot a_{2\sigma(2)} \cdots a_{n\sigma(n)}$$

is called a *term in the determinant*  $|A|$ .

**2.2.2. Parity of permutation.** How should we define the sign of a permutation? We say that a pair of elements  $a, b \in X = \{1, \dots, n\}$  forms an *inversion in the permutation*  $\sigma$ , if  $a < b$  and  $\sigma(a) > \sigma(b)$ . A permutation  $\sigma$  is called *even* or *odd*, if it contains an even or odd number of inversions, respectively.

Thus, the *parity*  $\text{sgn} \sigma$  of the permutation  $\sigma$  is  $(-1)^{\text{number of inversions}}$  and we denote it by  $\text{sgn}(\sigma)$ . This amounts to our definition of sign for computing determinant. But we should like to know how to calculate the parity. The following theorem reveals that the Sarrus rule really defines the determinant in dimension 3.

**Theorem.** Over the set  $X = \{1, 2, \dots, n\}$  there are exactly  $n!$  distinct permutations. These can be ordered in a sequence such that every two consecutive permutations differ in exactly one transposition. Every transposition changes parity.

For any chosen permutation  $\sigma$  there is such a sequence starting with  $\sigma$ .

**PROOF.** For  $n = 1$  or  $n = 2$ , the claim is trivial. We prove the theorem by induction on the size  $n$  of the set  $X$ .

Assume that the claim holds for all sets with  $n - 1$  elements and consider a permutation  $\sigma(1) = a_1, \dots, \sigma(n) = a_n$ . According to the induction assumption, all the permutations that end with  $a_n$  can be obtained in a sequence, where every two consecutive permutations differ in one transposition. There are  $(n - 1)!$  such permutations. In order to proceed further, we select the last of them, and use the transposition of  $\sigma(n) = a_n$  with some element  $a_i$  which has not been at the last position yet. Once again, we form a sequence of all permutations that end with  $a_i$ . After doing this procedure  $n$ -times, we obtain  $n(n - 1)! = n!$  distinct permutations – that

The third system is given by the extended matrix

$$\left( \begin{array}{ccc|c} 1 & -3 & 0 & 1 \\ 1 & -2 & 2 & -4 \\ 1 & -1 & 0 & 1 \\ -2 & -1 & 1 & -2 \end{array} \right),$$

which is the matrix  $A$  (only the last column is given after the vertical bar). If we try to simplify the matrix into the row echelon form, we must obtain a row

$$(0 \ 0 \ 0 \mid a), \quad \text{where } a \neq 0.$$

We know, that the column on the right-hand side is not a linear combination of the columns on the left-hand side (the rank of the matrix is 4). This system thus has no solution.  $\square$

For further examples see 2.E.7

### B. Determinants

In order to be able to define the key object of the matrix calculus, the determinant, we must deal with permutations (bijections of a finite set) and their parities.

We shall use the two-row notation for permutations (see 2.2.1). In the first row we list all elements of the given set, and every column then corresponds to a pair (preimage, image) in the given permutation. Because a permutation is a bijection, the second row is indeed a permutation (ordering) of the first row, in accordance with the definition from combinatorics.

#### 2.B.1. Decompose the permutation

$$\sigma = \begin{pmatrix} 1 & 2 & 3 & 4 & 5 & 6 & 7 & 8 & 9 \\ 3 & 1 & 6 & 7 & 8 & 9 & 5 & 4 & 2 \end{pmatrix}$$

into a product of transpositions.

**Solution.** We first decompose the permutation into a product of independent cycles. Start with the first element 1 and look on the second row to see what the image of 1 is. It is 3. Now look on the column that starts with 3, and see that the image of 3 is 6, and so on. Continue until we again reach the starting element 1. We obtain the following sequence of elements, which map to each other under the given permutation:

$$1 \mapsto 3 \mapsto 6 \mapsto 9 \mapsto 2 \mapsto 1.$$

The mapping which maps elements in such a manner is called a cycle (see 2.2.3) which we denote by  $(1, 3, 6, 9, 2)$ .

Now choose any element not contained in the obtained cycle. With the same procedure as with 1, we obtain the cycle  $(4, 7, 5, 8)$ . From the method is clear that the result does not depend on the first obtained cycle. Each element from the set

is, all permutations on  $n$  elements. The resulting sequence satisfies the condition.

Note that the last sentence of the theorem does not seem to be useful in practice. But it is a very important part for proving the theorem by induction over the size of  $X$ .

It remains to prove the part of the theorem about parities. Consider the ordering

$$(a_1, \dots, a_i, a_{i+1}, \dots, a_n),$$

containing  $r$  inversions. Then in the ordering

$$(a_1, \dots, a_{i+1}, a_i, \dots, a_n)$$

there are either  $r - 1$  or  $r + 1$  inversions. Every transposition  $(a_i, a_j)$  is obtainable by doing  $(j-i) + (j-i-1) = 2(j-i) - 1$  transpositions of neighbouring elements.

Therefore any transposition changes the parity. Also, we already know that all permutations can be obtained by applying transpositions.  $\square$

We found that applying a transposition changes the parity of a permutation and any ordering of numbers  $\{1, 2, \dots, n\}$  can be obtained through transposing of neighbouring elements. Therefore we have proven

**Corollary.** *On every finite set  $X = \{1, \dots, n\}$  with  $n$  elements,  $n > 1$ , there are exactly  $\frac{1}{2}n!$  even permutations, and  $\frac{1}{2}n!$  odd permutations.*

If we compose two permutations, it means first doing all transpositions forming the first permutation and then all the transpositions forming the second one. Therefore for any two permutations  $\sigma, \eta : X \rightarrow X$  we have

$$\text{sgn}(\sigma \circ \eta) = \text{sgn}(\sigma) \cdot \text{sgn}(\eta)$$

and also

$$\text{sgn}(\sigma^{-1}) = \text{sgn}(\sigma).$$

**2.2.3. Decomposing permutations into cycles.** A good tool for practical work with permutations is the cycle decomposition, which is also a good exercise on the concept of equivalence.

#### CYCLES

A permutation  $\sigma$  over the set  $X = \{1, \dots, n\}$  is called a *cycle* of length  $k$ , if we can find elements  $a_1, \dots, a_k \in X$ ,  $2 \leq k \leq n$  such that  $\sigma(a_i) = a_{i+1}$ ,  $i = 1, \dots, k - 1$ , while  $\sigma(a_k) = a_1$ , and other elements in  $X$  are fixed-points of  $\sigma$ . Cycles of length two are transpositions.

Every permutation is a composition of cycles. Cycles of even length have parity  $-1$ , cycles of odd length have parity 1.

**PROOF.** The last claim has yet to be proved. Fix a permutation  $\sigma$  and define a relation  $R$  such that two elements  $x, y \in X$  are  $R$ -related if and only if  $\sigma^\ell(x) = y$  for some iteration  $\ell \in \mathbb{Z}$  of the permutation  $\sigma$  (notice  $\sigma^{-1}$  means the inverse bijection to  $\sigma$ ). Clearly, it is an equivalence relation

$\{1, 2, \dots, 9\}$  appears in one of the obtained cycles, we can thus write:

$$\sigma = (1, 3, 6, 9, 2) \circ (4, 7, 5, 8),$$

or

$$\sigma = (4, 7, 5, 8) \circ (1, 3, 6, 9, 2),$$

since independent cycles commute. For cycles the decomposition into transpositions is simple, we have

$$\begin{aligned} (1, 3, 6, 9, 2) &= (1, 3) \circ (3, 6) \circ (6, 9) \circ (9, 2) = \\ &= (1, 3)(3, 6)(6, 9)(9, 2). \end{aligned}$$

Thus we obtain:

$$\sigma = (1, 3)(3, 6)(6, 9)(9, 2)(4, 7)(7, 5)(5, 8).$$

□

**Remark.** The minimal number of transpositions in the decomposition of a permutation is obtained by carrying out exactly the procedure as above. That is, first decompose the permutation into the independent cycles, then the cycles canonically into the transpositions. Thus the found decomposition is the decomposition into the minimal number of transpositions.

Note also that the operation  $\circ$  is a composition of mappings, thus it is necessary to carry out the composition “backwards”, as we are used to in composition of mappings. Applying the given composition of transposition for instance on the element two we can successively write:

$$\begin{aligned} [(1, 3)(3, 6)(6, 9)(9, 2)](2) &= \\ [(1, 3)(3, 6)(6, 9)]((9, 2)(2)) &= \\ [(1, 3)(3, 6)(6, 9)](9) &= [(1, 3)(3, 6)](6) = (1, 3)(3) = 1, \end{aligned}$$

thus the mapping indeed maps the element 2 on the element 1 (it is actually just the cycle  $(1, 3, 6, 9, 2)$  written in a different way). When writing a composition of permutations, we often omit the sign “ $\circ$ ” and speak of the product of permutations.

When writing the cycle we write only the elements on which the cycle (that is, the mapping) nontrivially acts (that is, the element is mapped to some other element). Fixed-points of the cycle are not listed. Thus it is necessary to know on which set do we consider the given cycle (mostly it will be clear from the context). The cycle  $c = (4, 7, 5, 8)$  from the previous example is thus a mapping (permutation), which, in the two-row notation, looks like this

$$\begin{pmatrix} 1 & 2 & 3 & 4 & 5 & 6 & 7 & 8 & 9 \\ 1 & 2 & 3 & 7 & 8 & 6 & 5 & 4 & 9 \end{pmatrix}.$$

If the original permutation has some fixed-points they do not appear in the cycle decomposition.

(check it carefully!). Because  $X$  is a finite set, for some  $\ell$  it must be that  $\sigma^\ell(x) = x$ . If we pick one equivalence class  $\{x, \sigma(x), \dots, \sigma^{\ell-1}(x)\} \subset X$  and define other elements to be fixed-points, we obtain a cycle. Evidently, the original permutation  $X$  is then the composition of all these cycles for individual equivalence classes and it does not matter in which order we compose the cycles.

For determining the parity we just have to note that cycles of even length can be written as a composition of an odd number of transposition, therefore their parity is  $-1$ . Analogously, cycle of odd length can be obtained using an even number of transpositions and therefore it has parity 1. □

### 2.2.4. Expansion of determinant.

Our understanding of the permutations allows to find the *expansion* method of computing the determinants. The simple idea is to collect the terms containing an element in a fixed row in the determinant sum and to add these contributions along the row.

Consider a matrix  $A = (a_{ij})$  and let us look at all terms in  $|A|$  containing the element  $a_{11}$ . By the very definition, these terms correspond to all permutations  $\sigma$  with  $\sigma(1) = 1$ . Thus, the contribution of all these terms to  $|A|$  is  $a_{11}A_{11}$ , where  $A_{11}$  is the determinant of the matrix obtained from  $A$  by omitting the first row and the first column.

Similarly, we can take any other fixed element  $a_{ij}$  in  $A$  and look for the contribution of all terms containing it. Again, we could write  $A_{ij}$  for the determinant of the matrix obtained from  $A$  by omitting the  $i$ -th row and the  $j$ -th column, and the latter contribution must have terms like in  $a_{ij}A_{ij}$ , but we have to be very careful about the signs. While the actual terms of  $|A|$  would be  $\text{sgn } \sigma a_{ij} a_{1\sigma(1)} \dots \hat{\phantom{a}} \dots a_{n\sigma(n)}$  where the hat denotes the omission of the  $i$ -th entry and  $\sigma(i) = j$ , the signatures of the permutations in  $A_{ij}$ , with the  $i$  and  $j$  omitted might be different.

In order to compare it to the previous case  $i = 1, j = 1$ , we can change the initial ordering of the elements in the domain and target of the permutations  $\sigma$ . Clearly,  $i - 1$  changes on the domain and  $j - 1$  changes on the target do the job (by “bubbling” the index in question to the first position by consecutive swaps of neighboring positions).

Thus, the sign correction is  $(-1)^{i+j-2}$  and we have to adjust the value of  $A_{ij}$  as in the following algorithm, which is the simplest version of the more general Laplace expansion formula, see 2.2.9 below. The readers not sure about the details of our argumentation here may wait for the detailed proof in the more general situation.

Note further that the notation  $(1, 2, 3)$  gives the same cycle as for instance  $(2, 3, 1)$  or  $(3, 1, 2)$ . But the notation  $(1, 3, 2)$  is a different cycle.

**2.B.2.** Determine the parity of the following permutations:

$$\sigma = \begin{pmatrix} 1 & 2 & 3 & 4 & 5 & 6 & 7 & 8 & 9 \\ 3 & 1 & 6 & 7 & 8 & 9 & 5 & 4 & 2 \end{pmatrix},$$

$$\tau = \begin{pmatrix} 1 & 2 & 3 & 4 & 5 & 6 \\ 2 & 4 & 6 & 1 & 5 & 3 \end{pmatrix}.$$

**Solution.** According to our definition (see 2.2.2) we compute the number of inversions of  $\sigma$ : we go sequentially through the second row in the two-row notation and for every number  $k$  there we count the number of numbers which are smaller than  $k$  and are located after  $k$  in the second row. It is not hard to see that the number of inversions in a given permutation is exactly the number of pairs “larger before smaller” in the second row. For  $\sigma$  we compute (stepping through the second row): after three there is one and two, thus we add 2; after one there is no smaller number and we add 0; after six there is five, four and two, thus we add 3, similarly for seven, eight and nine, for five we add 2, for four we add 1 and for two nothing. Thus we have 17 inversions in total and thus the permutation is odd.

But we can compute the parity of  $\sigma$  otherwise. The theorem 2.2.2 implies that the parity of a permutation is given by the parity of the number of transpositions in its decomposition (this number is, unlike the number of transposition in an arbitrary decomposition, always the same)

The previous exercise gives us  $\sigma = (1, 3)(3, 6)(6, 9)(9, 2)(4, 7)(7, 5)(5, 8)$ . There are seven transpositions in the decomposition, thus the permutation is indeed odd.

Alternatively we can decompose  $\tau$  into either a product of three transpositions (using the cycle decomposition):

$$\tau = (1, 2, 4)(3, 6) = (1, 2)(2, 4)(3, 6),$$

or we count the number of inversions in  $\tau$ :  $1+2+3+0+1 = 7$ . Either way we find that  $\tau$  is an odd permutation.

In general, as soon as the decomposition to cycles is ready, we may just count the lengths of the cycles, since each cycle including  $k$  elements is clearly built of  $k - 1$  transpositions and thus contributes  $(-1)^{k-1}$  to the parity.  $\square$

For the following exercises, recall how to compute determinants of the type  $2 \times 2$  ( $a_{11} \cdot a_{22} - a_{12} \cdot a_{21}$ ) and  $3 \times 3$  (Sarrus rule), see 2.2.1.

EXPANSION OF DETERMINANT

The algebraic complement  $A_{ij}$  of the element  $a_{ij}$  in a matrix  $A$  is the  $(-1)^{i+j}$ -multiple of the determinant of the matrix obtained from  $A$  by omitting the  $i$ -th row and the  $j$ -th column.

Fixing the  $i$ -th row or  $j$ -th column,

$$|A| = \sum_{j=1}^n a_{ij}A_{ij}, \quad |A| = \sum_{i=1}^n a_{ij}A_{ij}.$$

The latter formulae correspond to splitting the determinant sum to parts containing terms with the individual elements in the row or column.

For example, an easy application derives the Sarrus rule from the formula in dimension 2 now.

**2.2.5. Simple properties.** Knowing the properties of permutations and their parities from previous paragraphs allows us to derive quickly basic properties of determinants.

For every matrix  $A = (a_{ij})$  of the type  $m/n$  over scalars from  $\mathbb{K}$  we define the transpose of  $A$  as the matrix  $A^T = (a'_{ij})$  with elements  $a'_{ij} = a_{ji}$ . The matrix  $A^T$  is of the type  $n/m$ .

A square matrix  $A$  with the property  $A = A^T$  is called symmetric. If  $A = -A^T$ , then  $A$  is called antisymmetric.

SIMPLE PROPERTIES OF DETERMINANTS

**Theorem.** Every square matrix  $A = (a_{ij})$  satisfies the following conditions:

- (1)  $|A^T| = |A|$ .
- (2) If one of the rows contains only zero elements from  $\mathbb{K}$ , then  $|A| = 0$ .
- (3) If a matrix  $B$  was obtained from  $A$  by transposing two rows, then  $|A| = -|B|$ .
- (4) If a matrix  $B$  was obtained from  $A$  by multiplying one row by a scalar  $a \in \mathbb{K}$ , then  $|B| = a|A|$ .
- (5) If all elements of the  $k$ -th row in  $A$  are of the form  $a_{kj} = c_{kj} + b_{kj}$  and all remaining rows in the matrices  $A, B = (b_{ij}), C = (c_{ij})$  are identical, then  $|A| = |B| + |C|$ .
- (6) A determinant  $|A|$  does not change if we add to any row of  $A$  a linear combination of other rows.

**PROOF.** (1) The terms of determinants  $|A|$  and  $|A^T|$  are in bijective correspondence, where the term  $\text{sgn}(\sigma)a_{1\sigma(1)} \cdot a_{2\sigma(2)} \cdots a_{n\sigma(n)}$  corresponds the following  $A^T$  term (notice it does not depend on the order of scalars)

$$\begin{aligned} \text{sgn}(\sigma)a_{\sigma(1)1} \cdot a_{\sigma(2)2} \cdots a_{\sigma(n)n} &= \\ &= \text{sgn}(\sigma)a_{1\sigma^{-1}(1)} \cdot a_{2\sigma^{-1}(2)} \cdots a_{n\sigma^{-1}(n)}, \end{aligned}$$

and we have to ensure that this member has the correct sign. But the parities of  $\sigma$  and  $\sigma^{-1}$  are the same, and so this is really a term in the determinant  $|A^T|$  and the first claim is proved.

**2.B.3.** Compute the determinant of the following matrices

$$\begin{pmatrix} 1 & 2 \\ 2 & 1 \end{pmatrix}, \quad \begin{pmatrix} 1 & 2 & 3 \\ 1 & -1 & 2 \\ 3 & 2 & 2 \end{pmatrix}, \quad \begin{pmatrix} 1 & 1 & 1 \\ 1 & 0 & 0 \\ -2 & 0 & 1 \end{pmatrix}.$$

**Solution.** The determinant of the first matrix is  $1 \cdot 1 - 2 \cdot 2 = -3$ .

As for the second matrix, according to the Sarrus rule we just have to enumerate the expression

$$1 \cdot (-1) \cdot 2 + 2 \cdot 2 \cdot 3 + 3 \cdot 1 \cdot 2 - 3 \cdot (-1) \cdot 3 - 1 \cdot 2 \cdot 2 - 1 \cdot 2 \cdot 2 = 17.$$

We can also bring the matrix into the row echelon form and then multiply the numbers on the diagonal but we have to remember that a multiplication of a row with a scalar changes the determinant of the matrix by the same multiple. Interchanging two rows changes the sign of the determinant of the matrix.

$$\begin{aligned} \begin{vmatrix} 1 & 2 & 3 \\ 1 & -1 & 2 \\ 3 & 2 & 2 \end{vmatrix} &= \begin{vmatrix} 1 & 2 & 3 \\ 0 & -3 & -1 \\ 0 & -4 & -7 \end{vmatrix} = \frac{1}{-4} \cdot \frac{1}{3} \cdot \begin{vmatrix} 1 & 2 & 3 \\ 0 & 12 & 4 \\ 0 & -12 & -21 \end{vmatrix} \\ &= -\frac{1}{12} \cdot \begin{vmatrix} 1 & 2 & 3 \\ 0 & 12 & 4 \\ 0 & 0 & -17 \end{vmatrix} \end{aligned}$$

We finish with an upper triangular matrix. The determinant of such matrices is the product of the numbers on the main diagonal. So the result is  $-\frac{1}{12}(1 \cdot 12 \cdot (-17)) = 17$ .

We can see, that using the Sarrus rule is quicker.

For the third matrix we have

$$1 \cdot 0 \cdot 1 + 1 \cdot 0 \cdot 1 + 1 \cdot 0 \cdot (-2) - 1 \cdot 0 \cdot (-2) - 1 \cdot 1 \cdot 1 - 1 \cdot 0 \cdot 0 = -1.$$

□

It is important to realize, that Sarrus rule can be used for matrices  $3 \times 3$  only. For higher dimension matrices you can either bring the matrix to the row echelon form (where you have to take in to account rules 2.2.5) or use the Laplace expansion (see 2.2.9).

**2.B.4.** Compute the determinant of the matrix

$$\begin{pmatrix} 1 & 3 & 5 & 6 \\ 1 & 2 & 2 & 2 \\ 1 & 1 & 1 & 2 \\ 0 & 1 & 2 & 1 \end{pmatrix}.$$

**Solution.** We compute this in two ways. First, convert the matrix to row echelon form. We can use already known elementary transformations,

(2) This comes straight from the definition of determinant, because all its terms contain exactly one member from every row. Thus, if one of the rows is zero, all terms of the determinant are also zero.

(3) The only change in the terms of  $|B|$  compared to  $|A|$  is the addition of one transposition in all permutations, therefore all the signs will be reversed.

(4) This follows straight from the definition, because terms of  $|B|$  are just terms of  $|A|$  multiplied by the scalar  $a$ .

(5) In every term of  $|A|$ , there is exactly one element from the  $k$ -th row of the matrix  $A$ . By the distributive law for multiplication and addition in  $\mathbb{K}$ , the claim follows directly from the definition of determinant.

(6) If there are two identical rows in  $A$ , then there are always two identical terms among all terms in the determinant, up to the sign. Therefore in this case  $|A| = 0$ . Thus, by (5), we can add any other row to the given row, without changing the value of the determinant. In view of the claims (4) and (5), we can in fact add a scalar multiple of any other row. □

**2.2.6. Computational corollaries.** By the previous theorem,

we can use elementary row transformations to bring any square matrix  $A$  into row echelon form, without changing the value of its determinant. We just have to be careful and add only linear combinations of other rows to a given one.

Thus let us look at the distribution of the elements in the individual terms of a determinant  $|A|$  with dimension of  $A$  equal to  $n > 1$ . There is just one term with all of its elements on the diagonal. In all other terms, there must be elements both above and below the diagonal (if we place one element outside of the diagonal, we block two diagonal entries and we leave only  $n - 2$  diagonal positions for the other  $n - 1$  elements).

Therefore, if the matrix  $A$  is in a row echelon form, then every term of  $|A|$  is zero, except the term with exclusively diagonal entries. This proves the following algorithm:

COMPUTING DETERMINANTS USING ELIMINATION

If  $A$  is in the row echelon form then

$$|A| = a_{11}a_{22} \cdots a_{nn}.$$

The previous theorem gives an effective method for computing determinants using the Gauss elimination method, see the paragraph 2.1.7.

Notice that the very same argumentation allows us to stop the elimination having the first  $k$  columns in the requested form and finding the determinant of the matrix  $B$  of dimension  $n - k$  in the right bottom corner of  $A$  in another way. The result will then be  $|A| = a_{11}a_{22} \cdots a_{kk}|B|$ .

Let us note a nice corollary of the first claim of the previous theorem about the equality of the determinants of the matrix and its transpose. It ensures that whenever we prove some claim about determinants formulated in terms of rows

$$\begin{vmatrix} 1 & 3 & 5 & 6 \\ 1 & 2 & 2 & 2 \\ 1 & 1 & 1 & 2 \\ 0 & 1 & 2 & 1 \end{vmatrix} = - \begin{vmatrix} 1 & 1 & 1 & 2 \\ 1 & 2 & 2 & 2 \\ 1 & 3 & 5 & 6 \\ 0 & 1 & 2 & 1 \end{vmatrix} = - \begin{vmatrix} 1 & 1 & 1 & 2 \\ 0 & 1 & 1 & 0 \\ 0 & 2 & 4 & 4 \\ 0 & 1 & 2 & 1 \end{vmatrix} \\ = - \begin{vmatrix} 1 & 1 & 1 & 2 \\ 0 & 1 & 1 & 0 \\ 0 & 0 & 2 & 4 \\ 0 & 0 & 1 & 1 \end{vmatrix} = \begin{vmatrix} 1 & 1 & 1 & 2 \\ 0 & 1 & 1 & 0 \\ 0 & 0 & 1 & 1 \\ 0 & 0 & 2 & 4 \end{vmatrix} = \begin{vmatrix} 1 & 1 & 1 & 2 \\ 0 & 1 & 1 & 0 \\ 0 & 0 & 1 & 1 \\ 0 & 0 & 0 & 2 \end{vmatrix} = 2.$$

Note, that we have interchanged the rows twice in the course of computation.

The other way of computing the determinant is by cofactor expansion along the first column (the one with the greatest number (one) of zeroes). Successively we obtain

$$\begin{vmatrix} 1 & 3 & 5 & 6 \\ 1 & 2 & 2 & 2 \\ 1 & 1 & 1 & 2 \\ 0 & 1 & 2 & 1 \end{vmatrix} = 1 \cdot \begin{vmatrix} 2 & 2 & 2 \\ 1 & 1 & 2 \\ 1 & 2 & 1 \end{vmatrix} - 1 \cdot \begin{vmatrix} 3 & 5 & 6 \\ 1 & 1 & 2 \\ 1 & 2 & 1 \end{vmatrix} + \\ 1 \cdot \begin{vmatrix} 3 & 5 & 6 \\ 2 & 2 & 2 \\ 1 & 2 & 1 \end{vmatrix} \stackrel{\text{using the Sarrus rule}}{=} -2 - 2 + 6 = 2.$$

**2.B.5.** Compute the determinant of the matrix

$$\begin{pmatrix} 1 & 0 & 1 & 0 & 1 \\ 0 & 2 & 0 & 2 & 0 \\ 0 & 0 & 3 & 0 & 3 \\ 4 & 0 & 0 & 4 & 4 \\ 0 & 0 & 0 & 0 & 5 \end{pmatrix}$$

**Solution.** We notice, that the last (fifth) row contains four zeros (as well as the second column). It is the most, we can find in a row or a column in the matrix, thus it will be advantageous to use Laplace theorem (2.3.10) and compute the determinant via expansion along the fifth row or second column.

We present the expansion via fifth row:

$$\begin{vmatrix} 1 & 0 & 1 & 0 & 1 \\ 0 & 2 & 0 & 2 & 0 \\ 0 & 0 & 3 & 0 & 3 \\ 4 & 0 & 0 & 4 & 4 \\ 0 & 0 & 0 & 0 & 5 \end{vmatrix} = 0 \cdot \begin{vmatrix} 0 & 1 & 0 & 1 \\ 2 & 0 & 2 & 0 \\ 0 & 3 & 0 & 3 \\ 0 & 0 & 4 & 4 \end{vmatrix} - 0 \cdot \begin{vmatrix} 1 & 1 & 0 & 1 \\ 0 & 0 & 2 & 0 \\ 0 & 3 & 0 & 3 \\ 4 & 0 & 4 & 4 \end{vmatrix} \\ + 0 \cdot \begin{vmatrix} 1 & 0 & 0 & 1 \\ 0 & 2 & 2 & 0 \\ 0 & 0 & 0 & 3 \\ 4 & 0 & 4 & 4 \end{vmatrix} - 0 \cdot \begin{vmatrix} 1 & 0 & 1 & 1 \\ 0 & 2 & 0 & 0 \\ 0 & 0 & 3 & 3 \\ 4 & 0 & 0 & 4 \end{vmatrix} + 5 \cdot \begin{vmatrix} 1 & 0 & 1 & 0 \\ 0 & 2 & 0 & 2 \\ 0 & 0 & 3 & 0 \\ 4 & 0 & 0 & 4 \end{vmatrix} \\ = 5 \cdot \begin{vmatrix} 1 & 0 & 1 & 0 \\ 0 & 2 & 0 & 2 \\ 0 & 0 & 3 & 0 \\ 4 & 0 & 0 & 4 \end{vmatrix} = 5 \cdot 2 \cdot \begin{vmatrix} 1 & 1 & 0 \\ 0 & 3 & 0 \\ 4 & 0 & 4 \end{vmatrix} = 120,$$

of the corresponding matrix, we immediately obtain an analogous claim in terms of the columns.

For instance, we can immediately formulate all the claims (2)–(6) for linear combinations of columns.

As a useful (theoretical) illustration of this principle, we shall derive the following formula for direct calculation of solutions of systems of linear equations. For sake of simplicity, we shall work with field of scalars now.

CRAMER RULE

**Proposition.** Consider the system of  $n$  linear equations for  $n$  variables with matrix of the system  $A = (a_{ij})$  and the column of values  $b = (b_1, \dots, b_n)$ . In matrix notation this means we are solving the equation  $A \cdot x = b$ .

If there exists the inverse  $|A|^{-1}$ , then the individual components of the unique solution  $x = (x_1, \dots, x_n)$  are given as

$$x_i = |A_i| |A|^{-1},$$

where the matrices  $A_i$  arise from the matrix  $A$  of the system by replacing the  $i$ -th column by the column  $b$  of values.

**PROOF.** As we have already seen, working over field of scalars the inverse of the matrix of the system exists if and only if the system has a unique solution, and this in turn happens if and only if  $|A|^{-1}$  exists. If we have such a solution  $x$ , we can express the column  $b$  in the matrix  $A_i$  by the corresponding linear combination of the columns of the matrix  $A$ , that is the values  $b_k = a_{k1}x_1 + \dots + a_{kn}x_n$ . Then, by subtracting the  $x_\ell$ -multiples of all the other  $\ell$ -th columns from this  $i$ -th column in  $A_i$ , we arrive at just the  $x_i$ -multiple of the original column of  $A$ . The number  $x_i$  can thus be brought in front of the determinant to obtain the equation  $|A_i| = x_i |A|$ , and thus  $|A_i| |A|^{-1} = x_i |A| |A|^{-1} = x_i$ , which is our claim.  $\square$

Notice also that the properties (3)–(5) from the previous theorem say that the determinant, (considered as a mapping which assigns a scalar to  $n$  vectors of dimension  $n$ ), is an antisymmetric mapping linear in every argument, exactly as we required in analogy to the 2-dimensional case.

**2.2.7. Further properties of the determinant.** Later we

will see that, exactly as in the dimension 2, the determinant of the matrix equals to the (oriented) volume of the parallelepiped determined by the columns of the matrix. We shall also see that considering the mapping  $x \mapsto A \cdot x$  given by the square matrix  $A$  on  $\mathbb{R}^n$  we can understand the determinant of this matrix as expressing the ratio between the volume of the parallelepipeds given by the vectors  $x_1, \dots, x_n$  and their images  $A \cdot x_1, \dots, A \cdot x_n$ .

Because the composition  $x \mapsto A \cdot x \mapsto B \cdot (A \cdot x)$  of mappings corresponds to the matrix multiplication, the *Cauchy theorem* below is easy to understand:

where we have used the expansion along the second column in the second step and computed the determinant of the  $3 \times 3$  matrix directly using the Sarrus rule.

Another option is to try to expand the determinant along several rows, exploiting vanishing of many sub-determinants there. For example, we may use the last two rows. Clearly there might be only two non-zero sub-determinants built from this row there. Thus the entire determinant must be (notice that choosing two lines and two columns always leads to the plus sign in the definition of the algebraic complement, see 2.3.10)

$$\begin{vmatrix} 4 & 4 & | & 0 & 1 & 0 \\ 0 & 5 & | & 2 & 0 & 2 \\ & & | & 0 & 3 & 0 \end{vmatrix} + \begin{vmatrix} 4 & 4 & | & 0 & 1 & 0 \\ 0 & 5 & | & 2 & 0 & 2 \\ & & | & 0 & 0 & 3 \end{vmatrix} = 20 \cdot 0 + 20 \cdot 6 = 120$$

□

**2.B.6.** Find all the values of  $a$  such that

$$\begin{vmatrix} a & 1 & 1 & 1 \\ 0 & a & 1 & 1 \\ 0 & 1 & a & 1 \\ 0 & 0 & 0 & -a \end{vmatrix} = 1.$$

For complex  $a$  give either its algebraic or polar form.

**Solution.** We compute the determinant by expanding the first row of the matrix:

$$D = \begin{vmatrix} a & 1 & 1 & 1 \\ 0 & a & 1 & 1 \\ 0 & 1 & a & 1 \\ 0 & 0 & 0 & -a \end{vmatrix} = a \cdot \begin{vmatrix} a & 1 & 1 \\ 1 & a & 1 \\ 0 & 0 & -a \end{vmatrix}.$$

Expand further using the last row:

$$D = a \cdot (-a) \begin{vmatrix} a & 1 \\ 1 & a \end{vmatrix} = -a^2(a^2 - 1).$$

We conclude that  $a^4 - a^2 + 1 = 0$ . Substituting  $t = a^2$  we have  $t^2 - t + 1$  with roots  $t_1 = \frac{1+i\sqrt{3}}{2} = \cos(\pi/3) + i\sin(\pi/3)$ ,  $t_2 = \frac{1-i\sqrt{3}}{2} = \cos(\pi/3) - i\sin(\pi/3) = \cos(-\pi/3) + i\sin(-\pi/3)$ , from where we obtain four possible values for the parameter  $a$ :  $a_1 = \cos(\pi/6) + i\sin(\pi/6) = \sqrt{3}/2 + i/2$ ,  $a_2 = \cos(7\pi/6) + i\sin(7\pi/6) = -\sqrt{3}/2 - i/2$ ,  $a_3 = \cos(-\pi/6) + i\sin(-\pi/6) = \sqrt{3}/2 - i/2$ ,  $a_4 = \cos(5\pi/6) + i\sin(5\pi/6) = -\sqrt{3}/2 + i/2$ .

Alternatively, we can multiply by  $a^2 + 1$  to obtain

$$a^6 + 1 = (a^2 + 1)(a^4 - a^2 + 1) = 0.$$

The equation  $a^6 = -1$  has six (complex) solutions given by  $a = \cos \varphi + i \sin \varphi$  where  $\varphi = \pi/6 + k\pi/3 = (2k + 1)\pi/6$ ,  $k = 0, 1, 2, 3, 4, 5$ . Of these, we must discard the two choices  $k = 1$ , and  $k = 4$ , since these choices solve  $a^2 + 1 = 0$  and

CAUCHY THEOREM

**Theorem.** Let  $A = (a_{ij})$ ,  $B = (b_{ij})$  be square matrices of dimension  $n$  over the ring of scalars  $\mathbb{K}$ . Then

$$|A \cdot B| = |A| \cdot |B|.$$

In the next paragraphs, we derive this theorem in a purely algebraic way, in particular because the previous argumentation based on geometrical intuition could hardly work for arbitrary scalars. The basic tool is the *determinant expansion* using one or more of the rows or columns which we have seen in simplest case of single rows or columns in 2.2.4.

We will also need a little technical preparation. The reader who is not fond of too much abstraction can skip these paragraphs and note only the statement of the Laplace theorem and its corollaries.

Notice also, the claims (2), (3) and (6) from the theorem 2.2.5 are easily deduced from the Cauchy theorem and the representation of the elementary row transformations as multiplication by suitable matrices (cf. 2.1.8).

**2.2.8. Minors of the matrix.** When investigating matrices and their properties we often work only with parts of the matrices. Therefore we need some new concepts.

SUBMATRICES AND MINORS

Let  $A = (a_{ij})$  be a matrix of the type  $m/n$  and let  $1 \leq i_1 < \dots < i_k \leq m$ ,  $1 \leq j_1 < \dots < j_\ell \leq n$  be fixed natural numbers. Then the matrix

$$M = \begin{pmatrix} a_{i_1 j_1} & a_{i_1 j_2} & \dots & a_{i_1 j_\ell} \\ \vdots & \vdots & \dots & \vdots \\ a_{i_k j_1} & a_{i_k j_2} & \dots & a_{i_k j_\ell} \end{pmatrix}$$

of the type  $k/\ell$  is called a *submatrix of the matrix A* determined by the rows  $i_1, \dots, i_k$  and columns  $j_1, \dots, j_\ell$ . The remaining  $(m - k)$  rows and  $(n - \ell)$  columns determine a matrix  $M^*$  of the type  $(m-k)/(n-\ell)$ , which is called *complementary submatrix* to  $M$  in  $A$ . When  $k = \ell$  we call the determinant  $|M|$  the *subdeterminant* or *minor* of the order  $k$  of the matrix  $A$ . If  $m = n$  and  $k = \ell$ , then  $M^*$  is also a square matrix and  $|M^*|$  is called the *minor complement* to  $|M|$ , or *complementary minor* of the submatrix  $M$  in the matrix  $A$ . The scalar

$$(-1)^{i_1 + \dots + i_k + j_1 + \dots + j_\ell} \cdot |M^*|$$

is then called the *algebraic complement* of the minor  $|M|$ .

The submatrices formed by the first  $k$  rows and columns are called *leading principal submatrices*, and their determinants are called *leading principal minors* of the matrix  $A$ . If we choose  $k$  sequential rows and columns starting with the  $i$ -th row, we speak of *principal submatrices* and *principal minors*.

not  $a^4 - a^2 + 1 = 0$ . We conclude that  $a = \cos \varphi + i \sin \varphi$  where  $\varphi = (2k + 1)\pi/6, k = 0, 2, 3, \text{ or } 5$ .  $\square$

**2.B.7. Vandermonde determinant.** Prove the formula for

the Vandermonde determinant, that is, the determinant of the Vandermonde matrix:

$$V_n = \begin{vmatrix} 1 & 1 & \dots & 1 \\ x_1 & x_2 & \dots & x_n \\ x_1^2 & x_2^2 & \dots & x_n^2 \\ \vdots & \vdots & & \vdots \\ x_1^{n-1} & x_2^{n-1} & \dots & x_n^{n-1} \end{vmatrix} = \prod_{1 \leq i < j \leq n} (x_j - x_i),$$

where  $x_1, \dots, x_n \in \mathbb{R}$  and on the right-hand side of the equation there is the product of all terms  $x_j - x_i$  where  $j > i$ .

**Solution.** We proceed by induction on  $n$ . From technical reasons we work with the transposed Vandermonde matrix (it has the same determinant). By subtracting the first row from all other rows and then expanding the first column we obtain

$$\begin{aligned} &V_n(x_1, x_2, \dots, x_n) \\ &= \begin{vmatrix} 1 & x_1 & x_1^2 & \dots & x_1^{n-1} \\ 0 & x_2 - x_1 & x_2^2 - x_1^2 & \dots & x_2^{n-1} - x_1^{n-1} \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 0 & x_n - x_1 & x_n^2 - x_1^2 & \dots & x_n^{n-1} - x_1^{n-1} \end{vmatrix} \\ &= \begin{vmatrix} x_2 - x_1 & x_2^2 - x_1^2 & \dots & x_2^{n-1} - x_1^{n-1} \\ \vdots & \vdots & \ddots & \vdots \\ x_n - x_1 & x_n^2 - x_1^2 & \dots & x_n^{n-1} - x_1^{n-1} \end{vmatrix}. \end{aligned}$$

If we take out  $x_{i+1} - x_1$  from the  $i$ -th row for  $i \in \{1, 2, \dots, n - 1\}$ , we obtain

$$\begin{aligned} &V_n(x_1, x_2, \dots, x_n) = (x_2 - x_1) \cdots (x_n - x_1) \\ &\cdot \begin{vmatrix} 1 & x_2 + x_1 & \dots & \sum_{j=0}^{n-2} x_2^{n-j-2} x_1^j \\ \vdots & \vdots & \ddots & \vdots \\ 1 & x_n + x_1 & \dots & \sum_{j=0}^{n-2} x_n^{n-j-2} x_1^j \end{vmatrix}. \end{aligned}$$

By subtracting from every column (starting with the last and ending with the second)  $x_1$ -multiple of the previous column, we obtain

$$\begin{aligned} &\begin{vmatrix} 1 & x_2 + x_1 & \dots & \sum_{j=0}^{n-2} x_2^{n-j-2} x_1^j \\ \vdots & \vdots & \ddots & \vdots \\ 1 & x_n + x_1 & \dots & \sum_{j=0}^{n-2} x_n^{n-j-2} x_1^j \end{vmatrix} \\ &= \begin{vmatrix} 1 & x_2 & \dots & x_2^{n-2} \\ \vdots & \vdots & \ddots & \vdots \\ 1 & x_n & \dots & x_n^{n-2} \end{vmatrix}. \end{aligned}$$

Specially, when  $k = \ell = 1, m = n$  we call the corresponding algebraic complementary minor the *algebraic complement*  $A_{ij}$  of the element  $a_{ij}$  of the matrix  $A$ , which we met already in 2.2.4.

**2.2.9. Laplace determinant expansion.** If the leading principal minor  $|M|$  of the matrix  $A$  is of the order

$k$ , then, directly from the definition of the determinant, each of the individual  $k!(n - k)!$  terms in the product of  $|M|$  with its algebraic complement is a term of  $|A|$ .

In general, consider a square submatrix  $M$ , that is, a square matrix given by the rows  $i_1 < i_2 < \dots < i_k$  and columns  $j_1 < \dots < j_k$ . Then using  $(i_1 - 1) + \dots + (i_k - k)$  exchanges of neighbouring rows and  $(j_1 - 1) + \dots + (j_k - k)$  exchanges of neighbouring columns in  $A$  we can transform this submatrix  $M$  into a leading principal submatrix and the complementary matrix gets transformed into its complementary matrix.

The whole matrix  $A$  gets transformed into a matrix  $B$  satisfying (cf. 2.2.5 and the definition of the determinant)  $|B| = (-1)^\alpha |A|$ , where  $\alpha = \sum_{h=1}^k (i_h + j_h) - 2(1 + \dots + k)$ . But  $(-1)^\alpha = (-1)^\beta$  with  $\beta = \sum_{h=1}^k (i_h + j_h)$ . Therefore we have checked:

**Proposition.** If  $A$  is a square matrix of dimension  $n$  and  $|M|$  is its minor of the order  $k < n$ , then the product of any term of  $|M|$  with any term of its algebraic complement is a term in the determinant  $|A|$ .

This claim suggests that we could perhaps express the determinant of the matrix by using some products of smaller determinants. We see that  $|A|$  contains exactly  $n!$  distinct terms, exactly one for each permutation. These terms are mutually distinct as polynomials in the components of a general matrix  $A$ . If we can show that there are exactly that many mutually distinct expressions from the previous claim, we obtain the determinant  $|A|$  as their sum.

It remains to show that the terms of the product  $|M| \cdot |M^*|$  contain exactly  $n!$  distinct members from  $|A|$ .

From the chosen  $k$  rows we can choose  $\binom{n}{k}$  minors  $M$  and using the previous lemma each of the  $k!(n - k)!$  terms in the products of  $|M|$  with their algebraic complements is a term in  $|A|$ . But for distinct choices of  $M$  we can never obtain the same terms and the individual terms in  $(-1)^{i_1 + \dots + i_k + j_1 + \dots + j_l} \cdot |M| \cdot |M^*|$  are also mutually distinct. Therefore we have exactly the required number  $k!(n - k)! \binom{n}{k} = n!$  of terms, and we have proved:

LAPLACE THEOREM

**Theorem.** Let  $A = (a_{ij})$  be a square matrix of dimension  $n$  over arbitrary ring of scalars with  $k$  rows fixed. Then  $|A|$  is a sum of all  $\binom{n}{k}$  products  $(-1)^{i_1 + \dots + i_k + j_1 + \dots + j_l} \cdot |M| \cdot |M^*|$  of minors of the order  $k$  chosen among the fixed rows with their algebraic complements.

Therefore

$$V_n(x_1, x_2, \dots, x_n) = (x_2 - x_1) \cdots (x_n - x_1) V_{n-1}(x_2, \dots, x_n).$$

Because it is clear that

$$V_2(x_{n-1}, x_n) = x_n - x_{n-1},$$

it follows by induction that

$$V_n(x_1, x_2, \dots, x_n) = \prod_{1 \leq i < j \leq n} (x_j - x_i).$$

Note that the determinant is non-zero whenever the numbers  $x_1, \dots, x_n$  are mutually distinct.  $\square$

**Remark.** Another (more beautiful?) proof of the formula can be found in 5.1.5.

**2.B.8.** Find whether or not the matrix

$$\begin{pmatrix} 3 & 2 & -1 & 2 \\ 4 & 1 & 2 & -4 \\ -2 & 2 & 4 & 1 \\ 2 & 3 & -4 & 8 \end{pmatrix}$$

is invertible.

**Solution.** The matrix is invertible (that is, there is an inverse matrix) whenever we can transform it by elementary row transformations into the unit matrix. That is equivalent for instance to the property that it has non-zero determinant. That we can compute using the Laplace Theorem (2.3.10) by expanding for instance the first row:

$$\begin{aligned} & \begin{vmatrix} 3 & 2 & -1 & 2 \\ 4 & 1 & 2 & -4 \\ -2 & 2 & 4 & 1 \\ 2 & 3 & -4 & 8 \end{vmatrix} = 3 \cdot \begin{vmatrix} 1 & 2 & -4 \\ 2 & 4 & 1 \\ 3 & -4 & 8 \end{vmatrix} \\ & -2 \cdot \begin{vmatrix} 4 & 2 & -4 \\ -2 & 4 & 1 \\ 2 & -4 & 8 \end{vmatrix} + (-1) \cdot \begin{vmatrix} 4 & 1 & -4 \\ -2 & 2 & 1 \\ 2 & 3 & 8 \end{vmatrix} \\ & -2 \cdot \begin{vmatrix} 4 & 1 & 2 \\ -2 & 2 & 4 \\ 2 & 3 & -4 \end{vmatrix} \\ & = 3 \cdot 90 - 2 \cdot 180 + (-1) \cdot 110 - 2 \cdot (-100) = 0, \end{aligned}$$

that is, the given matrix is not invertible.  $\square$

**2.B.9.** Solve the system from 2.A.2 using the Cramer rule (see 2.2.6).

The Laplace theorem transforms the computation of  $|A|$  into the computation of determinants of lower dimension. This method of computation is called the *Laplace expansion* along the chosen rows (or columns). For instance, the expansion along the  $i$ -th row or the  $j$ -th column is:

$$|A| = \sum_{j=1}^n a_{ij} A_{ij} = \sum_{i=1}^n a_{ij} A_{ij}$$

where  $A_{ij}$  are the algebraic complements of the elements  $a_{ij}$  (that is, minors of order one), as deduced in 2.2.4 already.

In practical computations, it is often efficient to combine the Laplace expansion with a direct method of Gaussian elimination.

**2.2.10. Proof of the Cauchy theorem.** The theorem is based on a clever but elementary application of the Laplace theorem. We just use the Laplace expansion twice on a particular arrangement of a well chosen matrix.

Consider first the following matrix  $H$  of dimension  $2n$  (we are using the so-called block symbolics, that is, we write the matrix as if composed of the (sub)matrices  $A$ ,  $B$ , and so on).

$$H = \begin{pmatrix} A & 0 \\ -E & B \end{pmatrix} = \begin{pmatrix} a_{11} & \dots & a_{1n} & 0 & \dots & 0 \\ \vdots & & \vdots & \vdots & & \vdots \\ a_{n1} & \dots & a_{nn} & 0 & \dots & 0 \\ -1 & & 0 & b_{11} & \dots & b_{1n} \\ & \ddots & & \vdots & & \vdots \\ 0 & & -1 & b_{n1} & \dots & b_{nn} \end{pmatrix}$$

The Laplace expansion along the first  $n$  rows gives

$$|H| = |A| \cdot |B|.$$

Now in sequence, we add linear combinations of the first  $n$  columns to the last  $n$  columns in order to obtain a matrix with zeros in the bottom right corner. We obtain

$$K = \begin{pmatrix} a_{11} & \dots & a_{1n} & c_{11} & \dots & c_{1n} \\ \vdots & & \vdots & \vdots & & \vdots \\ a_{n1} & \dots & a_{nn} & c_{n1} & \dots & c_{nn} \\ -1 & & 0 & 0 & \dots & 0 \\ & \ddots & & \vdots & & \vdots \\ 0 & & -1 & 0 & \dots & 0 \end{pmatrix}.$$

The elements of the submatrix on the top right part must satisfy

$$c_{ij} = a_{i1}b_{1j} + a_{i2}b_{2j} + \dots + a_{in}b_{nj},$$

that is, they are exactly the components of the product  $A \cdot B$  and  $|K| = |H|$ . The expansion of the last  $n$  columns gives us  $|K| = (-1)^n (-1)^{1+\dots+2n} |A \cdot B| = (-1)^{2n \cdot (n+1)} \cdot |A \cdot B| = |A \cdot B|$ . This proves the Cauchy theorem.

**Solution.** We just plug in the values to the rule:

$$x_1 = \frac{\begin{vmatrix} 2 & 2 & 3 \\ -3 & -3 & -1 \\ -3 & 1 & 2 \end{vmatrix}}{\begin{vmatrix} 1 & 2 & 3 \\ 2 & -3 & 1 \\ -3 & 1 & 2 \end{vmatrix}} = 1, \quad x_2 = \frac{\begin{vmatrix} 1 & 2 & 3 \\ 2 & -3 & -1 \\ -3 & -3 & 2 \end{vmatrix}}{\begin{vmatrix} 1 & 2 & 3 \\ 2 & -3 & 1 \\ -3 & 1 & 2 \end{vmatrix}} = 2$$

$$x_3 = \frac{\begin{vmatrix} 1 & 2 & 2 \\ 2 & -3 & -3 \\ -3 & 1 & -3 \end{vmatrix}}{\begin{vmatrix} 1 & 2 & 3 \\ 2 & -3 & 1 \\ -3 & 1 & 2 \end{vmatrix}} = -1.$$

**2.B.10.** Find the algebraically adjoint matrix and the inverse of the matrix

$$A = \begin{pmatrix} 1 & 0 & 2 & 0 \\ 0 & 3 & 0 & 4 \\ 5 & 0 & 6 & 0 \\ 0 & 7 & 0 & 8 \end{pmatrix}.$$

**Solution.** The adjoint matrix is

$$A^* = \begin{pmatrix} A_{11} & A_{12} & A_{13} & A_{14} \\ A_{21} & A_{22} & A_{23} & A_{24} \\ A_{31} & A_{32} & A_{33} & A_{34} \\ A_{41} & A_{42} & A_{43} & A_{44} \end{pmatrix}^T,$$

where  $A_{ij}$  is the algebraic complement of the element  $a_{ij}$  of the matrix  $A$ , that is, the product of the number  $(-1)^{i+j}$  and the determinant of the matrix given by  $A$  without the  $i$ -th row and  $j$ -th column. We have

$$\begin{aligned} A_{11} &= \begin{vmatrix} 3 & 0 & 4 \\ 0 & 6 & 0 \\ 7 & 0 & 8 \end{vmatrix} = -24, & A_{12} &= -\begin{vmatrix} 0 & 0 & 4 \\ 0 & 0 & 8 \\ 0 & 0 & 8 \end{vmatrix} = 0, \\ A_{13} &= \begin{vmatrix} 0 & 3 & 4 \\ 5 & 0 & 0 \\ 0 & 7 & 8 \end{vmatrix} = 20, & A_{14} &= -\begin{vmatrix} 0 & 3 & 0 \\ 5 & 0 & 6 \\ 0 & 7 & 0 \end{vmatrix} = 0, \\ A_{21} &= -\begin{vmatrix} 0 & 2 & 0 \\ 0 & 6 & 0 \\ 7 & 0 & 8 \end{vmatrix} = 0, & A_{22} &= \begin{vmatrix} 1 & 2 & 0 \\ 5 & 6 & 0 \\ 0 & 0 & 8 \end{vmatrix} = -32, \\ A_{23} &= -\begin{vmatrix} 1 & 0 & 0 \\ 5 & 0 & 0 \\ 0 & 7 & 8 \end{vmatrix} = 0, & A_{24} &= \begin{vmatrix} 1 & 0 & 2 \\ 5 & 0 & 6 \\ 0 & 7 & 0 \end{vmatrix} = -28, \\ A_{31} &= \begin{vmatrix} 0 & 2 & 0 \\ 3 & 0 & 4 \\ 7 & 0 & 8 \end{vmatrix} = 8, & A_{32} &= -\begin{vmatrix} 1 & 2 & 0 \\ 0 & 0 & 4 \\ 0 & 0 & 8 \end{vmatrix} = -0, \\ A_{33} &= \begin{vmatrix} 1 & 0 & 0 \\ 0 & 3 & 4 \\ 0 & 7 & 8 \end{vmatrix} = -4, & A_{34} &= -\begin{vmatrix} 1 & 0 & 2 \\ 0 & 3 & 0 \\ 0 & 7 & 0 \end{vmatrix} = -0, \end{aligned}$$

**2.2.11. Determinant and the inverse matrix.** Assume first

that there is an inverse matrix of the matrix  $A$ , that is,  $A \cdot A^{-1} = E$ . Since the unit matrix always satisfies  $|E| = 1$ , it follows that for every invertible matrix its determinant is an invertible scalar and by the Cauchy theorem we have  $|A^{-1}| = |A|^{-1}$ .

But we can say more, combining the Laplace and Cauchy theorems.

#### INVERSE MATRIX DETERMINANT FORMULA

For any square matrix  $A = (a_{ij})$  of dimension  $n$  we define a matrix  $A^* = (a_{ij}^*)$ , where  $a_{ij}^* = A_{ji}$  are algebraic complements of the elements  $a_{ji}$  in  $A$ . The matrix  $A^*$  is called the *algebraically adjoint matrix* of the matrix  $A$  (or the *adjugate matrix*  $A^*$ ).

□ **Theorem.** For every square matrix  $A$  over a ring of scalars  $\mathbb{K}$  we have that

$$(1) \quad AA^* = A^*A = |A| \cdot E.$$

In particular,

- (i)  $A^{-1}$  exists as a matrix over the ring of scalars  $\mathbb{K}$  if and only if  $|A|^{-1}$  exists in  $\mathbb{K}$ .
- (ii) If  $A^{-1}$  exists, then  $A^{-1} = |A|^{-1} \cdot A^*$ .

**PROOF.** As already mentioned, the Cauchy theorem shows that the existence of  $A^{-1}$  implies the invertibility of  $|A| \in \mathbb{K}$ .

For an arbitrary square matrix  $A$  we can directly compute  $A \cdot A^* = (c_{ij})$ , where

$$c_{ij} = \sum_{k=1}^n a_{ik} a_{kj}^* = \sum_{k=1}^n a_{ik} A_{jk}.$$

If  $i = j$ , it is exactly the Laplace expansion of  $|A|$  along the  $i$ -th row.

If  $i \neq j$ , then we may imagine we expand the determinant along the  $j$ -th row, but plug in the values of the  $i$ -th row instead of the  $a_{jk}$ 's. This is the expansion of the determinant of a matrix where the  $i$ -th and  $j$ -th row is the same, therefore  $c_{ij} = 0$ .

This implies that  $A \cdot A^* = |A| \cdot E$ , and we have proven one of the equalities (1). In particular, if  $|A|^{-1}$  exists, then  $A \cdot (|A|^{-1} A^*) = E$ .

If  $|A|$  is an invertible scalar, we may repeat the previous computation for  $A^* \cdot A$ , and we obtain  $(|A|^{-1} A^*) \cdot A = E$ . Therefore our computation really gives the inverse matrix of  $A$ , as claimed in the theorem. □

Notice that for fields of scalars we have already proved that the right inverse of a matrix is automatically the left inverse and thus the inverse, too. Here we have obtained the same result for all rings of scalars, together with a strong and effective existence condition. On the other hand the exact formula for the inverse has become rather theoretical with little practical value.

$$A_{41} = - \begin{vmatrix} 0 & 2 & 0 \\ 3 & 0 & 4 \\ 0 & 6 & 0 \end{vmatrix} = 0, \quad A_{42} = \begin{vmatrix} 1 & 2 & 0 \\ 0 & 0 & 4 \\ 5 & 6 & 0 \end{vmatrix} = -16,$$

$$A_{43} = - \begin{vmatrix} 1 & 0 & 0 \\ 0 & 3 & 4 \\ 5 & 0 & 0 \end{vmatrix} = 0, \quad A_{44} = \begin{vmatrix} 1 & 0 & 2 \\ 0 & 3 & 0 \\ 5 & 0 & 6 \end{vmatrix} = -12.$$

By substitution we obtain

$$A^* = \begin{pmatrix} -24 & 0 & 20 & 0 \\ 0 & -32 & 0 & 28 \\ 8 & 0 & -4 & 0 \\ 0 & 16 & 0 & -12 \end{pmatrix}^T$$

$$= \begin{pmatrix} -24 & 0 & 8 & 0 \\ 0 & -32 & 0 & 16 \\ 20 & 0 & -4 & 0 \\ 0 & 28 & 0 & -12 \end{pmatrix}.$$

We compute the inverse matrix  $A^{-1}$  from the relation  $A^{-1} = |A|^{-1} \cdot A^*$ . The determinant of the matrix  $A$  is (expanding the first row) equal to

$$|A| = \begin{vmatrix} 1 & 0 & 2 & 0 \\ 0 & 3 & 0 & 4 \\ 5 & 0 & 6 & 0 \\ 0 & 7 & 0 & 8 \end{vmatrix} = \begin{vmatrix} 3 & 0 & 4 \\ 0 & 6 & 0 \\ 7 & 0 & 8 \end{vmatrix} + 2 \begin{vmatrix} 0 & 3 & 4 \\ 5 & 0 & 0 \\ 0 & 7 & 8 \end{vmatrix} = 16.$$

By substitution, we obtain

$$A^{-1} = \begin{pmatrix} -3/2 & 0 & 1/2 & 0 \\ 0 & -2 & 0 & 1 \\ 5/4 & 0 & -1/4 & 0 \\ 0 & 7/4 & 0 & -3/4 \end{pmatrix}.$$

□

### C. Vector spaces and linear mappings

Typical properties of vector spaces (met already in the plane or three dimensional space) can be observed in many other situations. We illustrate this by examples.

**2.C.1. Vector space – yes or no?** Decide whether following sets form a vector space over the field of real numbers:

i) The set of solutions of the system

$$\begin{aligned} x_1 + x_2 + \dots + x_{98} + x_{99} + x_{100} &= 100x_1, \\ x_1 + x_2 + \dots + x_{98} + x_{99} &= 99x_1, \\ x_1 + x_2 + \dots + x_{98} &= 98x_1, \\ \vdots & \\ x_1 + x_2 &= 2x_1. \end{aligned}$$

As a direct corollary of this theorem we can once again prove the Cramer rule for solving the systems of linear equations, see 2.2.6. Really, for the solution of the system  $A \cdot x = b$  we just need to read in the equation

$$x = A^{-1} \cdot b = |A|^{-1} A^* \cdot b$$

the individual components of the expression  $A^* \cdot b$  as the Laplace expansions of the determinant of the matrix  $A_i$  which arose through the exchange of the  $i$ -th column of  $A$  for the column  $b$ .

### 3. Vector spaces and linear mappings

**2.3.1. Abstract vector spaces.** Let us go back for a while to the systems of  $m$  linear equations of  $n$  variables from 2.1.3 and further, let us assume that the system is the homogeneous system  $A \cdot x = 0$ , that is

$$\begin{pmatrix} a_{11} & \dots & a_{1n} \\ \vdots & & \vdots \\ a_{m1} & \dots & a_{mn} \end{pmatrix} \cdot \begin{pmatrix} x_1 \\ \vdots \\ x_n \end{pmatrix} = \begin{pmatrix} 0 \\ \vdots \\ 0 \end{pmatrix}.$$

By the distributivity of the matrix multiplication it is clear that the sum of two solutions  $x = (x_1, \dots, x_n)$  and  $y = (y_1, \dots, y_n)$  satisfies

$$A \cdot (x + y) = A \cdot x + A \cdot y = 0$$

and thus is also a solution. Similarly, a scalar multiple  $a \cdot x$  is also a solution. The set of all solutions of a fixed system of equations is therefore closed under vector addition and scalar multiplication. These are the basic properties of vectors of dimension  $n$  in  $\mathbb{K}^n$ , see 2.1.1. Now we have the vectors in the solution space with  $n$  coordinates. The “dimension” of this space is given by the difference of the number of variables and the rank of the matrix  $A$ . Thus we can easily deal with the solution of a system of 1000 equations in 1000 variables and need only one or two free parameters. Thus the whole solution space will behave as a plane or a line, as we have already seen in 1.5.3 at the page 29, although the vectors themselves are given by so many components.

We go further. Already in paragraph 1.2.1 we have encountered an interesting example of a space of all solutions of a homogeneous linear difference equation of first order. All solutions have been obtained from a single one by scalar multiplication and are also closed under addition and scalar multiples. These “vectors” of solutions are infinite sequences of numbers, although we intuitively expect that the “dimension” of the whole space of solutions should be one. We shall understand such phenomena with the help of a more general definition of vector space and its dimension.

ii) The set of solutions of the equation

$$x_1 + x_2 + \cdots + x_{100} = 0$$

iii) The set of solutions of the equation

$$x_1 + 2x_2 + 3x_3 + \cdots + 100x_{100} = 1.$$

iv) The set of all real (or complex) sequences. (Real or complex sequence is a mapping  $f : \mathbb{N} \rightarrow \mathbb{R}$  or  $f : \mathbb{N} \rightarrow \mathbb{C}$ . The image of number  $n$  is then called  $n$ -th member of the sequence, we usually denote it by lower index, say  $a_n$ .)

v) The set of solutions of a homogeneous difference equation.

vi) The set of solutions of a non-homogeneous difference equation.

vii)  $\{f : \mathbb{R} \rightarrow \mathbb{R} \mid f(1) = f(2) = c, c \in \mathbb{R}\}$

**Solution.** We check the properties of a vector space, see 2.3.1. Actually all we have to do is to check whether the given sets are closed to linear combinations of it's elements. Then all the axioms of a vector space are satisfied.

i) Yes. They all are real multiples of the vector  $(1, 1, 1, \dots, 1)$ . A sum of two multiples of the same 100 ones vector is again a multiple of the vector. The reverse vector is again a multiple of the vector and all other axioms are trivially satisfied. By the way, the solution space is thus a vector space of dimension 1, see also 2.3.7.

ii) Yes. It is a space of dimension 99 (corresponds to the number of free parameters of the solution). In general the set of all solutions of any system of homogeneous linear equations forms a vector space.

iii) No. For instance, taking twice the solution  $x_1 = 1, x_i = 0, i = 2, \dots, 100$  we do not obtain a solution. But the set of solutions forms an affine space (see 4.1.1).

iv) Yes. The set of all real or complex sequences clearly forms a real (complex) vector space. Adding the sequences and scalar multiplication is defined term-wise, where it is clearly the vector space of all real (complex) numbers.

v) Yes. In order to show that the set of sequences which satisfy given difference homogeneous equation it is enough to show that it is closed under addition and real number multiplication (as the set of all real sequences is a vector space, as we know). Consider two sequences  $(x_j)_{j=0}^{\infty}$

VECTOR SPACE DEFINITION

A vector space  $V$  over a field of scalars  $\mathbb{K}$  is a set where we define the operations

- addition, which satisfies the axioms (CG1)–(CG4) from the paragraph 1.1.1 on the page 5,
- scalar multiplication, for which the axioms (V1)–(V4) from the paragraph 2.1.1 on the page 69 hold.

Recall our simple notational convention: scalars are usually denoted by letters from the beginning of the alphabet, that is,  $a, b, c, \dots$ , while for vectors we shall use letters from the end, that is,  $u, v, w, x, y, z$ . Usually,  $x, y, z$  will denote  $n$ -tuples of scalars. For completeness, the letters from the centre of the alphabet, for instance  $i, j, k, \ell$ , will mostly denote indices.

In order to gain some practice in the formal approach, we check some simple properties of vectors. These are trivial for  $n$ -tuples for scalars, but not so evident for general vectors in our new abstract sense.

**2.3.2. Proposition.** Let  $V$  be a vector space over a field of scalars  $\mathbb{K}$ . Suppose  $a, b, a_i \in \mathbb{K}$ , and  $u, v, u_j \in V$ . Then

- (1)  $a \cdot u = 0$  if and only if  $a = 0$  or  $u = 0$ ,
- (2)  $(-1) \cdot u = -u$ ,
- (3)  $a \cdot (u - v) = a \cdot u - a \cdot v$ ,
- (4)  $(a - b) \cdot u = a \cdot u - b \cdot u$ ,
- (5)  $(\sum_{i=1}^n a_i) \cdot (\sum_{j=1}^m u_j) = \sum_{i=1}^n \sum_{j=1}^m a_i \cdot u_j$ .

PROOF. We can expand

$$a \cdot u = (a + 0) \cdot u \stackrel{(V2)}{=} a \cdot u + 0 \cdot u$$

which, according to the axiom (CG4), implies  $0 \cdot u = 0$ . Now

$$u + (-1) \cdot u \stackrel{(V2)}{=} (1 + (-1)) \cdot u = 0 \cdot u = 0$$

and thus  $-u = (-1) \cdot u$ . Further,

$$a \cdot (u + (-1) \cdot v) \stackrel{(V2, V3)}{=} a \cdot u + (-a) \cdot v = a \cdot u - a \cdot v,$$

which proves (3). It follows that

$$(a - b) \cdot u \stackrel{(V2, V3)}{=} a \cdot u + (-b) \cdot u = a \cdot u - b \cdot u$$

which proves (4). Property (5) follows using induction with (V2) and (V1).

It remains to prove (1):  $a \cdot 0 = a \cdot (u - u) = a \cdot u - a \cdot u = 0$ , which along with the first derived proposition in this proof proves one implication. For the other implication, we use an axiom for the field of scalars, and axiom (V4) for vector spaces: if  $p \cdot u = 0$  and  $p \neq 0$ , then  $u = 1 \cdot u = (p^{-1} \cdot p) \cdot u = p^{-1} \cdot 0 = 0$ .  $\square$

**2.3.3. Linear (in)dependence.** In paragraph 2.1.11 we worked with linear combinations of rows of a matrix. With vectors we work analogously:

and  $(y_j)_{j=0}^\infty$  satisfying the given equation, that is,

$$\begin{aligned} a_n x_{n+k} + a_{n-1} x_{n+k-1} + \cdots + a_0 x_k &= 0 \\ a_n y_{n+k} + a_{n-1} y_{n+k-1} + \cdots + a_0 y_k &= 0. \end{aligned}$$

By adding these equations, we obtain

$$\begin{aligned} a_n(x_{n+k} + y_{n+k}) + a_{n-1}(x_{n+k-1} + y_{n+k-1}) \\ + \cdots + a_0(x_k + y_k) = 0, \end{aligned}$$

therefore also the sequence  $(x_j + y_j)_{j=0}^\infty$  satisfies the given equation. Analogously, if the sequence  $(x_j)_{j=0}^\infty$  satisfies the given equation, then also  $(ux_j)_{j=0}^\infty$ , where  $u \in \mathbb{R}$ .

- vi) No. The sum of two solutions of a non-homogeneous equation

$$\begin{aligned} a_n x_{n+k} + a_{n-1} x_{n+k-1} + \cdots + a_0 x_k &= c \\ a_n y_{n+k} + a_{n-1} y_{n+k-1} + \cdots + a_0 y_k &= c, \quad c \in \mathbb{R} - \{0\} \end{aligned}$$

satisfies the equation

$$\begin{aligned} a_n(x_{n+k} + y_{n+k}) + a_{n-1}(x_{n+k-1} + y_{n+k-1}) \\ + \cdots + a_0(x_k + y_k) = 2c, \end{aligned}$$

that is, it does not satisfy the original non-homogeneous equation. But the set of solutions forms an affine space, see 4.1.1.

- vii) It is a vector space if and only if  $c = 0$ . If we take two functions  $f$  and  $g$  from the given set, then  $(f + g)(1) = (f + g)(2) = f(1) + g(1) = 2c$ . Thus if  $f + g$  is to be a member of the given set, it must be that  $(f + g)(1) = c$ , therefore  $2c = c$ , hence  $c = 0$ .

**2.C.2.** Find out, whether the set

$$U_1 = \{(x_1, x_2, x_3) \in \mathbb{R}^3; |x_1| = |x_2| = |x_3|\}$$

is a subspace of a vector space  $\mathbb{R}^3$  and the set

$$U_2 = \{ax^2 + c; a, c \in \mathbb{R}\}$$

a subspace of the space of polynomials of degree at most 2.

**Solution.** The only property we have to check is whether the given subset is closed under linear combination of vectors in it, that is if it forms a vector space. The set  $U_1$  is not a vector (sub)space. We can see that, for instance,

$$(1, 1, 1) + (-1, 1, 1) = (0, 2, 2) \notin U_1.$$

LINEAR COMBINATION AND INDEPENDENCE

An expression of the form  $a_1 v_1 + \cdots + a_k v_k$  is called a *linear combination* of vectors  $v_1, \dots, v_k \in V$ .

A finite sequence of vectors  $v_1, \dots, v_k$  is called *linearly independent*, if the only zero linear combination is the one with all coefficients zero. That is, for any scalars  $a_1, \dots, a_k \in \mathbb{K}$ ,  $a_1 v_1 + \cdots + a_k v_k = 0$  implies  $a_1 = a_2 = \cdots = a_k = 0$ . It is clear that for an independent sequence of vectors, all vectors are mutually distinct and nonzero.

The set of vectors  $M \subset V$  in a vector space  $V$  over  $\mathbb{K}$  is called *linearly independent*, if every finite  $k$ -tuple of vectors  $v_1, \dots, v_k \in M$  is linearly independent.

The set of vectors  $M$  is *linearly dependent*, if it is not linearly independent.

A nonempty subset  $M$  of vectors in a vector space over a field of scalars  $\mathbb{K}$  is dependent if and only if one of its vectors can be expressed as a finite linear combination using other vectors in  $M$ . This follows directly from the definition.

At least one of the coefficients in the corresponding linear combination must be nonzero, and since we are over a field of scalars, we can multiply whole combination by the inverse of this nonzero coefficient and thus express its corresponding vector as a linear combination of the others.

Every subset of a linearly independent set  $M$  is clearly also linearly independent (we require the same conditions on a smaller set of vectors). Similarly, we can see that  $M \subset V$  is linearly independent if and only if every finite subset of  $M$  is linearly independent.

**2.3.4. Generators and subspaces.** A subset  $M \subset V$  is called a *vector subspace* if it forms, together with the restricted operations of addition and scalar multiplication, a vector space. That is, we require

$$\forall a, b \in \mathbb{K}, \forall v, w \in M, a \cdot v + b \cdot w \in M.$$

We investigate a couple of cases: The space of  $m$ -tuples of scalars  $\mathbb{R}^m$  with coordinate-wise addition and multiplication is a vector space over  $\mathbb{R}$ , but also a vector space over  $\mathbb{Q}$ . For instance for  $m = 2$ , the vectors  $(1, 0), (0, 1) \in \mathbb{R}^2$  are linearly independent, because from

$$a \cdot (1, 0) + b \cdot (0, 1) = (0, 0)$$

follows  $a = b = 0$ . Further, the vectors  $(1, 0), (\sqrt{2}, 0) \in \mathbb{R}^2$  are linearly dependent over  $\mathbb{R}$ , because  $\sqrt{2} \cdot (1, 0) = (\sqrt{2}, 0)$ , but over  $\mathbb{Q}$  they are linearly independent! Over  $\mathbb{R}$  these two vectors “generate” a one-dimensional subspace, while over  $\mathbb{Q}$  the subspace is “larger”.

Polynomials with real coefficients and of degree at most  $m$  form a vector space  $\mathbb{R}_m[x]$ . We can consider the polynomials as mappings  $f : \mathbb{R} \rightarrow \mathbb{R}$  and define the addition and scalar multiplication like this:  $(f + g)(x) = f(x) + g(x)$ ,  $(a \cdot f)(x) = a \cdot f(x)$ .

The set  $U_2$  is a subspace (there is a clear identification with  $\mathbb{R}^2$ ), because

$$(a_1x^2 + c_1) + (a_2x^2 + c_2) = (a_1 + a_2)x^2 + (c_1 + c_2),$$

$$k \cdot (ax^2 + c) = (ka)x^2 + kc$$

for all numbers  $a_1, c_1, a_2, c_2, a, c, k \in \mathbb{R}$ . □

**2.C.3.** Determine whether or not the vectors  $(1, 2, 3, 1)$ ,  $(1, 0, -1, 1)$ ,  $(2, 1, -1, 3)$  and  $(0, 0, 3, 2)$  are linearly independent.

**Solution.** Because

$$\begin{vmatrix} 1 & 2 & 3 & 1 \\ 1 & 0 & -1 & 1 \\ 2 & 1 & -1 & 3 \\ 0 & 0 & 3 & 2 \end{vmatrix} = 10 \neq 0,$$

the given vectors are linearly independent. □

**2.C.4.** Given arbitrary linearly independent vectors  $u, v, w, z$  in a vector space  $V$ , decide whether or not in  $V$  the vectors  $u - 2v, 3u + w - z, u - 4v + w + 2z, 4v + 8w + 4z$  are linearly independent.

**Solution.** Considered vectors are linearly independent if and only if the vectors  $(1, -2, 0, 0), (3, 0, 1, -1), (1, -4, 1, 2), (0, 4, 8, 4)$  are linearly independent in  $\mathbb{R}^4$ . We have

$$\begin{vmatrix} 1 & -2 & 0 & 0 \\ 3 & 0 & 1 & -1 \\ 1 & -4 & 1 & 2 \\ 0 & 4 & 8 & 4 \end{vmatrix} = -36 \neq 0,$$

thus the vectors are linearly independent. □

**2.C.5.** The vectors

$$(1, 2, 1), \quad (-1, 1, 0), \quad (0, 1, 1)$$

are linearly independent, and therefore together form a basis of  $\mathbb{R}^3$  (for basis it is important to give an order of the vectors). Every three-dimensional vector is therefore some linear combination of them. What linear combination corresponds to the vector  $(1, 1, 1)$ , or equivalently, what are the coordinates of the vector  $(1, 1, 1)$  in the basis formed by the given vectors?

**Solution.** We seek  $a, b, c \in \mathbb{R}$  such that  $a(1, 2, 1) + b(-1, 1, 0) + c(0, 1, 1) = (1, 1, 1)$ . The equation must hold in every coordinate, so we have a system of three linear equations in three variables:

$$\begin{aligned} a - b &= 1 \\ 2a + b + c &= 1 \\ a + c &= 1, \end{aligned}$$

Polynomials of all degrees also form a vector space  $\mathbb{R}[x]$  (or  $\mathbb{R}_\infty[x]$ ) and  $\mathbb{R}_m[x] \subset \mathbb{R}_n[x] \subset \mathbb{R}[x]$  is a vector subspace for any  $m \leq n \leq \infty$ . Further examples of subspaces is given by all even polynomials or all odd polynomials, that is, polynomials satisfying  $f(-x) = \pm f(x)$ .

In complete analogy with polynomials, we can define a vector space structure on a set of all mappings  $\mathbb{R} \rightarrow \mathbb{R}$  or of all mappings  $M \rightarrow V$  of an arbitrary fixed set  $M$  into the vector space  $V$ .

Because the condition in the definition of subspace consists only of universal quantifiers, the intersection of subspaces is still a subspace. We can see this also directly: Let  $W_i, i \in I$ , be vector subspaces in  $V, a, b \in \mathbb{K}, u, v \in \bigcap_{i \in I} W_i$ . Then  $a \cdot u + b \cdot v \in W_i$  for all  $i \in I$ . Hence  $a \cdot u + b \cdot v \in \bigcap_{i \in I} W_i$ .

It can be noted that the intersection of all subspaces  $W \subset V$  that contain some given set of vectors  $M \subset V$  is a subspace. It is called the *linear span* or *linear hull* of  $M$  and we write  $\text{span } M$ .

We say that a set  $M$  *generates* the subspace  $\text{span } M$ , or that the elements of  $M$  are *generators* of the subspace  $\text{span } M$ .

We formulate a few simple claims about subspace generation:

**Proposition.** For every nonempty set  $M \subset V$ , we have

- (1)  $\text{span } M = \{a_1 \cdot u_1 + \dots + a_k \cdot u_k; k \in \mathbb{N}, a_i \in \mathbb{K}, u_j \in M, j = 1, \dots, k\}$ ;
- (2)  $M = \text{span } M$  if and only if  $M$  is a vector subspace;
- (3) if  $N \subset M$  then  $\text{span } N \subset \text{span } M$  is a vector subspace; the subspace  $\text{span } \emptyset$  generated by the empty subspace is the trivial subspace  $\{0\} \subset V$ .

**PROOF.** (1) The set of all linear combinations

$$a_1u_1 + \dots + a_ku_k$$

on the right-hand side of (1) is clearly a vector subspace and of course it contains  $M$ . On the other hand, each of the linear combinations must be in  $\text{span } M$  and thus the first claim is proved.

Claim (2) follows immediately from claim (1) and from the definition of vector space. Analogously, (1) implies most of the third claim.

Finally, the smallest possible vector subspace is  $\{0\}$ . Notice that the empty set is contained in every subspace and each of them contains the vector 0. This proves the last claim. □

#### BASIS AND DIMENSION

A subset  $M \subset V$  is called a *basis of the vector space*  $V$  if  $\text{span } M = V$  and  $M$  is linearly independent.

A vector space with a finite basis is called *finitely dimensional*. The number of elements of the basis is called the *dimension of*  $V$ .

If  $V$  does not have a finite basis, we say that  $V$  is *infinitely dimensional*. We write  $\dim V = k, k \in \mathbb{N}$  or  $k = \infty$ .

whose solution gives us  $a = \frac{1}{2}, b = -\frac{1}{2}, c = \frac{1}{2}$ , thus we have

$$(1, 1, 1) = \frac{1}{2} \cdot (1, 2, 1) - \frac{1}{2} \cdot (-1, 1, 0) + \frac{1}{2} \cdot (0, 1, 1),$$

that is, the coordinates of the vector  $(1, 1, 1)$  in the basis  $((1, 2, 1), (-1, 1, 0), (0, 1, 1))$  are  $(\frac{1}{2}, -\frac{1}{2}, \frac{1}{2})$ .  $\square$

**2.C.6.** Determine all constants  $a \in \mathbb{R}$  such that the polynomials  $ax^2 + x + 2, -2x^2 + ax + 3$  and  $x^2 + 2x + a$  are linearly dependent (in the vector space  $P_3[x]$  of polynomials of one variable of degree at most three over real numbers).

**Solution.** In the basis  $1, x, x^2$  the coefficients of the given vectors (polynomials) are  $(a, 1, 2), (-2, a, 3), (1, 2, a)$ . Polynomials are linearly independent if and only if the matrix whose columns are given by the coordinates of the vectors has a rank lower than the number of the vectors. In this case the rank must be two or less. In the case of a square matrix, a rank less than the number of rows means that the determinant is zero. The condition for  $a$  thus reads

$$\begin{vmatrix} a & -2 & 1 \\ 1 & a & 2 \\ 2 & 3 & a \end{vmatrix} = 0,$$

that is,  $a$  is a root of the polynomial  $a^3 - 6a - 5 = (a + 1)(a^2 - a - 5)$ , thus there are 3 such constants  $a_1 = -1, a_2 = \frac{1+\sqrt{21}}{2}, a_3 = \frac{1-\sqrt{21}}{2}$ .  $\square$

**2.C.7.** Consider the complex numbers  $\mathbb{C}$  as a real vector space. Determine the coordinates of the number  $2 + i$  in the basis given by the roots of the polynomial  $x^2 + x + 1$ .

**Solution.** Because roots of the given polynomial are  $-\frac{1}{2} + i\frac{\sqrt{3}}{2}$  and  $-\frac{1}{2} - i\frac{\sqrt{3}}{2}$ , we have to determine the coordinates  $(a, b)$  of the vector  $2 + i$  in the basis  $(-\frac{1}{2} + i\frac{\sqrt{3}}{2}, -\frac{1}{2} - i\frac{\sqrt{3}}{2})$ . These real numbers  $a, b$  are uniquely determined by the condition

$$a \cdot (-\frac{1}{2} + i\frac{\sqrt{3}}{2}) + b \cdot (-\frac{1}{2} - i\frac{\sqrt{3}}{2}) = 2 + i.$$

By equating separately the real and the imaginary parts of the equation, we obtain a system of two linear equations in two variables:

$$\begin{aligned} -\frac{1}{2}a - \frac{1}{2}b &= 2 \\ \frac{\sqrt{3}}{2}a - \frac{\sqrt{3}}{2}b &= 1. \end{aligned}$$

The solution gives us  $a = -2 + \frac{\sqrt{3}}{3}, b = -2 - \frac{\sqrt{3}}{3}$ , therefore the coordinates are  $(-2 + \frac{1}{\sqrt{3}}, -2 - \frac{1}{\sqrt{3}})$ .  $\square$

In order to be satisfied with such a definition of dimension, we must know that different bases of the same space will always have the same number of elements. We shall show this below, cf. 2.3.9. But we note immediately, that the trivial subspace is generated by the empty set, which is an “empty” basis. Thus it has dimension zero.

The linearly independent vectors

$$e_i = (0, \dots, 1, \dots, 0) \in \mathbb{K}^n, \quad i = 1, \dots, n$$

(all zeros, but one value 1 at the  $i$ -th position) are the most useful example of a basis in the vector space  $\mathbb{K}^n$ . We call it the *standard basis* of  $\mathbb{K}^n$ .

**2.3.5. Linear equations again.** It is a good time now to recall the properties of systems of linear equation in terms of abstract vector spaces and their bases. As we have already noted in the introduction to this section (cf. 2.3.1), the set of all solutions of the *homogeneous system*

$$A \cdot x = 0$$

is a vector space. If  $A$  is a matrix with  $m$  rows and  $n$  columns, and the rank of the matrix is  $k$ , then using the row echelon transformation (see 2.1.7) to solve the system, we find that the dimension of the space of all solutions is exactly  $n - k$ .

Indeed, the left hand side of the equation can be understood as the linear combination of the columns of  $A$  with coefficients given by  $x$  and the rank  $k$  of the matrix provides the number of linearly independent columns in  $A$ , thus the dimension of the subspace of all possible linear combinations of the given form. Therefore, after transforming the system into row echelon form, exactly  $m - k$  zero rows remain. In the next step, we are left with exactly  $n - k$  free parameters. By setting one of them to have value one, while all others are zero, we obtain exactly  $n - k$  linearly independent solutions. Then all solutions are given by all the linear combinations of these  $n - k$  solutions. Every  $(n - k)$ -tuple of linearly independent solutions is called a *fundamental system of solutions* of the given homogeneous system of equations. We have proved:

**Proposition.** *The set of all solutions of the homogeneous system of equations*

$$A \cdot x = 0$$

*for  $n$  variables with the matrix  $A$  of rank  $k$  is a vector subspace in  $\mathbb{K}^n$  of dimension  $n - k$ . Every basis of this space forms a fundamental system of solutions of the given homogeneous system.*

Next, consider the general system of equations

$$A \cdot x = b.$$

Notice that the columns of the matrix  $A$  are actually images of the vectors of the standard basis in  $\mathbb{K}^n$  under the mapping assigning the vector  $A \cdot x$  to each vector  $x$ . If there should be a solution,  $b$  must be in the image under this mapping and thus it must be a linear combination of the columns in  $A$ .

**2.C.8. Remark.** As a perceptive reader may have spotted, the problem statement is not unambiguous – we are not given the order of the roots of the polynomial, thus we do not have the order of the basis vectors. The result is thus given up to the permutation of the coordinates.

We add a remark about rationalising the denominator, that is, removing the square roots from the denominator. The authors do not have a distinctive attitude whether this should always be done or not (Does  $\frac{\sqrt{3}}{3}$  look better than  $\frac{1}{\sqrt{3}}$ ?). In some cases the rationalising is undesirable: from the fraction  $\frac{6}{\sqrt{35}}$  we can immediately spot that its value is a little greater than 1 (because  $\sqrt{35}$  is just a little smaller than 6), while for the rationalised fraction  $\frac{6\sqrt{35}}{35}$  we cannot spot anything. But in general the convention is to normalize.

**2.C.9.** Consider complex numbers  $\mathbb{C}$  as a real vector space. Determine the coordinates of the number  $2 + i$  in the basis given by the roots of the polynomial  $x^2 - x + 1$ . ○

**2.C.10.** For what values of the parameters  $a, b, c \in \mathbb{R}$  are the vectors  $(1, 1, a, 1), (1, b, 1, 1), (c, 1, 1, 1)$  linearly dependent? ○

**2.C.11.** Let a vector space  $V$  be given along with a basis formed by the vectors  $u, v, w, z$ . Determine whether or not the vectors

$$u - 3v + z, \quad v - 5w - z, \quad 3w - 7z, \quad u - w + z$$

are linearly independent. ○

**2.C.12.** Complete the vectors  $1 - x^2 + x^3, 1 + x^2 + x^3, 1 - x - x^3$  to a basis of the space of polynomials of degree at most 3. ○

**2.C.13.** Do the matrices

$$\begin{pmatrix} 1 & 0 \\ 1 & -2 \end{pmatrix}, \quad \begin{pmatrix} 1 & 4 \\ 0 & -1 \end{pmatrix}, \quad \begin{pmatrix} -5 & 0 \\ 3 & 0 \end{pmatrix}, \quad \begin{pmatrix} 1 & -2 \\ 0 & 3 \end{pmatrix}$$

form a basis of the vector space of square two-dimensional matrices?

**Solution.** The four given matrices are as vectors in the space of  $2 \times 2$  matrices linearly independent. It follows from the fact that the matrix

$$\begin{pmatrix} 1 & 1 & -5 & 1 \\ 0 & 4 & 0 & -2 \\ 1 & 0 & 3 & 0 \\ -2 & -1 & 0 & 3 \end{pmatrix}$$

If we extend the matrix  $A$  by the column  $b$ , the number of linearly independent columns and thus also rows might increase (but does not have to). If this number increases, then  $b$  is not in the image and the system of equations does not have a solution. If on the other hand the number of linearly independent rows does not change after adding the column  $b$  to the matrix  $A$ , it means that  $b$  must be a linear combination of the columns of  $A$ . Coefficients of such combinations are then exactly the solutions of our system.

Consider now two fixed solutions  $x$  and  $y$  of our system and some solution  $z$  of the homogeneous system with the same matrix. Then clearly

$$A \cdot (x - y) = b - b = 0$$

$$A \cdot (x + z) = b + 0 = b.$$

Thus we can summarise in the form of the so called *Kronecker-Capelli theorem*<sup>1</sup>:

#### KRONECKER-CAPELLI THEOREM

**Theorem.** *The solution of a non-homogeneous system of linear equations  $A \cdot x = b$  exists if and only if adding the column  $b$  to the matrix  $A$  does not increase the number of linearly independent rows. In such a case the space of all solutions is given by all sums of one fixed particular solution of the system and all solutions of the homogeneous system that has the same matrix.*

**2.3.6. Sums of subspaces.** Since we now have some intuition about generators and the subspaces generated by them, we should understand the possibilities of how some subspaces can generate the whole space  $V$ .

#### SUM OF SUBSPACES

Let  $V_i, i \in I$  be subspaces of  $V$ . Then the subspace generated by their union, that is,  $\text{span} \cup_{i \in I} V_i$ , is called the *sum of subspaces*  $V_i$ . We denote it as  $W = \sum_{i \in I} V_i$ . Notably, for a finite number of subspaces  $V_1, \dots, V_k \subset V$  we write

$$W = V_1 + \dots + V_k = \text{span}(V_1 \cup V_2 \cup \dots \cup V_k).$$

We see that every element in the considered sum  $W$  can be expressed as a linear combination of vectors from the subspaces  $V_i$ . Because vector addition is commutative, we can aggregate summands that belong to the same subspace and for a finite sum of  $k$  subspaces we obtain

$$V_1 + V_2 + \dots + V_k = \{v_1 + \dots + v_k; v_i \in V_i, i = 1, \dots, k\}.$$

<sup>1</sup>A common formulation of this fact is “system has a solution if and only if the rank of its matrix equals the rank of its extended matrix”. Leopold Kronecker was a very influential German Mathematician, who dealt with algebraic equations in general and in particular pushed forward Number Theory in the middle of 19th century. Alfredo Capelli, an Italian, worked on algebraic identities. This theorem is equally often called by different names, e.g. *Rouché-Frobenius theorem* or *Rouché-Capelli theorem* etc. This is a very common feature in Mathematics.

is invertible (which is by the way equivalent to any of the following claims: its rank equals its dimension; it can be transformed into the unit matrix by elementary row transformations; it has the inverse matrix; it has a non-zero determinant (equal to 116); it stands for a system of homogeneous linear equations with only zero solution; every non-homogeneous linear system with left-hand side given by this matrix has a unique solution; the range of a linear mapping given by this matrix is a vector space of dimension 4 – this mapping is injective).  $\square$

**2.C.14.** In the vector space  $\mathbb{R}^4$  we are given three-dimensional subspaces

$$U = \text{span}\{u_1, u_2, u_3\}, \quad V = \text{span}\{v_1, v_2, v_3\},$$

while

$$u_1 = \begin{pmatrix} 1 \\ 1 \\ 1 \\ 0 \end{pmatrix}, \quad u_2 = \begin{pmatrix} 1 \\ 1 \\ 0 \\ 1 \end{pmatrix}, \quad u_3 = \begin{pmatrix} 1 \\ 0 \\ 1 \\ 1 \end{pmatrix}, \quad v_1 = \begin{pmatrix} 1 \\ 1 \\ -1 \\ -1 \end{pmatrix},$$

$v_2 = (1, -1, 1, -1)^T$ ,  $v_3 = (1, -1, -1, 1)^T$ . Determine the dimension and find a basis of the subspace  $U \cap V$ .

**Solution.** The subspace  $U \cap V$  contains exactly the vectors that can be obtained as a linear combinations of vectors  $u_i$  and also as a linear combination of vectors  $v_i$ . Thus we search for numbers  $x_1, x_2, x_3, y_1, y_2, y_3 \in \mathbb{R}$  such that the following holds:

$$x_1 \begin{pmatrix} 1 \\ 1 \\ 1 \\ 0 \end{pmatrix} + x_2 \begin{pmatrix} 1 \\ 1 \\ 0 \\ 1 \end{pmatrix} + x_3 \begin{pmatrix} 1 \\ 0 \\ 1 \\ 1 \end{pmatrix} = y_1 \begin{pmatrix} 1 \\ 1 \\ -1 \\ -1 \end{pmatrix} + y_2 \begin{pmatrix} 1 \\ -1 \\ 1 \\ -1 \end{pmatrix} + y_3 \begin{pmatrix} 1 \\ -1 \\ -1 \\ 1 \end{pmatrix},$$

that is, we are looking for a solution of a system

$$\begin{aligned} x_1 + x_2 + x_3 &= y_1 + y_2 + y_3, \\ x_1 + x_2 &= y_1 - y_2 - y_3, \\ x_1 + x_3 &= -y_1 + y_2 - y_3, \\ x_2 + x_3 &= -y_1 - y_2 + y_3. \end{aligned}$$

Using matrix notation of this homogeneous system (and preserving the order of the variables) we have

$$\begin{pmatrix} 1 & 1 & 1 & -1 & -1 & -1 \\ 1 & 1 & 0 & -1 & 1 & 1 \\ 1 & 0 & 1 & 1 & -1 & 1 \\ 0 & 1 & 1 & 1 & 1 & -1 \end{pmatrix} \sim \begin{pmatrix} 1 & 1 & 1 & -1 & -1 & -1 \\ 0 & 0 & -1 & 0 & 2 & 2 \\ 0 & -1 & 0 & 2 & 0 & 2 \\ 0 & 1 & 1 & 1 & 1 & -1 \end{pmatrix}$$

The sum  $W = V_1 + \dots + V_k \subset V$  is called the *direct sum* of subspaces if the intersection of each  $V_i$  with the sum of the other spaces is trivial, that is,  $V_i \cap \sum_{j \neq i} V_j = \{0\}$ . We show that in such a case, every vector  $w \in W$  can be written in a unique way as the sum

$$w = v_1 + \dots + v_k,$$

where  $v_i \in V_i$ . Indeed, if we could simultaneously write  $w$  as  $w = v'_1 + \dots + v'_k$ , then

$$0 = w - w = (v_1 - v'_1) + \dots + (v_k - v'_k).$$

If  $v_i - v'_i$  is the first nonzero term of the right-hand side, then this vector from  $V_i$  can be expressed using vectors from the other subspaces. This is a contradiction to the assumption that  $V_i$  has zero intersection with all the other subspaces. The only possibility is then that all the vectors on the right-hand side are zero and thus the expression of  $w$  is unique.

For direct sums of subspaces we write

$$W = V_1 \oplus \dots \oplus V_k = \bigoplus_{i=1}^k V_i.$$

**2.3.7. Basis.** Now we have everything prepared for understanding minimal sets of generators as we understood them in the plane  $\mathbb{R}^2$  and to prove the promised independence of the number of basis elements on any choices.

A basis of a  $k$ -dimensional space will usually be denoted as a  $k$ -tuple  $\underline{v} = (v_1, \dots, v_k)$  of basis vectors. This is just a matter of convention: with finitely dimensional vector spaces we shall always consider the bases along with a given order of the elements, even if we have not defined it that way (strictly speaking).

Clearly, if  $(v_1, \dots, v_n)$  is a basis of  $V$ , then the whole space  $V$  is the direct sum of the one-dimensional subspaces

$$V = \text{span}\{v_1\} \oplus \dots \oplus \text{span}\{v_n\}.$$

An immediate corollary of the derived uniqueness of decomposition of any vector  $w$  in  $V$  into the components in the direct sum gives a unique decomposition

$$w = x_1 v_1 + \dots + x_n v_n.$$

This allows us, after choosing a basis, to see the abstract vectors again as  $n$ -tuples of scalars. We shall return to this idea in paragraph 2.3.11, when we finish the discussion of the existence of bases and sums of subspaces in the general case.

**2.3.8. Theorem.** *From any finite set of generators of a vector space  $V$  we can choose a basis. Every basis of a finitely dimensional space  $V$  has the same number of elements.*

**PROOF.** The first claim is easily proved using induction on the number of generators  $k$ .

Only the zero subspace does not need a generator and thus we are able to choose an empty basis. On the other hand, we are not able to choose the zero vector (the generators would then be linearly dependent) and there is nothing else in the subspace.

In order to have our inductive step more natural, we deal with the case  $k = 1$  first. We have  $V = \text{span}\{v\}$  and  $v \neq 0$ ,

$$\begin{aligned}
 & \sim \begin{pmatrix} 1 & 1 & 1 & -1 & -1 & -1 \\ 0 & 1 & 1 & 1 & 1 & -1 \\ 0 & 0 & -1 & 0 & 2 & 2 \\ 0 & 0 & 1 & 3 & 1 & 1 \end{pmatrix} \\
 & \sim \begin{pmatrix} 1 & 1 & 1 & -1 & -1 & -1 \\ 0 & 1 & 1 & 1 & 1 & -1 \\ 0 & 0 & 1 & 0 & -2 & -2 \\ 0 & 0 & 0 & 1 & 1 & 1 \end{pmatrix} \\
 & \sim \begin{pmatrix} 1 & 1 & 1 & 0 & 0 & 0 \\ 0 & 1 & 1 & 0 & 0 & -2 \\ 0 & 0 & 1 & 0 & -2 & -2 \\ 0 & 0 & 0 & 1 & 1 & 1 \end{pmatrix} \\
 & \sim \begin{pmatrix} 1 & 0 & 0 & 0 & 0 & 2 \\ 0 & 1 & 0 & 0 & 2 & 0 \\ 0 & 0 & 1 & 0 & -2 & -2 \\ 0 & 0 & 0 & 1 & 1 & 1 \end{pmatrix}.
 \end{aligned}$$

We obtain a solution

$$\begin{aligned}
 x_1 = -2t, \quad x_2 = -2s, \quad x_3 = 2s + 2t, \quad y_1 = -s - t, \quad y_2 = s, \\
 y_3 = t, \quad t, s \in \mathbb{R}.
 \end{aligned}$$

We obtain a general vector of the intersection by substituting

$$\begin{pmatrix} x_1 + x_2 + x_3 \\ x_1 + x_2 \\ x_1 + x_3 \\ x_2 + x_3 \end{pmatrix} = \begin{pmatrix} 0 \\ -2t - 2s \\ 2s \\ 2t \end{pmatrix}.$$

We see that

$$\dim U \cap V = 2, \quad U \cap V = \text{span} \left\{ \begin{pmatrix} 0 \\ -1 \\ 1 \\ 0 \end{pmatrix}, \begin{pmatrix} 0 \\ -1 \\ 0 \\ 1 \end{pmatrix} \right\}.$$

□

**2.C.15.** Let there be in  $\mathbb{R}^3$  two vector spaces  $U$  and  $V$  generated by the vectors

$$(1, 1, -3), (1, 2, 2) \quad \text{and} \quad (1, 1, -1), (1, 2, 1), (1, 3, 3),$$

respectively. Determine the intersection of these two subspaces.

**Solution.** According to the definition of intersection, the vectors in the intersection are in both, the span of the vectors  $(1, 1, -3), (1, 2, 2)$ , as well as in the span of the vectors  $(1, 1, -1), (1, 2, 1), (1, 3, 3)$ . It helps to consider first the geometry. Firstly,  $U$  is spanned by two linearly independent vectors. So  $U$  is a plane in  $\mathbb{R}^3$ . Next,  $V$  is spanned by three vectors. But these are linearly dependent since

$$\begin{vmatrix} 1 & 1 & 1 \\ 1 & 2 & 3 \\ -1 & 1 & 3 \end{vmatrix} = \begin{vmatrix} 1 & 1 & -1 \\ 1 & 2 & 1 \\ 1 & 3 & 3 \end{vmatrix} = 0.$$

So  $V$  is also a plane.

because  $\{v\}$  is a linearly independent set of vectors. Then  $\{v\}$  is also a basis of the vector space  $V$  and any other vector is a multiple of  $v$ , so all bases of  $V$  must contain exactly one vector, which can be chosen from any set of generators.

Assume that the claim holds for  $k = n$  and consider  $V = \text{span}\{v_1, \dots, v_{n+1}\}$ . If  $v_1, \dots, v_{n+1}$  are linearly independent, then they form a basis. If they are linearly dependent, there exists  $i$  such that

$$v_i = a_1 v_1 + \dots + a_{i-1} v_{i-1} + a_{i+1} v_{i+1} + \dots + a_{n+1} v_{n+1}.$$

Then  $V = \text{span}\{v_1, \dots, v_{i-1}, v_{i+1}, \dots, v_{n+1}\}$  and we can choose a basis, using the inductive assumption.

It remains to show that bases always have the same number of elements. Consider a basis  $\underline{v} = (v_1, \dots, v_n)$  of the space  $V$  and for an arbitrary nonzero vector  $u$ , consider

$$u = a_1 v_1 + \dots + a_n v_n \in V$$

with  $a_i \neq 0$  for some  $i$ . Then

$$v_i = \frac{1}{a_i} (u - (a_1 v_1 + \dots + a_{i-1} v_{i-1} + a_{i+1} v_{i+1} + \dots + a_n v_n))$$

and therefore also  $\text{span}\{u, v_1, \dots, v_{i-1}, v_{i+1}, \dots, v_n\} = V$ .

We show that this is again a basis. For if adding  $u$  to the linearly independent vectors  $v_1, \dots, v_{i-1}, v_{i+1}, \dots, v_n$  leads to a set of linearly dependent vectors, then

$$V = \text{span}\{v_1, \dots, v_{i-1}, v_{i+1}, \dots, v_n\},$$

which implies a basis of  $n - 1$  vectors chosen from  $\underline{v}$ , which is not possible.

Thus we have proved that for any nonzero vector  $u \in V$  there exists  $i$ ,  $1 \leq i \leq n$ , such that  $(u, v_1, \dots, v_{i-1}, v_{i+1}, \dots, v_n)$  is again a basis of  $V$ .

Similarly, instead of one vector  $u$ , we can consider a linearly independent set  $u_1, \dots, u_k$ . We will sequentially add  $u_1, u_2, \dots$ , always exchanging for some  $v_i$  using our previous approach. We have to ensure that there always is such  $v_i$  to be replaced (that is, that the vectors  $u_i$  will not consequently replace each other).

Assume thus that we have already placed  $u_1, \dots, u_\ell$  instead of some  $v_j$ 's. Then the vector  $u_{\ell+1}$  can be expressed as a linear combination of the latter vectors  $u_i$  and the remaining  $v_j$ 's. As we have seen,  $u_{\ell+1}$  may replace any vector with non-zero coefficient in this linear combination. If only the coefficients at  $u_1, \dots, u_\ell$  were nonzero, then it would mean that the vectors  $u_1, \dots, u_{\ell+1}$  were linearly dependent, which is a contradiction.

Summarizing, for every  $k \leq n$  we can arrive after  $k$  steps at a basis in which  $k$  vectors from the original basis were exchanged for the new  $u_i$ 's. If  $k > n$ , then in the  $n$ -th step we would obtain a basis consisting only of new vectors  $u_i$ , which means that the original set could not be linearly independent.

In particular, it is not possible for two bases to have a different number of elements. □

In fact, we have proved a much stronger claim, the *Steinitz exchange lemma*:

If the vector  $(x_1, x_2, x_3)$  lies in  $U$ , then  $(x_1, x_2, x_3) = \lambda(1, 1, -3) + \mu(1, 2, 2)$  for some scalars  $\lambda, \mu$ . Similarly  $(x_1, x_2, x_3)$  lies in  $V$ , so  $(x_1, x_2, x_3) = \alpha(1, 1, -1) + \beta(1, 2, 1) + \gamma(1, 3, 3)$  for scalars  $\alpha, \beta, \gamma$ . When written in full, this is a set of six equations in eight unknowns. Solving these is possible but can be quite cumbersome. Some simplification is obtained as follows:

The first three equations, which describe  $U$  are

$$\begin{aligned} x_1 &= \lambda + \mu \\ x_2 &= \lambda + 2\mu \\ x_3 &= -3\lambda + 2\mu \end{aligned}$$

If we solve these three equations for the two "unknowns"  $\lambda$  and  $\mu$ , (which in any case we do not want), or alternatively if we eliminate  $\lambda$  and  $\mu$ , from these equations, we obtain the single equation  $8x_1 - 5x_2 + x_3 = 0$  to replace the first three.

The second set of three equations, which describe  $V$  are

$$\begin{aligned} x_1 &= \alpha + \beta + \gamma \\ x_2 &= \alpha + 2\beta + \gamma \\ x_3 &= -\alpha + \beta + 3\gamma \end{aligned}$$

If we solve these three equations for the three "unknowns"  $\alpha, \beta$  and  $\gamma$ , (which in any case we do not want), or alternatively if we eliminate  $\alpha, \beta$  and  $\gamma$ , from these equations, we obtain the single equation  $3x_1 - 2x_2 + x_3 = 0$  to describe  $V$ . Introducing the parameter  $t$ , it is straightforward write the solution as the line  $(x_1, x_2, x_3) = t(3, 5, 1)$ .

□

Now we move to unions of vector spaces. There is a simple algorithm, how to choose the maximal linearly independent set of vectors out of a given set of vectors. Write the given vectors as columns in a matrix. Then transform the matrix with row transformation into the row echelon form. The vectors, who correspond to the columns, where the "stairs" begin, form a maximal linearly independent set. To justify this, just think of the system of linear equations describing that a linear combination of the given vectors is zero. The matrix of the system is exactly the one described. If you put in the system only vectors corresponding to columns where are stairs, you get a system which can be transformed into a one in row echelon form with non-zero numbers on the diagonal and thus only solution of the systems are zeros, that is the vectors are linearly independent. Similarly, the system together with any

STEINITZ EXCHANGE LEMMA

For every finite basis  $\underline{v}$  of a vector space  $V$  and every set of linearly independent vectors  $u_i, i = 1, \dots, k$  in  $V$  we can find a subset of the basis vectors  $v_j$  which will complete the set of  $u_i$ 's into a new basis.

**2.3.9. Corollaries of the Steinitz lemma.** Because of the possibility of freely choosing and replacing basis vectors we can immediately derive nice (and intuitively expectable) properties of bases of vector spaces:

**Proposition.** (1) Every two bases of a finite dimensional vector space have the same number of elements, that is, our definition of dimension is basis-independent.

(2) If  $V$  has a finite basis, then every linearly independent set can be extended to a basis.

(3) A basis of a finite dimensional vector space is a maximal linearly independent set of vectors.

(4) The bases of a vector space are the minimal sets of generators.

A little more complicated, but now easy to deal with, is the situation of dimensions of subspaces and their sums:

**Corollary.** Let  $W, W_1, W_2 \subset V$  be subspaces of a space  $V$  of finite dimension. Then

(1)  $\dim W \leq \dim V$ ,

(2)  $V = W$  if and only if  $\dim V = \dim W$ ,

(3)  $\dim W_1 + \dim W_2 = \dim(W_1 + W_2) + \dim(W_1 \cap W_2)$ .

**PROOF.** It remains to prove only the last claim. This is evident if the dimension of one of the spaces is zero. Assume  $\dim W_1 = r \geq 1, \dim W_2 = s \geq 1$  and let  $(w_1, \dots, w_t)$  be a basis of  $W_1 \cap W_2$  (or empty set, if the intersection is trivial).

According to the Steinitz exchange lemma this basis of the intersection can be extended to a basis  $(w_1, \dots, w_t, u_{t+1}, \dots, u_r)$  for  $W_1$  and to a basis  $(w_1, \dots, w_t, v_{t+1}, \dots, v_s)$  for  $W_2$ . Vectors

$$w_1, \dots, w_t, u_{t+1}, \dots, u_r, v_{t+1}, \dots, v_s$$

clearly generate  $W_1 + W_2$ . We show that they are linearly independent. Let

$$\begin{aligned} a_1 w_1 + \dots + a_t w_t + b_{t+1} u_{t+1} + \dots \\ \dots + b_r u_r + c_{t+1} v_{t+1} + \dots + c_s v_s = 0. \end{aligned}$$

Then necessarily

$$\begin{aligned} -(c_{t+1} \cdot v_{t+1} + \dots + c_s \cdot v_s) = \\ = a_1 \cdot w_1 + \dots + a_t \cdot w_t + b_{t+1} \cdot u_{t+1} + \dots + b_r \cdot u_r \end{aligned}$$

must belong to  $W_2 \cap W_1$ . This implies that

$$b_{t+1} = \dots = b_r = 0,$$

since this is the way we have defined our bases. Then also

$$a_1 \cdot w_1 + \dots + a_t \cdot w_t + c_{t+1} \cdot v_{t+1} + \dots + c_s \cdot v_s = 0$$

of the vectors which correspond to “no stair” columns has a lower rank than the number of variables (coefficients of a linear combination), thus according to 2.3.5 has a nontrivial (non-zero) solution.

**2.C.16.** Determine the vector subspace (of the space  $\mathbb{R}^4$ ) generated by the vectors  $u_1 = (-1, 3, -2, 1)$ ,  $u_2 = (2, -1, -1, 2)$ ,  $u_3 = (-4, 7, -3, 0)$ ,  $u_4 = (1, 5, -5, 4)$ , by choosing a maximal set of linearly independent vectors  $u_i$  (that is, by choosing a basis).

**Solution.** Write the vectors  $u_i$  into the columns of a matrix and transform it using elementary row transformations. This way we obtain

$$\begin{aligned} & \begin{pmatrix} -1 & 2 & -4 & 1 \\ 3 & -1 & 7 & 5 \\ -2 & -1 & -3 & -5 \\ 1 & 2 & 0 & 4 \end{pmatrix} \sim \begin{pmatrix} 1 & 2 & 0 & 4 \\ -1 & 2 & -4 & 1 \\ 3 & -1 & 7 & 5 \\ -2 & -1 & -3 & -5 \end{pmatrix} \\ & \sim \begin{pmatrix} 1 & 2 & 0 & 4 \\ 0 & 4 & -4 & 5 \\ 0 & -7 & 7 & -7 \\ 0 & 3 & -3 & 3 \end{pmatrix} \sim \begin{pmatrix} 1 & 2 & 0 & 4 \\ 0 & 1 & -1 & 5/4 \\ 0 & 1 & -1 & 1 \\ 0 & 0 & 0 & 0 \end{pmatrix} \\ & \sim \begin{pmatrix} 1 & 2 & 0 & 4 \\ 0 & 1 & -1 & 5/4 \\ 0 & 0 & 0 & -1/4 \\ 0 & 0 & 0 & 0 \end{pmatrix} \sim \begin{pmatrix} \textcircled{1} & 0 & 2 & 0 \\ 0 & \textcircled{1} & -1 & 0 \\ 0 & 0 & 0 & \textcircled{1} \\ 0 & 0 & 0 & 0 \end{pmatrix}. \end{aligned}$$

And (according to the algorithm) it follows that the vectors corresponding to the columns with circled elements, namely vectors  $u_1, u_2$  and  $u_4$  form a maximal linearly independent set.  $\square$

**Remark.** Note, that the maximal set of linearly independent vectors is not unique. Unique is only the number of vectors in it (the dimension of the vector space generated by the given vectors). For example from vectors  $(1, 0)$ ,  $(0, 1)$ ,  $(1, 1)$  you can pick any two to form a maximal linearly independent set, from vectors  $(1, 0)$ ,  $(2, 0)$ ,  $(0, 1)$ . This fact is also reflected in the algorithm, because it is independent of an order, in which you put the given vectors as columns in a matrix.

**2.C.17.** Find a basis of the subspace

$$U = \text{span} \left\{ \begin{pmatrix} 1 & 2 \\ 3 & 4 \\ 5 & 6 \end{pmatrix}, \begin{pmatrix} 0 & 1 \\ 2 & 3 \\ 4 & 5 \end{pmatrix}, \begin{pmatrix} -1 & 0 \\ 1 & 2 \\ 3 & 4 \end{pmatrix}, \begin{pmatrix} -2 & -1 \\ 0 & 1 \\ 2 & 3 \end{pmatrix} \right\}$$

of the vector space of real matrices  $3 \times 2$ . Extend this basis to a basis of the whole space.

and because the corresponding vectors form a basis  $W_2$ , all the coefficients are zero.

The claim (3) now follows by directly counting the generators.  $\square$

**2.3.10. Examples.** (1)  $\mathbb{K}^n$  has (as a vector space over  $\mathbb{K}$ ) dimension  $n$ . The  $n$ -tuple of vectors

$$((1, 0, \dots, 0), (0, 1, \dots, 0), \dots, (0, \dots, 0, 1))$$

is clearly a basis, called the *standard basis of  $\mathbb{K}^n$* .

Note that in the case of a finite field of scalars, say  $\mathbb{Z}_k$  with  $k$  prime, the whole space  $\mathbb{K}^n$  has only a finite number  $k^n$  of elements.

(2)  $\mathbb{C}$  as a vector space over  $\mathbb{R}$  has dimension 2. A basis is for instance the pair of numbers 1 and  $i$ , or any other two complex numbers which are not a real multiple of each other, eg.  $1 + i$  and  $1 - i$ .

(3)  $\mathbb{K}_m[x]$ , that is, the space of all polynomials with coefficients in  $\mathbb{K}$  of degree at most  $m$ , has dimension  $m + 1$ . A basis is for instance the sequence  $1, x, x^2, \dots, x^m$ .

The vector space of all polynomials  $\mathbb{K}[x]$  has dimension  $\infty$ , but we can still find a basis (although infinite in size):  $1, x, x^2, \dots$ .

(4) The vector space  $\mathbb{R}$  over  $\mathbb{Q}$  has dimension  $\infty$ . It does not have a countable basis.

(5) The vector space of all mappings  $f : \mathbb{R} \rightarrow \mathbb{R}$  has also dimension  $\infty$ . It does not have any countable basis.

**2.3.11. Vector coordinates.** If we fix a basis  $(v_1, \dots, v_n)$  of a finite dimensional space  $V$ , then every vector  $w \in V$  can be expressed as a linear combination  $w = a_1 v_1 + \dots + a_n v_n$  in a unique way. Indeed, assume that we can do it in two ways:

$$w = a_1 v_1 + \dots + a_n v_n = b_1 v_1 + \dots + b_n v_n.$$

Then

$$0 = (a_1 - b_1) \cdot v_1 + \dots + (a_n - b_n) \cdot v_n$$

and thus  $a_i = b_i$  for all  $i = 1, \dots, n$ , because the vectors  $v_i$  are linearly independent. We have reached the concept of coordinates:

#### COORDINATES OF VECTORS

**Definition.** The coefficients of the unique linear combination expressing the given vector  $w \in V$  in the chosen basis  $\underline{v} = (v_1, \dots, v_n)$  are called the *coordinates of the vector  $w$*  in this basis.

Whenever we speak about coordinates  $(a_1, \dots, a_n)$  of a vector  $w$ , which we express as a sequence, we must have a fixed ordering of the basis vectors  $\underline{v} = (v_1, \dots, v_n)$ . Although we have defined the basis as a minimal set of generators, in reality we work with them as with sequences (that is, with ordered sets).

**Solution.** Recall that a basis of a subspace is a set of linearly independent vectors which generate given subspace. By writing the entries of the matrices in a row, we can consider the matrices as vectors in  $\mathbb{R}^6$ . In this way, the four given matrices can be identified with the rows of the matrix

$$\begin{pmatrix} 1 & 2 & 3 & 4 & 5 & 6 \\ 0 & 1 & 2 & 3 & 4 & 5 \\ -1 & 0 & 1 & 2 & 3 & 4 \\ -2 & -1 & 0 & 1 & 2 & 3 \end{pmatrix}.$$

It is easy to show that this matrix has rank 2, and hence that the subspace  $U$  is generated just by the first two matrices, which consequently form a basis for  $U$ . In fact, it follows easily that

$$\begin{pmatrix} -1 & 0 \\ 1 & 2 \\ 3 & 4 \end{pmatrix} = -1 \cdot \begin{pmatrix} 1 & 2 \\ 3 & 4 \\ 5 & 6 \end{pmatrix} + 2 \cdot \begin{pmatrix} 0 & 1 \\ 2 & 3 \\ 4 & 5 \end{pmatrix}$$

$$\begin{pmatrix} -2 & -1 \\ 0 & 1 \\ 2 & 3 \end{pmatrix} = -2 \cdot \begin{pmatrix} 1 & 2 \\ 3 & 4 \\ 5 & 6 \end{pmatrix} + 3 \cdot \begin{pmatrix} 0 & 1 \\ 2 & 3 \\ 4 & 5 \end{pmatrix}.$$

There are many options for extending this basis to be a basis for the whole space. One option is to choose the first two of the given matrices together with the last four (actually, any four would do) of the six linearly independent matrices

$$\begin{pmatrix} 1 & 0 \\ 0 & 0 \\ 0 & 0 \end{pmatrix}, \begin{pmatrix} 0 & 1 \\ 0 & 0 \\ 0 & 0 \end{pmatrix}, \begin{pmatrix} 0 & 0 \\ 1 & 0 \\ 0 & 0 \end{pmatrix}, \begin{pmatrix} 0 & 0 \\ 0 & 1 \\ 0 & 0 \end{pmatrix}, \begin{pmatrix} 0 & 0 \\ 0 & 0 \\ 1 & 0 \end{pmatrix}, \begin{pmatrix} 0 & 0 \\ 0 & 0 \\ 0 & 1 \end{pmatrix}$$

. Linear independence of these six matrices is established by computing

$$\begin{vmatrix} 1 & 2 & 3 & 4 & 5 & 6 \\ 0 & 1 & 2 & 3 & 4 & 5 \\ 0 & 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 \end{vmatrix} = 1 \neq 0.$$

Clearly the dimension is 6, so spanning is automatic, and hence we have a basis.  $\square$

How can we describe simple mappings analytically? For example, how can we describe a rotation, an axial symmetry, a mirror symmetry, a projection of a three-dimensional space onto a two-dimensional one in the plane or in the space? How can we describe the scaling of a diagram? What do they have in common? These all are linear mappings. This means that they preserve a certain structure of the space or a subspace. What structure? The structure of a vector space. Every point in the plane is described by two coordinates, every point in the 3-dimensional space is described by three coordinates. If we fix the origin, then it makes sense to say that a point is in some direction twice that far from the origin as some other point.

ASSIGNING COORDINATES TO VECTORS

A mapping assigning the vector  $v = a_1v_1 + \dots + a_nv_n$  to its coordinates in the basis  $\underline{v}$  will be denoted by the same symbol  $\underline{v} : V \rightarrow \mathbb{K}^n$ . It has the following properties:

- (1)  $\underline{v}(u + w) = \underline{v}(u) + \underline{v}(w); \forall u, w \in V,$
- (2)  $\underline{v}(a \cdot u) = a \cdot \underline{v}(u); \forall a \in \mathbb{K}, \forall u \in V.$

Note that the operations on the two sides of these equations are not identical. Quite the opposite; they are operations on different vector spaces!

Sometimes it is really useful to understand vectors as mappings from fixed set of independent generators to coordinates (without having the generators ordered). In this way, we may think about the basis  $M$  of infinite dimensional vector spaces  $V$ . Even though the set  $M$  will be infinite, there can be only a finite number of non-zero values for any mapping representing a vector. The vector space of all polynomials  $\mathbb{K}_\infty[x]$ , with the basis  $M = \{1, x, x^2, \dots\}$  is a good example.

**2.3.12. Linear mappings.** The above properties of the assignments of coordinates are typical for what we have called linear mappings in the geometry of the plane  $\mathbb{R}^2$ .

For any vector space (of finite or infinite dimension) we define “linearity” of a mapping between spaces in a similar way to the case of the plane  $\mathbb{R}^2$ :

LINEAR MAPPINGS

Let  $V$  and  $W$  be vector spaces over the same field of scalars  $\mathbb{K}$ . The mapping  $f : V \rightarrow W$  is called a *linear mapping*, or *homomorphism*, if the following holds:

- (1)  $f(u + v) = f(u) + f(v), \forall u, v \in V$
- (2)  $f(a \cdot u) = a \cdot f(u), \forall a \in \mathbb{K}, \forall u \in V.$

We have seen such mappings already in the case of matrix multiplication:

$$f : \mathbb{K}^n \rightarrow \mathbb{K}^m, \quad x \mapsto A \cdot x$$

with a fixed matrix  $A$  of the type  $m/n$  over  $\mathbb{K}$ .

The *image* of a linear mapping,  $\text{Im } f = f(V) \subset W$ , is always a vector subspace, since for any set of vectors  $u_i$ , the linear combination of images  $f(u_i)$  is the image of the linear combination of the vectors  $u_i$  with the same coefficients.

Analogously, the set of all vectors  $\text{Ker } f = f^{-1}(\{0\}) \subset V$  is a subspace, since the linear combination of zero images will always be a zero vector. The subspace  $\text{Ker } f$  is called the *kernel of the linear mapping*  $f$ .

A linear mapping which is a bijection is called an *isomorphism*.

Analogously to the abstract definition of vector spaces, it is again necessary to prove seemingly trivial claims that follow from the axioms:

We also know where arrive at if we translate or shift by some amount in a given direction and then by some other amount in another direction. These properties can be formalized – we speak of vectors in the plane or in space, and we consider their multiplication and addition. Linear mappings have the property that the image of a sum of vectors is a sum of the images of the vectors. The image of a multiple of a vector is the same multiple as the image of the vector. These properties are shared among the mappings stated at the beginning of this paragraph. Such a mapping is then uniquely determined by its behaviour on the vectors of a basis. (In the plane, a basis consists of two vectors not on the same line. In space a basis consists of three vectors not all in the same plane).

How can we write down some linear mapping  $f$  on a vector space  $V$ ? For simplicity, we start with the plane  $\mathbb{R}^2$ . Assume that the image of the point (vector)  $(1, 0)$  is  $(a, b)$  and the image of the point (vector)  $(0, 1)$  is  $(c, d)$ . This uniquely determines the image of an arbitrary point with coordinates  $(u, v)$ :  $f((u, v)) = f(u(1, 0) + v(0, 1)) = uf(1, 0) + vf(0, 1) = (ua, ub) + (vc, vd) = (au + cv, bu + dv)$ . This can be written down more efficiently as follows:

$$\begin{pmatrix} a & c \\ b & d \end{pmatrix} \begin{pmatrix} u \\ v \end{pmatrix} = \begin{pmatrix} au + cv \\ bu + dv \end{pmatrix}$$

A linear mapping is thus a mapping uniquely determined (in a fixed basis) by a matrix. Furthermore, when we have another linear mapping  $g$  given by the matrix  $\begin{pmatrix} e & f \\ g & h \end{pmatrix}$ , then we can easily compute (an interested reader can fill in the details by himself) that their composition  $g \circ f$  is given by the matrix

$$\begin{pmatrix} a & b \\ c & d \end{pmatrix} \cdot \begin{pmatrix} e & f \\ g & h \end{pmatrix} = \begin{pmatrix} ae + fc & be + df \\ ag + ch & bg + dh \end{pmatrix}.$$

This leads us to the definition of matrix multiplication in exactly this way. That is, an application of a mapping on a vector is given by the matrix multiplication of the matrix of the mapping with the given vector, and that the mapping of a composition is given by the product of the corresponding matrices. This works analogously in the spaces of higher dimension. Further, this again shows what has already been proven in (2.1.5), namely, that matrix multiplication is associative but not commutative, just as with mapping composition. That is another motivation to study vector spaces.

Recall that already in the first chapter we worked with the matrices of some linear mappings in the plane  $\mathbb{R}^2$ , notably with the rotation around a point and with axial symmetry (see 1.5.8 and 1.5.9).

**Proposition.** Let  $f : V \rightarrow W$  be a linear mapping between two vector spaces over the same field of scalars  $\mathbb{K}$ . The following is true for all vectors  $u, u_1, \dots, u_k \in V$  and scalars  $a_1, \dots, a_k \in \mathbb{K}$

- (1)  $f(0) = 0$ ,
- (2)  $f(-u) = -f(u)$ ,
- (3)  $f(a_1 \cdot u_1 + \dots + a_k \cdot u_k) = a_1 \cdot f(u_1) + \dots + a_k \cdot f(u_k)$ ,
- (4) for every vector subspace  $V_1 \subset V$ , its image  $f(V_1)$  is a vector subspace in  $W$ ,
- (5) for every vector subspace  $W_1 \subset W$ , the set  $f^{-1}(W_1) = \{v \in V; f(v) \in W_1\}$  is a vector subspace in  $V$ .

**PROOF.** We rely on the axioms, definitions and already proved results (in case you are not sure what has been used, look it up!):

$$\begin{aligned} f(0) &= f(u - u) = f((1 - 1) \cdot u) = 0 \cdot f(u) = 0, \\ f(-u) &= f((-1) \cdot u) = (-1) \cdot f(u) = -f(u). \end{aligned}$$

Property (3) is derived easily from the definition for two summands, using induction on the number of summands.

Next, (3) implies  $\text{span } f(V_1) = f(V_1)$ , thus it is a vector subspace. On the other hand, if  $f(u) \in W_1$  and  $f(v) \in W_1$  then for any scalars we arrive at  $f(a \cdot u + b \cdot v) = a \cdot f(u) + b \cdot f(v) \in W_1$ .  $\square$

**2.3.13. Proposition** (Simple corollaries). (1) The composition  $g \circ f : V \rightarrow Z$  of two linear mappings  $f : V \rightarrow W$  and  $g : W \rightarrow Z$  is again a linear mapping.

- (2) The linear mapping  $f : V \rightarrow W$  is an isomorphism if and only if  $\text{Im } f = W$  and  $\text{Ker } f = \{0\} \subset V$ . The inverse mapping of an isomorphism is again an isomorphism.
- (3) For any two subspaces  $V_1, V_2 \subset V$  and linear mapping  $f : V \rightarrow W$ ,

$$\begin{aligned} f(V_1 + V_2) &= f(V_1) + f(V_2), \\ f(V_1 \cap V_2) &\subset f(V_1) \cap f(V_2). \end{aligned}$$

- (4) The “coordinate assignment” mapping  $\underline{u} : V \rightarrow \mathbb{K}^n$  given by an arbitrarily chosen basis  $\underline{u} = (u_1, \dots, u_n)$  of a vector space  $V$  is an isomorphism.
- (5) Two finitely dimensional vector spaces are isomorphic if and only if they have the same dimension.
- (6) The composition of two isomorphisms is an isomorphism.

**PROOF.** Proving the first claim is a very easy exercise left to the reader. In order to verify (2), notice that  $f$  is surjective if and only if  $\text{Im } f = W$ . If  $\text{Ker } f = \{0\}$  then  $f(u) = f(v)$  ensures  $f(u - v) = 0$ , that is,  $u = v$ . In this case  $f$  is injective. Finally, if  $f$  is a linear bijection, then the vector  $w$  is the preimage of a linear combination  $au + bv$ , that is  $w = f^{-1}(au + bv)$ , if and only if

$$f(w) = au + bv = f(a \cdot f^{-1}(u) + b \cdot f^{-1}(v)).$$

We try now to write down matrices of linear mappings from  $\mathbb{R}^3$  to  $\mathbb{R}^3$ . What does the matrix of a rotation in three dimensions look like? We begin with some special (easier for description) rotations about coordinate axes:

**2.C.18. Matrix of rotation about coordinate axes in  $\mathbb{R}^3$ .**

We write down the matrices of rotations by the angle  $\varphi$ , about the (oriented) axes  $x, y$  and  $z$  in  $\mathbb{R}^3$ .

**Solution.** When rotating a particular point about the given axis (say  $x$ ), the corresponding coordinate ( $x$ ) does not change. The remaining two coordinates are then given by the rotation in the plane which we already know (a matrix of the type  $2 \times 2$ ).

Thus we obtain the following matrices – rotation about the axis  $z$ :

$$\begin{pmatrix} \cos \varphi & -\sin \varphi & 0 \\ \sin \varphi & \cos \varphi & 0 \\ 0 & 0 & 1 \end{pmatrix}$$

rotation about the axis  $x$ :

$$\begin{pmatrix} 1 & 0 & 0 \\ 0 & \cos \varphi & -\sin \varphi \\ 0 & \sin \varphi & \cos \varphi \end{pmatrix}.$$

rotation about the axis  $y$ :

$$\begin{pmatrix} \cos \varphi & 0 & \sin \varphi \\ 0 & 1 & 0 \\ -\sin \varphi & 0 & \cos \varphi \end{pmatrix}$$

Note the sign of  $\varphi$  in the matrix for rotation about  $y$ . We want, as with any other rotation, the rotation about the  $y$  axis to be in the positive sense — that is, when we look in the opposite direction of the direction of the  $y$  axis, the world turns anti-clockwise. The signs in the matrices depend on the orientation of our coordinate system. Usually, in the 3-dimensional space the “dextrorotary coordinate system” is chosen: if we place our hand on the  $x$  axis such that the fingers point in the direction of the axis and such that we can rotate the  $x$  axis in the  $xy$  plane so that  $x$  coincides with the  $y$  axis and they point in the same direction, then the thumb should point in the direction of the  $z$  axis. In such a system, this is a rotation in the negative sense in the plane  $xz$  (that is, the axis  $z$  turns in the direction towards  $x$ ). Think about the positive and negative sense of rotations by all three axes. The sign is also consistent with the cycle  $x$  to  $y$  to  $z$  to  $x$  to  $y$  etc.... or 1 to 2 to 3 to 1 to.... etc.  $\square$

Knowledge of matrices allows us to write the matrix of rotation about any oriented axis. Let us start with a specific example:

Thus we also get  $w = af^{-1}(u) + bf^{-1}(v)$  and therefore the inversion of a linear bijection is again a linear bijection.

The third property is obvious from the definition, but try finding an example showing that the inequality in the second equation can indeed be sharp.

The remaining claims all follow immediately from the definition.  $\square$

**2.3.14. Coordinates again.** Consider any two vector spaces

$V$  and  $W$  over  $\mathbb{K}$  with  $\dim V = n, \dim W = m$  and consider some linear mapping  $f : V \rightarrow W$ . For every choice of basis  $\underline{u} = (u_1, \dots, u_n)$  on  $V$ ,  $\underline{v} = (v_1, \dots, v_m)$  on  $W$  there are the following linear mappings as shown in the diagram:

The bottom arrow  $f_{\underline{u}, \underline{v}}$  is defined by the remaining three, i.e. the composition of linear mappings

$$f_{\underline{u}, \underline{v}} = \underline{v} \circ f \circ \underline{u}^{-1}.$$

MATRIX OF A LINEAR MAPPING

Every linear mapping is uniquely determined by its values on an arbitrary set of generators, in particular, on the vectors of a basis  $\underline{u}$ . Denote by

$$f(u_1) = a_{11} \cdot v_1 + a_{21} \cdot v_2 + \dots + a_{m1} v_m$$

$$f(u_2) = a_{12} \cdot v_1 + a_{22} \cdot v_2 + \dots + a_{m2} v_m$$

$\vdots$

$$f(u_n) = a_{1n} \cdot v_1 + a_{2n} \cdot v_2 + \dots + a_{mn} v_m,$$

that is, scalars  $a_{ij}$  form a matrix  $A$ , where the columns are coordinates of the values  $f(u_j)$  of the mapping  $f$  on the basis vectors expressed in the basis  $\underline{v}$  on the target space  $W$ .

A matrix  $A = (a_{ij})$  is called the *matrix of the mapping*  $f$  in the bases  $\underline{u}, \underline{v}$ .

For a general vector  $u = x_1 u_1 + \dots + x_n u_n \in V$  we calculate (recall that vector addition is commutative and distributive with respect to scalar multiplication)

$$f(u) = x_1 f(u_1) + \dots + x_n f(u_n)$$

$$= x_1 (a_{11} v_1 + \dots + a_{m1} v_m) + \dots + x_n (a_{1n} v_1 + \dots)$$

$$= (x_1 a_{11} + \dots + x_n a_{1n}) v_1 + \dots + (x_1 a_{m1} + \dots) v_m.$$

Using matrix multiplication we can now very easily and clearly write down the values of the mapping  $f_{\underline{u}, \underline{v}}(w)$  defined uniquely by the previous diagram. Recall that vectors in  $\mathbb{K}^\ell$  are understood as columns, that is, matrices of the type  $\ell/1$

$$f_{\underline{u}, \underline{v}}(\underline{u}(w)) = \underline{v}(f(w)) = A \cdot \underline{u}(w).$$

On the other hand, if we have fixed bases on  $V$  and  $W$ , then every choice of a matrix  $A$  of the type  $m/n$  gives a unique linear mapping  $\mathbb{K}^n \rightarrow \mathbb{K}^m$  and thus also a mapping

**2.C.19.** Find the matrix of the rotation in the positive sense by the angle  $\pi/3$  about the line passing through the origin with the oriented directional vector  $(1, 1, 0)$  under the standard basis  $\mathbb{R}^3$ .

**Solution.** The given rotation is easily obtained by composing these three mappings:

- rotation through the angle  $\pi/4$  in the negative sense about the axis  $z$  (the axis of the rotation goes over on the  $x$  axis);
- rotation through the angle  $\pi/3$  in the positive sense about the  $x$  axis;
- rotation through the angle  $\pi/4$  in the positive sense about the  $z$  axis (the  $x$  axis goes over on the axis of the rotation).

The matrix of the resulting rotation is the product of the matrices corresponding to the given three mappings, while the order of the matrices is given by the order of application of the mappings – the first mapping applied is in the product the rightmost one. Thus we obtain the desired matrix

$$\begin{pmatrix} \frac{\sqrt{2}}{2} & -\frac{\sqrt{2}}{2} & 0 \\ \frac{\sqrt{2}}{2} & \frac{\sqrt{2}}{2} & 0 \\ 0 & 0 & 1 \end{pmatrix} \cdot \begin{pmatrix} 1 & 0 & 0 \\ 0 & \frac{1}{2} & -\frac{\sqrt{3}}{2} \\ 0 & \frac{\sqrt{3}}{2} & \frac{1}{2} \end{pmatrix} \cdot \begin{pmatrix} \frac{\sqrt{2}}{2} & \frac{\sqrt{2}}{2} & 0 \\ -\frac{\sqrt{2}}{2} & \frac{\sqrt{2}}{2} & 0 \\ 0 & 0 & 1 \end{pmatrix} \\ = \begin{pmatrix} \frac{3}{4} & \frac{1}{4} & \frac{\sqrt{6}}{4} \\ \frac{1}{4} & \frac{3}{4} & -\frac{\sqrt{6}}{4} \\ -\frac{\sqrt{6}}{4} & \frac{\sqrt{6}}{4} & \frac{1}{2} \end{pmatrix}$$

Note that the resulting rotation could be also obtained for instance by taking the composition of the three following mappings:

- rotation through the angle  $\pi/4$  in the positive sense about the axis  $z$  (the axis of rotation goes over on the axis  $y$ );
- rotation through the angle  $\pi/3$  in the positive sense about the axis  $y$ ;
- rotation through the angle  $\pi/4$  in the negative sense about the axis  $z$  (the axis  $y$  goes over to the axis of rotation).

Analogously we obtain

$$\begin{pmatrix} \frac{\sqrt{2}}{2} & \frac{\sqrt{2}}{2} & 0 \\ -\frac{\sqrt{2}}{2} & \frac{\sqrt{2}}{2} & 0 \\ 0 & 0 & 1 \end{pmatrix} \cdot \begin{pmatrix} \frac{1}{2} & 0 & \frac{\sqrt{3}}{2} \\ 0 & 1 & 0 \\ -\frac{\sqrt{3}}{2} & 0 & \frac{1}{2} \end{pmatrix} \cdot \begin{pmatrix} \frac{\sqrt{2}}{2} & -\frac{\sqrt{2}}{2} & 0 \\ \frac{\sqrt{2}}{2} & \frac{\sqrt{2}}{2} & 0 \\ 0 & 0 & 1 \end{pmatrix} \\ = \begin{pmatrix} \frac{3}{4} & \frac{1}{4} & \frac{\sqrt{6}}{4} \\ \frac{1}{4} & \frac{3}{4} & -\frac{\sqrt{6}}{4} \\ -\frac{\sqrt{6}}{4} & \frac{\sqrt{6}}{4} & \frac{1}{2} \end{pmatrix}$$

$f : V \rightarrow W$ . We have found the bijective correspondence between matrices of the fixed types (determined by dimensions of  $V$  and  $W$ ) and linear mappings  $V \rightarrow W$ .

**2.3.15. Coordinate transition matrix.** If we choose  $V = W$  to be the same space, but with two different bases  $\underline{u}$ ,  $\underline{v}$ , and consider the identity mapping for  $f$ , then the approach from the previous paragraph expresses the vectors of the basis  $\underline{u}$  in coordinates with respect to the basis  $\underline{v}$ . Let the resulting matrix be  $T$ .

Thus, we are applying the concept of the matrix of a linear mapping to the special case of the identity mapping  $\text{id}_V$ .

$$\begin{array}{ccc} V & \xrightarrow{\text{id}_V} & V \\ \underline{u} \downarrow \simeq & & \simeq \downarrow \underline{v} \\ \mathbb{K}^n & \xrightarrow{T=(\text{id}_V)_{\underline{u}, \underline{v}}} & \mathbb{K}^n \end{array}$$

The resulting matrix  $T$  is called the *coordinate transition matrix* for changing the basis from  $\underline{u}$  to the basis  $\underline{v}$ .

The fact that the matrix  $T$  of the identity mapping yields exactly the transformation of coordinates between the two bases is easily seen.

Consider the expression of  $u$  with the basis  $\underline{u}$

$$u = x_1 u_1 + \dots + x_n u_n,$$

and replace the vectors  $u_i$  by their expressions as linear combinations of the vectors  $v_i$  in the basis  $\underline{v}$ . Collecting the terms properly, we obtain the coordinate expression  $\bar{x} = (\bar{x}_1, \dots, \bar{x}_n)$  of the same vector  $u$  in the basis  $\underline{v}$ . It is enough just to reorder the summands and express the individual scalars at the vectors of the basis. But this is exactly what we do when forming the matrix for the identity mapping, thus  $\bar{x} = T \cdot x$ .

We have arrived at the following instruction for building the coordinate transition matrix:

CALCULATING THE MATRIX FOR CHANGING THE BASIS

**Proposition.** The matrix  $T$  for the transition from the basis  $\underline{u}$  to the basis  $\underline{v}$  is obtained by taking the coordinates of the vectors of the basis  $\underline{u}$  expressed in the basis  $\underline{v}$  and writing them as the columns of the matrix  $T$ . The new coordinates  $\bar{x}$  in terms of the new basis  $\underline{v}$  are then  $\bar{x} = T \cdot x$ , where  $x$  is the coordinate vector in the original basis  $\underline{u}$ .

Because the inverse mapping to the identity mapping is again the identity mapping, the coordinate transition matrix is always invertible and its inverse  $T^{-1}$  is the coordinate transition matrix in the opposite direction, that is from the basis  $\underline{v}$  to the basis  $\underline{u}$  (just have a look at the diagram above and invert all the arrows).

**2.3.16. More coordinates.** Next, we are interested in the matrix of a composition of the linear mappings.

Thus, consider another vector space  $Z$  over  $\mathbb{K}$  of dimension  $k$  with basis  $\underline{w}$ , linear mapping

□  $g : W \rightarrow Z$  and denote the corresponding matrix by  $g_{\underline{v}, \underline{w}}$ .

**2.C.20. Matrix of general rotation in  $\mathbb{R}^3$ .** Derive the matrix of a general rotation in  $\mathbb{R}^3$ .

**Solution.** We can do the same things as in the previous example with general values. Consider an arbitrary unit vector  $(x, y, z)$ . Rotation

in the positive sense by the angle  $\varphi$  about this vector can be written down as a composition of the following rotations whose matrices we already know:

- i) rotation  $\mathcal{R}_1$  in the negative sense about the  $z$  axis through the angle with cosine equal to  $x/\sqrt{x^2+y^2} = x/\sqrt{1-z^2}$ , that is, with sine  $y/\sqrt{1-z^2}$ , under which the line with the directional vector  $(x, y, z)$  goes over on the line with the directional vector  $(0, y, z)$ . The matrix of this rotation is

$$R_1 = \begin{pmatrix} x/\sqrt{1-z^2} & y/\sqrt{1-z^2} & 0 \\ -y/\sqrt{1-z^2} & x/\sqrt{1-z^2} & 0 \\ 0 & 0 & 1 \end{pmatrix},$$

- ii) rotation  $\mathcal{R}_2$  in the positive sense about the  $y$  axis through the angle with cosine  $\sqrt{1-z^2}$ , that is, with sine  $z$ , under which the line with the directional vector  $(0, y, z)$  goes over on the line with the directional vector  $(1, 0, 0)$ . The matrix of this rotation is

$$R_2 = \begin{pmatrix} \sqrt{1-z^2} & 0 & z \\ 0 & 1 & 0 \\ -z & 0 & \sqrt{1-z^2} \end{pmatrix},$$

- iii) rotation  $\mathcal{R}_3$  in the positive sense about the  $x$  axis through the angle  $\varphi$  with the matrix

$$R_3 = \begin{pmatrix} 1 & 0 & 0 \\ 0 & \cos(\varphi) & -\sin(\varphi) \\ 0 & \sin(\varphi) & \cos(\varphi) \end{pmatrix},$$

- iv) rotation  $\mathcal{R}_2^{-1}$  with the matrix  $R_2^{-1}$ ,

- v) rotation  $\mathcal{R}_1^{-1}$  with the matrix  $R_1^{-1}$ .

The matrix of the composition of these mappings, that is, the matrix we are looking for, is given by the product of the rotations in the reverse order:

$$\begin{aligned} R_1^{-1} \cdot R_2^{-1} \cdot R_3 \cdot R_2 \cdot R_1 &= \\ &= \begin{pmatrix} 1-t+tx^2 & txy-zs & txz+ys \\ yxt+zs & 1-t+ty^2 & tyz-xs \\ zxt-ys & tzy+xs & 1-t+tz^2 \end{pmatrix}, \end{aligned}$$

where  $t = 1 - \cos \varphi$  and  $s = \sin \varphi$ .

□

We got familiar with matrices of linear maps now. But what happen with the matrix of a linear mapping, if we change the base of the vector space? (we can imagine it for example

The composition  $g \circ f$  on the upper row corresponds to the matrix of the mapping  $\mathbb{K}^n \rightarrow \mathbb{K}^k$  on the bottom and we calculate directly (we write  $A$  for the matrix of  $f$  and  $B$  for the matrix of  $g$  in the chosen bases):

$$\begin{aligned} g_{v,w} \circ f_{u,v}(x) &= \underline{w} \circ g \circ \underline{v}^{-1} \circ \underline{v} \circ f \circ \underline{u}^{-1} \\ &= B \cdot (A \cdot x) = (B \cdot A) \cdot x = (g \circ f)_{u,w}(x) \end{aligned}$$

for every  $x \in \mathbb{K}^n$ . By the associativity of matrix multiplications, the composition of mappings corresponds to multiplication of the corresponding matrices. Note that the isomorphisms correspond exactly to invertible matrices and that the matrix of the inverse mapping is the inverse matrix.

The same approach shows how the matrix of a linear mapping changes, if we change the coordinates on both the domain and the codomain:

where  $T$  is the coordinate transition matrix from  $\underline{u}'$  to  $\underline{u}$  and  $S$  is the coordinate change matrix from  $\underline{v}'$  to  $\underline{v}$ . If  $A$  is the original matrix of the mapping, then the matrix of the new mapping is given by  $A' = S^{-1}AT$ .

In the special case of a linear mapping  $f : V \rightarrow V$ , that is the domain and the codomain are the same space  $V$ , we express  $f$  usually in terms of a single basis  $\underline{u}$  of the space  $V$ . Then the change from the old basis to the new basis  $\underline{u}'$  with the coordinate transition matrix  $T$  leads to the new matrix  $A' = T^{-1}AT$ .

**2.3.17. Linear forms.** A simple but very important case of

linear mappings on an arbitrary vector space  $V$  over the scalars  $\mathbb{K}$  appears with the codomain being the scalars themselves, i.e. mappings  $f : V \rightarrow \mathbb{K}$ . We call them *linear forms*.

If we are given the coordinates on  $V$ , the assignments of a single  $i$ -th coordinate to the vectors is an example of a linear form. More precisely, for every choice of basis  $\underline{v} = (v_1, \dots, v_n)$ , there are the linear forms  $v_i^* : V \rightarrow \mathbb{K}$  such that  $v_i^*(v_j) = \delta_{ij}$ , that is,  $v_i^*(v_j) = 1$  when  $i = j$ , and  $v_i^*(v_j) = 0$  when  $i \neq j$ .

The vector space of all linear forms on  $V$  is denoted by  $V^*$  and we call it the *dual space* of the vector space  $V$ . Let us now assume that the vector space  $V$  has finite dimension  $n$ . The basis of  $V^*$ ,  $\underline{v}^* = (v_1^*, \dots, v_n^*)$ , composed of assignments of individual coordinates as above, is called the *dual basis* to  $\underline{v}$ . Clearly this is a basis of the space  $V^*$ , because these forms are evidently linearly independent (prove

as the change of coordinate system of the observer) We have to understand, what happens with the coordinates of vectors first. The key to all this is the transition matrix (see 2.3.15). We will further write  $\underline{e}$  for the standard basis, that is vectors  $((1, 0, 0), (0, 1, 0), (0, 0, 1))$  (these vectors could be any three linearly independent vectors in a vector space; with naming them as we did, we identified the vector space with  $\mathbb{R}^3$ )

**2.C.21.** A vector has coordinates  $(1, 2, 3)$  in the standard basis  $\underline{e}$ . What are its coordinates in the basis  $\underline{u} = ((1, 1, 0), (1, -1, 2), (3, 1, 5))$ ?

**Solution.** We write the transition matrix  $T$  for  $\underline{u}$  to the standard basis first. We just write coordinates of the vectors which form the basis  $\underline{u}$  in the columns:

$$T = \begin{pmatrix} 1 & 1 & 3 \\ 1 & -1 & 1 \\ 3 & 1 & 5 \end{pmatrix}.$$

For expressing the sought coordinates we albeit need the transition matrix from the standard basis to  $\underline{u}$ . No problem, it is just  $T^{-1}$ . (see 2.3.15 if you have not done so yet). We already know how to compute inverse matrix (see 2.1.10).

$$T^{-1} = \begin{pmatrix} -\frac{3}{2} & -\frac{1}{2} & 1 \\ -\frac{1}{2} & -1 & \frac{1}{2} \\ 1 & \frac{1}{2} & -\frac{1}{2} \end{pmatrix}.$$

Finally the sought coordinates are

$$T^{-1}(1, 2, 3)^T = \left(\frac{1}{2}, -1, \frac{1}{2}\right)^T.$$

□

Similarly we work with the matrix of a linear mapping.

**2.C.22.** We are given a linear mapping  $\mathbb{R}^3 \rightarrow \mathbb{R}^3$  in the standard basis as the following matrix:

$$\begin{pmatrix} 1 & -1 & 0 \\ 0 & 1 & 1 \\ 2 & 0 & 0 \end{pmatrix}.$$

Write down the matrix of this mapping in the basis

$$(f_1, f_2, f_3) = ((1, 1, 0), (-1, 1, 1), (2, 0, 1)).$$

**Solution.** Again the transition matrix  $T$  for changing the basis from the basis  $\underline{f} = (f_1, f_2, f_3)$  to the standard basis  $\underline{e}$  can be obtained by writing down the coordinates of the vectors  $f_1, f_2, f_3$  in the standard basis as the columns of the matrix  $T$ . Thus we have

$$T = \begin{pmatrix} 1 & -1 & 2 \\ 1 & 1 & 0 \\ 0 & 1 & 1 \end{pmatrix}.$$

it!) and if  $\alpha \in V^*$  is an arbitrary form, then for every vector  $u = x_1v_1 + \dots + x_nv_n$

$$\begin{aligned} \alpha(u) &= x_1\alpha(v_1) + \dots + x_n\alpha(v_n) \\ &= \alpha(v_1)v_1^*(u) + \dots + \alpha(v_n)v_n^*(u) \end{aligned}$$

and thus the linear form  $\alpha$  is a linear combination of the forms  $v_i^*$ .

Taking into account the standard basis  $\{1\}$  on the one-dimensional space of scalars  $\mathbb{K}$ , any choice of a basis  $\underline{v}$  on  $V$  identifies the linear forms  $\alpha$  with matrices of the type  $1/n$ , that is, with rows  $y$ . The components of these rows are coordinates of the general linear forms  $\alpha$  in the dual basis  $\underline{v}^*$ . Expressing such a form on a vector is then given by multiplying the corresponding row vector  $y$  with the column of the coordinates  $x$  of the vector  $u \in V$  in the basis  $\underline{v}$ :

$$\alpha(u) = y \cdot x = y_1x_1 + \dots + y_nx_n.$$

Thus we can see that for every finitely dimensional space  $V$ , the dual space  $V^*$  is isomorphic to the space  $V$ . The choice of the dual basis provides such an isomorphism.

In this context we meet again the scalar product of a row of  $n$  scalars with a column of  $n$  scalars. We have worked with it already in the paragraph 2.1.3 on the page 70.

The situation is different for infinitely dimensional spaces. For instance the simplest example of the space of all polynomials  $\mathbb{K}[x]$  in one variable is a vector space with a countable basis with elements  $v_i = x^i$ . As before, we can define linearly independent forms  $v_i^*$ . Every formal infinite sum  $\sum_{i=0}^{\infty} a_i v_i^*$  is now a well-defined linear form on  $\mathbb{K}[x]$ , because it will be evaluated only for a finite linear combination of the basis polynomials  $x^i, i = 0, 1, 2, \dots$ .

The countable set of all  $v_i^*$  is thus not a basis. Actually, it can be proved that this dual space cannot have a countable basis.

**2.3.18. The length of vectors and scalar product.** When

dealing with the geometry of the plane  $\mathbb{R}^2$  in the first chapter we also needed the concept of the length of vectors and their angles, see 1.5.7. For defining these concepts we used the scalar product of two vectors  $u = (x, y)$  and  $v = (x', y')$  in the form  $u \cdot v = xx' + yy'$ .

Indeed, the expression for the length of  $v = (x, y)$  is given by

$$\|v\| = \sqrt{x^2 + y^2} = \sqrt{v \cdot v},$$

while the (oriented) angle  $\varphi$  of two vectors  $u = (x, y)$  and  $v = (x', y')$  is in the planar geometry given by the formula

$$\cos \varphi = \frac{xx' + yy'}{\|v\| \|v'\|}.$$

Note that this scalar product is linear in each of its arguments, and we denote it by  $u \cdot v$  or by  $\langle u, v \rangle$ . The scalar product defined in such a way is symmetric in its arguments and of

The transition matrix for changing the basis from the standard basis to the basis  $\underline{f}$  is then the inverse of  $T$ :

$$T^{-1} = \begin{pmatrix} \frac{1}{4} & \frac{3}{4} & -\frac{1}{2} \\ -\frac{1}{4} & \frac{1}{4} & \frac{1}{2} \\ \frac{1}{4} & -\frac{1}{4} & \frac{1}{2} \end{pmatrix}.$$

The matrix of the mapping in the basis  $\underline{f}$  is then given by (see 2.2.11)

$$T^{-1}AT = \begin{pmatrix} \frac{1}{4} & 2 & -\frac{3}{4} \\ \frac{5}{4} & 0 & \frac{7}{4} \\ \frac{3}{4} & -2 & \frac{9}{4} \end{pmatrix}.$$

□

**2.C.23.** Consider the vector space of polynomials of one variable of degree at most 2 with real coefficients. In this space, consider the basis  $1, x, x^2$ . Write down the matrix of the derivative mapping in this basis and also in the basis  $\underline{f} = (1 + x^2, x, x + x^2)$ .

**Solution.** First we have to determine the matrix of the derivative mapping (let us denote the mapping as  $d$ , its matrix as  $D$ ). We chose the basis  $(1, x, x^2)$  as a standard basis  $\underline{e}$ , so we have coordinates  $1 \sim (1, 0, 0)$ ,  $x \sim (0, 1, 0)$  and  $x^2 \sim (0, 0, 1)$ . We look at the images of the basis vectors:  $d(1) = 0 \sim (0, 0, 0)$ ,  $d(x) = 1 \sim (1, 0, 0)$  and  $d(x^2) = 2x \sim (0, 2, 0)$ . Now we write the images as columns into the matrix  $D$ :

$$D = \begin{pmatrix} 0 & 1 & 0 \\ 0 & 0 & 2 \\ 0 & 0 & 0 \end{pmatrix}.$$

Now we write the coordinates of the basis vectors of the basis  $\underline{f}$  into the columns:

$$T = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 1 \\ 1 & 0 & 1 \end{pmatrix},$$

to get the transition matrix from  $\underline{f}$  to  $\underline{e}$ . As in the previous example we get the matrix of  $d$  in the basis  $\underline{f}$  as

$$T^{-1}DT = \begin{pmatrix} 0 & 1 & 1 \\ 2 & 1 & 3 \\ 0 & -1 & -1 \end{pmatrix},$$

where we had to compute

$$T^{-1} = \begin{pmatrix} 1 & 0 & 0 \\ 1 & 1 & -1 \\ -1 & 0 & 1 \end{pmatrix}$$

□

course  $\|v\| = 0$  if and only if  $v = 0$ . We also see immediately that two vectors in the Euclidean plane are perpendicular whenever their scalar product is zero.

Now we shall mimic this approach for higher dimensions. First, observe that the angle between two vectors is always a two-dimensional concept (we want the angle to be the same in the two-dimensional space containing the two vectors  $u$  and  $v$ ). In the subsequent paragraphs, we shall consider only finitely dimensional vector spaces over real scalars  $\mathbb{R}$ .

### SCALAR PRODUCT AND ORTHOGONALITY

A *scalar product* on a vector space  $V$  over real numbers is a mapping  $\langle \cdot, \cdot \rangle : V \times V \rightarrow \mathbb{R}$  which is symmetric in its arguments, linear in each of them, and such that  $\langle v, v \rangle \geq 0$  and  $\|v\|^2 = \langle v, v \rangle = 0$  if and only if  $v = 0$ .

The number  $\|v\| = \sqrt{\langle v, v \rangle}$  is called the length of the vector  $v$ .

Vectors  $v$  and  $w \in V$  are called *orthogonal* or *perpendicular* whenever  $\langle v, w \rangle = 0$ . We also write  $v \perp w$ . The vector  $v$  is called *normalised* whenever  $\|v\| = 1$ .

The basis of the space  $V$  composed exclusively of mutually orthogonal vectors is called an *orthogonal basis*. If the vectors in such a basis are all normalised, we call the basis *orthonormal*.

A scalar product is very often denoted by the common dot, that is,  $\langle u, v \rangle = u \cdot v$ . Thus, it is then necessary to recognize from the context whether the dot means a product of two vectors (the result is a scalar) or something different (e.g. we often denote the product of matrices and product of scalars in the same way).

Because the scalar product is linear in each of its arguments, it is completely determined by its values on pairs of basis vectors. Indeed, choose a basis  $\underline{u} = (u_1, \dots, u_n)$  of the space  $V$  and denote

$$s_{ij} = \langle u_i, u_j \rangle.$$

Then from the symmetry of the scalar product we know  $s_{ij} = s_{ji}$  and from the linearity of the product in each of its arguments we get

$$\left\langle \sum_i x_i u_i, \sum_j y_j u_j \right\rangle = \sum_{i,j} x_i y_j \langle u_i, u_j \rangle = \sum_{i,j} s_{ij} x_i y_j.$$

If the basis is orthonormal, the matrix  $S$  is the unit matrix. This proves the following useful claim:

### SCALAR PRODUCT IN COORDINATES

**Proposition.** For every orthonormal basis, the scalar product is given by the coordinate expression

$$\langle x, y \rangle = y^T \cdot x.$$

For each basis of the space  $V$  there is the symmetric matrix  $S$  such that the coordinate expression of the scalar product is

$$\langle x, y \rangle = y^T \cdot S \cdot x.$$

**2.C.24.** In the standard basis in  $\mathbb{R}^3$ , determine the matrix of the rotation through the angle  $90^\circ$  in the positive sense about the line  $(t, t, t)$ ,  $t \in \mathbb{R}$ , oriented in the direction of the vector  $(1, 1, 1)$ . Further, find the matrix of this rotation in the basis  $\underline{g} = ((1, 1, 0), (1, 0, -1), (0, 1, 1))$ .

**Solution.** We can easily determine the matrix of the given rotation in a suitable basis, that is, in a basis given by the directional vector of the line and by two mutually perpendicular vectors in the plane  $x + y + z = 0$ , that is, in the plane of vectors perpendicular to the vector  $(1, 1, 1)$ . We note that the matrix of the rotation in the positive sense through  $90^\circ$  in an orthonormal basis in  $\mathbb{R}^2$  is  $\begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix}$ . In the orthogonal basis with vectors of length  $k, l$  respectively, it is  $\begin{pmatrix} 0 & -k/l \\ l/k & 0 \end{pmatrix}$ .

If we choose perpendicular vectors  $(1, -1, 0)$  and  $(1, 1, -2)$  in the plane  $x + y + z = 0$  with lengths  $\sqrt{2}$  and  $\sqrt{6}$ , then in the basis  $\underline{f} = ((1, 1, 1), (1, -1, 0), (1, 1, -2))$  the rotation

we are looking for has matrix  $\begin{pmatrix} 1 & 0 & 0 \\ 0 & 0 & -\sqrt{3} \\ 0 & 1/\sqrt{3} & 0 \end{pmatrix}$ . In order

to obtain the matrix of the rotation in the standard basis, it is enough to change the basis. The transition matrix  $T$  for changing the basis from the basis  $\underline{f}$  to the standard basis is obtained by writing the coordinates (under the standard basis) of the vectors of the basis  $\underline{f}$  as the columns of the matrix

$T: T = \begin{pmatrix} 1 & 1 & 1 \\ 1 & -1 & 1 \\ 1 & 0 & -2 \end{pmatrix}$ . Finally, for the desired matrix  $R$ ,

we have

$$R = T \cdot \begin{pmatrix} 1 & 0 & 0 \\ 0 & 0 & -\sqrt{3} \\ 0 & 1/\sqrt{3} & 0 \end{pmatrix} \cdot T^{-1} = \begin{pmatrix} 1/3 & 1/3 - \sqrt{3}/3 & 1/3 + \sqrt{3}/3 \\ 1/3 + \sqrt{3}/3 & 1/3 & 1/3 - \sqrt{3}/3 \\ 1/3 - \sqrt{3}/3 & 1/3 + \sqrt{3}/3 & 1/3 \end{pmatrix}$$

This result can be checked by substituting into the matrix of general rotation (2.C.20). By normalizing the vector  $(1, 1, 1)$  we obtain the vector  $(x, y, z) = (1/\sqrt{3}, 1/\sqrt{3}, 1/\sqrt{3})$ ,  $\cos(\varphi) = 0$ ,  $\sin(\varphi) = 1$ .  $\square$

**2.C.25. Matrix of general rotation revisited.** We derive the matrix of (general) rotation from (2.C.20) through the angle  $\varphi$  in the positive sense about the unit vector  $(x, y, z)$  in a different way, analogically to the previous exercise. In the basis

Notice, that with symmetric matrix  $S$  it is just a matter of convention in which order we insert the vectors: the formula

$$x^T \cdot S \cdot y = (x^T \cdot S \cdot y)^T = y^T \cdot S^T \cdot x = y^T \cdot S \cdot x$$

produces the same value. However, we shall later consider the second argument as a linear form, thus it seems to be more convenient to use the expression  $y^T \cdot S \cdot x$ .

**2.3.19. Orthogonal complements and projections.** For every fixed subspace  $W \subset V$  in a space with scalar product, we define its *orthogonal complement* as

$$W^\perp = \{u \in V; u \perp v \text{ for all } v \in W\}.$$

It follows directly from the definition that  $W^\perp$  is a vector subspace. If  $W \subset V$  has a basis  $(u_1, \dots, u_k)$  then the description for  $W^\perp$  is given as  $k$  homogeneous equations for  $n$  variables. Thus  $W^\perp$  will have dimension at least  $n - k$ . Also  $u \in W \cap W^\perp$  means that  $\langle u, u \rangle = 0$ , and thus also  $u = 0$  by the definition of scalar product. Clearly then,  $V$  is the direct sum

$$V = W \oplus W^\perp.$$

A linear mapping  $f : V \rightarrow V$  on any vector space is called a *projection*, if we have

$$f \circ f = f.$$

In such a case, we can write, for every vector  $v \in V$ ,

$$v = f(v) + (v - f(v)) \in \text{Im}(f) + \text{Ker}(f) = V$$

and if  $v \in \text{Im}(f)$  and  $f(v) = 0$ , then also  $v = 0$ . Thus the above sum of the subspaces is direct. We say that  $f$  is a projection to the subspace  $W = \text{Im}(f)$  along the subspace  $U = \text{Ker}(f)$ . In words, the projection can be described naturally as follows: we decompose the given vector into a component in  $W$  and a component in  $U$ , and forget the second one.

If  $V$  has a scalar product, we say that the projection is orthogonal if the kernel is orthogonal to the image.

Every subspace  $W \neq V$  thus defines an *orthogonal projection* to  $W$ . It is a projection to  $W$  along  $W^\perp$ , given by the unique decomposition of every vector  $u$  into components  $u_W \in W$  and  $u_{W^\perp} \in W^\perp$ , that is, linear mapping which maps  $u_W + u_{W^\perp}$  to  $u_W$ .

**2.3.20. Existence of orthonormal bases.** It is easy to see that on every finite dimensional real vector space there exist scalar products. Just choose any basis. Define lengths so that each basis vector is of unit length. Call it orthonormal. Immediately we have a scalar product. In this basis the scalar products of vectors are computed as in the formula in the Theorem 2.3.18.

More often we are given a scalar product on a vector space  $V$ , and we want to find an appropriate orthonormal basis for it. We present an algorithm using suitable orthogonal projections in order to transform any basis into an orthogonal one. It is called the *Gramm-Schmidt orthogonalization process*.

$\underline{f} = ((x, y, z), (-y, x, 0), (zx, zy, z^2 - 1))$ , that is, in the orthogonal basis composed of the directional vector of the axis of rotation and of two mutually perpendicular vectors with sizes  $\sqrt{1 - z^2}$  lying in a plane perpendicular to the axis of rotation, the matrix corresponding to the rotation is  $A = \begin{pmatrix} 1 & 0 & 0 \\ 0 & \cos(\varphi) & -\sin(\varphi) \\ 0 & \sin(\varphi) & \cos(\varphi) \end{pmatrix}$ . The matrix for changing the basis from  $\underline{f}$  to the standard basis is then  $T = \begin{pmatrix} x & -y & zx \\ y & x & zy \\ z & 0 & z^2 - 1 \end{pmatrix}$  with the inverse matrix

$$T^{-1} = \begin{pmatrix} x & y & z \\ -\frac{y}{1-z^2} & \frac{x}{1-z^2} & 0 \\ \frac{zx}{1-z^2} & \frac{zy}{1-z^2} & -1 \end{pmatrix}.$$

Finally, for the matrix  $R$  of the rotation we obtain

$$R = T \cdot A \cdot T^{-1} = \begin{pmatrix} 1 - t + tx^2 & txy - zs & txz + ys \\ yxt + zs & 1 - t + ty^2 & tyz - xs \\ zxt - ys & tzy + xs & 1 - t + tz^2 \end{pmatrix},$$

where again  $t = 1 - \cos \varphi$  and  $s = \sin \varphi$ , and we get the same matrix as before.

When multiplying and simplifying, we must repeatedly use the assumption  $x^2 + y^2 + z^2 = 1$ .

Through a more detailed analysis of properties of various types of linear mapping we now obtain a deeper understanding of tools we are given by vector spaces for linear modeling of processes and systems.

**2.C.26.** Consider complex numbers as a real vector space and choose 1 and  $i$  for its basis. Determine in this basis the matrix of the following linear mappings:

- conjugation,
- multiplication by the number  $(2 + i)$ .

Determine the matrix of these mappings in the basis  $\underline{f} = ((1 - i), (1 + i))$ .

**Solution.** In order to determine the matrix of a linear mapping in some basis, it is enough to determine the images of the basis vectors.

a) For conjugation we have  $1 \mapsto 1, i \mapsto -i$ , written in the coordinates  $(1, 0) \mapsto (1, 0)$  and  $(0, 1) \mapsto (0, -1)$ . By writing the images into the columns we obtain the matrix  $\begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}$ . In the basis  $\underline{f}$  the conjugation interchanges basis vectors, that is,  $(1, 0) \mapsto (0, 1)$  and  $(0, 1) \mapsto (1, 0)$  and the matrix of conjugation under this basis is  $\begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}$ .

The point of this procedure is to transform a given sequence of independent generators  $v_1, \dots, v_k$  of a finite dimensional space  $V$  into an orthogonal set of independent generators of  $V$ .

#### GRAMM-SCHMIDT ORTHOGONALIZATION

**Proposition.** Let  $(u_1, \dots, u_k)$  be a linearly independent  $k$ -tuple of vectors of a space  $V$  with scalar product. Then there exists an orthogonal system of vectors  $(v_1, \dots, v_k)$  such that  $v_i \in \text{span}\{u_1, \dots, u_i\}$ , and  $\text{span}\{u_1, \dots, u_i\} = \text{span}\{v_1, \dots, v_i\}$ , for all  $i = 1, \dots, k$ . We obtain it by the following procedure:

- The independence of the vectors  $u_i$  ensures that  $u_1 \neq 0$ ; we choose  $v_1 = u_1$ .
- If we have already constructed the vectors  $v_1, \dots, v_\ell$  with the required properties and if  $\ell < k$ , we choose  $v_{\ell+1} = u_{\ell+1} + a_1 v_1 + \dots + a_\ell v_\ell$ , where  $a_i = -\frac{\langle u_{\ell+1}, v_i \rangle}{\|v_i\|^2}$ .

**PROOF.** We begin with the first (nonzero) vector  $v_1$  and calculate the orthogonal projection  $v_2$  to

$$\text{span}\{v_1\}^\perp \subset \text{span}\{v_1, v_2\}.$$

The result is nonzero if and only if  $v_2$  is independent of  $v_1$ . All other steps are similar:

In step  $\ell, \ell > 1$  we seek the vector  $v_{\ell+1} = u_{\ell+1} + a_1 v_1 + \dots + a_\ell v_\ell$  satisfying  $\langle v_{\ell+1}, v_i \rangle = 0$  for all  $i = 1, \dots, \ell$ . This implies

$$0 = \langle u_{\ell+1} + a_1 v_1 + \dots + a_\ell v_\ell, v_i \rangle = \langle u_{\ell+1}, v_i \rangle + a_i \langle v_i, v_i \rangle$$

and we can see that the vectors with the desired properties are determined uniquely up to a scalar multiple.  $\square$

Whenever we have an orthogonal basis of a vector space  $V$ , we just have to normalise the vectors in order to obtain an orthonormal basis. Thus, starting the Gram-Schmidt orthogonalization with any basis of  $V$ , we have proven:

**Corollary.** On every finite dimensional real vector space with scalar product there exists an orthonormal basis.

In an orthonormal basis, the coordinates and orthogonal projections are very easy to calculate. Indeed, suppose we have an orthonormal basis  $(e_1, \dots, e_n)$  for a space  $V$ . Then every vector  $v = x_1 e_1 + \dots + x_n e_n$  satisfies

$$\langle e_i, v \rangle = \langle e_i, x_1 e_1 + \dots + x_n e_n \rangle = x_i$$

and so we can always express

$$(1) \quad v = \langle e_1, v \rangle e_1 + \dots + \langle e_n, v \rangle e_n.$$

If we are given a subspace  $W \subset V$  and its orthonormal basis  $(e_1, \dots, e_k)$ , then we can extend it to an orthonormal basis  $(e_1, \dots, e_n)$  for  $V$ . Orthogonal projection of a general vector  $v \in V$  to  $W$  is then given by the expression

$$v \mapsto \langle e_1, v \rangle e_1 + \dots + \langle e_k, v \rangle e_k.$$

b) For the basis  $(1, i)$  we obtain  $1 \mapsto 2 + i, i \mapsto 2i - 1$ , that is,  $(1, 0) \mapsto (2, 1), (0, 1) \mapsto (2, -1)$ . Thus the matrix of multiplication by the number  $2 + i$  under the basis  $(1, i)$  is:

$$\begin{pmatrix} 2 & -1 \\ 1 & 2 \end{pmatrix}.$$

We determine the matrix in the basis  $\underline{f}$ . Multiplication by  $(2+i)$  gives us:  $(1-i) \mapsto (1-i)(2+i) = 3-i, (1+i) \mapsto (1+3i)$ . Coordinates  $(a, b)_{\underline{f}}$  of the vector  $3-i$  in the basis  $\underline{f}$  are given, as we know, by the equation  $a \cdot (1-i) + b \cdot (1+i) = 3+i$ , that is,  $(3+i)_{\underline{f}} = (2, 1)$ . Analogously  $(1+3i)_{\underline{f}} = (-1, 2)$ .

Altogether, we obtain the matrix  $\begin{pmatrix} 2 & -1 \\ 1 & 2 \end{pmatrix}$ .

Think about the following: why is the matrix of multiplication by  $2 + i$  the same in both bases? Would the two matrices in these bases be the same for multiplication by any complex number?  $\square$

**2.C.27.** Determine the matrix  $A$  which, under the standard basis of the space  $\mathbb{R}^3$ , gives the orthogonal projection on the vector subspace generated by the vectors  $u_1 = (-1, 1, 0)$  and  $u_2 = (-1, 0, 1)$ .

**Solution.** Note first that the given subspace is a plane containing the origin with normal vector  $u_3 = (1, 1, 1)$ . The ordered triple  $(1, 1, 1)$  is clearly a solution to the system

$$\begin{aligned} -x_1 + x_2 &= 0, \\ -x_1 + x_3 &= 0, \end{aligned}$$

that is, the vector  $u_3$  is perpendicular to the vectors  $u_1, u_2$ .

Under the given projection the vectors  $u_1$  and  $u_2$  must map to themselves and the vector  $u_3$  on the zero vector. In the basis composed of  $u_1, u_2, u_3$  (in this order) is thus the matrix of this projection

$$\begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 0 \end{pmatrix}.$$

Using the the transition matrix for changing the basis

$$T = \begin{pmatrix} -1 & -1 & 1 \\ 1 & 0 & 1 \\ 0 & 1 & 1 \end{pmatrix}, \quad T^{-1} = \begin{pmatrix} -\frac{1}{3} & \frac{2}{3} & -\frac{1}{3} \\ -\frac{1}{3} & -\frac{1}{3} & \frac{2}{3} \\ \frac{1}{3} & \frac{1}{3} & \frac{1}{3} \end{pmatrix}$$

from the basis  $(u_1, u_2, u_3)$  to the standard basis, and from the standard basis to the basis  $(u_1, u_2, u_3)$  we obtain

$$\begin{aligned} A &= \begin{pmatrix} -1 & -1 & 1 \\ 1 & 0 & 1 \\ 0 & 1 & 1 \end{pmatrix} \cdot \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 0 \end{pmatrix} \cdot \begin{pmatrix} -\frac{1}{3} & \frac{2}{3} & -\frac{1}{3} \\ -\frac{1}{3} & -\frac{1}{3} & \frac{2}{3} \\ \frac{1}{3} & \frac{1}{3} & \frac{1}{3} \end{pmatrix} \\ &= \begin{pmatrix} \frac{2}{3} & -\frac{1}{3} & -\frac{1}{3} \\ -\frac{1}{3} & \frac{2}{3} & -\frac{1}{3} \\ -\frac{1}{3} & -\frac{1}{3} & \frac{2}{3} \end{pmatrix}. \end{aligned}$$

In particular, we need only consider an orthonormal basis of the subspace  $W$  in order to write the orthogonal projection to  $W$  explicitly.

Note that in general the projection  $f$  to the subspace  $W$  along  $U$  and the projection  $g$  to  $U$  along  $W$  is constrained by the equality  $g = \text{id}_V - f$ . Thus, when dealing with orthogonal projections to a given subspace  $W$ , it is always more efficient to calculate the orthonormal basis of that space  $W$  or  $W^\perp$  whose dimension is smaller.

Note also that the existence of an orthonormal basis guarantees that for every real space  $V$  of dimension  $n$  with a scalar product, there exists a linear mapping which is an isomorphism between  $V$  and the space  $\mathbb{R}^n$  with the standard scalar product (i.e. respecting the scalar products as well). We saw already in Theorem 2.3.18 that the desired isomorphism is exactly the coordinate assignment. In words – in every orthonormal basis the scalar product is computed by the same formula as the standard scalar product in  $\mathbb{R}^n$ .

We shall return to the questions of the length of a vector and to projections in the following chapter in a more general context.

**2.3.21. Angle between two vectors.** As we have already noted, the angle between two linearly independent vectors in the space must be the same as when we consider them in the two-dimensional subspace they generate. Basically, this is the reason why the notion of angle is independent of the dimension of the original space. If we choose an orthogonal basis such that its first two vectors generate the same subspace as the two given vectors  $u$  and  $v$  (whose angle we are measuring), we can simply take the definition from the planar geometry. Independently of the choice of coordinates we can formulate the definition as follows:

ANGLE BETWEEN TWO VECTORS

The angle  $\varphi$  between two vectors  $v$  and  $w$  in a vector space with a scalar product is given by the relation

$$\cos \varphi = \frac{\langle v, w \rangle}{\|v\| \|w\|}.$$

The angle defined in this way does not depend on the order of the vectors  $v, w$  and it is chosen in the interval  $0 \leq \varphi \leq \pi$ .

We shall return to scalar products and angles between vectors in further chapters.

**2.3.22. Multilinear forms.** The scalar product was given as a mapping from the product of two copies of a vector space  $V$  into the space of scalars, which was linear in each of its arguments. Similarly, we will work with mappings from the product of  $k$  copies of a vector space  $V$  into the scalars, which are linear in each of its  $k$  arguments. We speak of  $k$ -linear forms.

Most often we will meet *bilinear forms*, that is, the case  $\alpha : V \times V \rightarrow \mathbb{K}$ , where for any four vectors  $u, v, w, z$  and

**D. Properties of linear maps**

**2.D.1.** Write down the matrix of the mapping of orthogonal projection on the plane passing through the origin and perpendicular to the vector  $(1, 1, 1)$ .

**Solution.** The image of an arbitrary point (vector)  $\mathbf{x} = (x_1, x_2, x_3) \in \mathbb{R}^3$  under the considered mapping can be obtained by subtracting from the given vector its orthogonal projection onto the direction normal to the considered plane, that is, onto the direction  $(1, 1, 1)$ . This projection  $\mathbf{p}$  is given by (see 1) as

$$\frac{\langle \mathbf{x}, (1, 1, 1) \rangle}{|(1, 1, 1)|^2} = \left( \frac{x_1 + x_2 + x_3}{3}, \frac{x_1 + x_2 + x_3}{3}, \frac{x_1 + x_2 + x_3}{3} \right).$$

The resulting mapping is thus

$$\begin{aligned} \mathbf{x} - \mathbf{p} &= \left( \frac{2x_1}{3} - \frac{x_2 + x_3}{3}, \frac{2x_2}{3} - \frac{x_1 + x_3}{3}, \frac{2x_3}{3} - \frac{x_1 + x_2}{3} \right) = \\ &= \begin{pmatrix} \frac{2}{3} & -\frac{1}{3} & -\frac{1}{3} \\ -\frac{1}{3} & \frac{2}{3} & -\frac{1}{3} \\ -\frac{1}{3} & -\frac{1}{3} & \frac{2}{3} \end{pmatrix} \begin{pmatrix} x_1 \\ x_2 \\ x_3 \end{pmatrix}. \end{aligned}$$

We have (correctly) obtained the same matrix as in the exercise 2.C.27.  $\square$

**2.D.2.** In  $\mathbb{R}^3$  write down the matrix of the mirror symmetry with respect to the plane containing the origin and  $(1, 1, 1)$  being its normal vector.

**Solution.** As in 2.D.1 we get the image of an arbitrary vector  $x = (x_1, x_2, x_3) \in \mathbb{R}^3$  with the help of the orthogonal projection onto the direction  $(1, 1, 1)$ . Unlike in the previous example, we need to subtract the projection twice (see image). Thus we get the matrix:

$$\begin{aligned} x - 2p &= \left( \frac{x_1}{3} - \frac{2(x_2 + x_3)}{3}, \frac{x_2}{3} - \frac{2(x_1 + x_3)}{3}, \frac{x_3}{3} - \frac{2(x_1 + x_2)}{3} \right) \\ &= \begin{pmatrix} \frac{1}{3} & -\frac{2}{3} & -\frac{2}{3} \\ -\frac{2}{3} & \frac{1}{3} & -\frac{2}{3} \\ -\frac{2}{3} & -\frac{2}{3} & \frac{1}{3} \end{pmatrix} \begin{pmatrix} x_1 \\ x_2 \\ x_3 \end{pmatrix}. \end{aligned}$$

**Second solution.** The normed normal vector of the mirror plane is  $n = \frac{1}{\sqrt{3}}(1, 1, 1)$ . We can express the mirror image of  $v$  under the mirror symmetry  $Z$  as follows:  $Z(v) = v - 2\langle v, n \rangle n = v - 2n \cdot (n^T \cdot v) = v - 2(n \cdot n^T) \cdot v = ((E - 2n \cdot n^T)v$  (where we have used  $\langle v, n \rangle = v \cdot n^T$  for the standard scalar product and the associativity of the matrix

scalars  $a, b, c$  and  $d$  we have

$$\alpha(au + bv, cw + dz) = ac\alpha(u, w) + ad\alpha(u, z) + bc\alpha(v, w) + bd\alpha(v, z).$$

If additionally we always have

$$\alpha(u, w) = \alpha(w, u),$$

then we speak of a *symmetric bilinear form*. If interchanging the arguments leads to a change of sign, we speak of an *antisymmetric bilinear form*.

Already in planar geometry we have defined the determinant as a bilinear antisymmetric form  $\alpha$ , that is,  $\alpha(u, w) = -\alpha(w, u)$ . In general, due to the theorem 2.2.5, we know that the determinant with dimension  $n$  can be seen as an  $n$ -linear antisymmetric form.

As with linear mappings it is clear that every  $k$ -linear form is completely determined by its values on all  $k$ -tuples of basis elements in a fixed basis. In analogy to linear mappings we can see these values as  $k$ -dimensional analogues to matrices. We show this by an example with  $k = 2$ , where it will correspond to matrices as we have defined them.

MATRIX OF A BILINEAR FORM

If we choose a basis  $\underline{u}$  on  $V$  and define for a given bilinear form  $\alpha$  scalars  $a_{ij} = \alpha(u_i, u_j)$  then we obtain for vectors  $v, w$  with coordinates  $x$  and  $y$  (as columns of coordinates)

$$\alpha(v, w) = \sum_{i,j=1}^n a_{ij}x_iy_j = y^T \cdot A \cdot x,$$

where  $A$  is a matrix  $A = (a_{ij})$ .

Directly from the definition of the matrix of a bilinear form we see that the form is symmetric or antisymmetric if and only if the corresponding matrix has this property.

Every bilinear form  $\alpha$  on a vector space  $V$  defines a mapping  $V \rightarrow V^*, v \mapsto \alpha(v, \cdot)$ . That is, by placing a fixed vector in the second argument we obtain a linear form which is the image of this vector. If we choose a fixed basis on a finitely dimensional space  $V$  and a dual basis  $V^*$ , then we have the mapping

$$y \mapsto (x \mapsto y^T \cdot A \cdot x).$$

All this is a matter of convention. Also we may fix the first vector and get a linear form again.

**4. Properties of linear mappings**

In order to exploit vector spaces and linear mappings in modelling real processes and systems in other sciences, we need a more detailed analysis of properties of diverse types of linear mappings.

**2.4.1.** We begin with four examples in the lowest dimension of interest. With the standard basis of the plane  $\mathbb{R}^2$  and with the standard scalar product we consider the following matrices of mappings  $f : \mathbb{R}^2 \rightarrow \mathbb{R}^2$ :

multiplication). We get the same matrix:

$$E - 2n \cdot n^T = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix} - \frac{2}{3} \begin{pmatrix} 1 & 1 & 1 \\ 1 & 1 & 1 \\ 1 & 1 & 1 \end{pmatrix} \\ = \frac{1}{3} \begin{pmatrix} 1 & -2 & -2 \\ -2 & 1 & -2 \\ -2 & -2 & 1 \end{pmatrix}.$$

□

**2.D.3.** Consider  $\mathbb{R}^3$ , with the standard coordinate system. In the plane  $z = 0$  there is a mirror and at the point  $[4, 3, 5]$  there is a candle. The observer at the point  $[1, 2, 3]$  is not aware of the mirror, but sees in it the reflection of the candle. Where does he think the candle is?

**Solution.** Independently of our position, we see the mirror image of the scene in the mirror (that is why it is called a mirror image). The mirror image is given by reflecting the scene (space) by the plane of the mirror, the plane  $z = 0$ . The reflection with respect to this plane changes the sign of the  $z$ -coordinate. That is we can see the candle at the point  $[4, 3, -5]$ . □

By using the inner product we can determine the (angular) deflection of the vectors:

**2.D.4.** Determine the deflection of the roots of the polynomial  $x^2 - i$  considered as vectors in the complex plane.

**Solution.** The roots of the given polynomial are square roots of  $i$ . The arguments of the square roots of any complex numbers differ according to the de Moivre theorem by  $\pi$ . Their deflection is thus always  $\pi$ . □

**2.D.5.** Determine the cosine of the deflection of the lines  $p, q$  in  $\mathbb{R}^3$  given by the equations

$$p : \begin{aligned} -2x + y + z &= 1 \\ x + 3y - 4z &= 5 \end{aligned} \\ q : \begin{aligned} x - y &= -2 \\ z &= 6 \end{aligned}$$

○

**2.D.6.** Using the Gram-Schmidt orthogonalisation, obtain the orthogonal basis of the subspace

$$U = \{(x_1, x_2, x_3, x_4)^T \in \mathbb{R}^4; x_1 + x_2 + x_3 + x_4 = 0\}$$

of the space  $\mathbb{R}^4$ .

$$A = \begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix}, B = \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix}, C = \begin{pmatrix} a & 0 \\ 0 & b \end{pmatrix}, D = \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix}$$

The matrix  $A$  describes the orthogonal projection along the subspace

$$W = \{(0, a); a \in \mathbb{R}\} \subset \mathbb{R}^2$$

to the subspace

$$V = \{(a, 0); a \in \mathbb{R}\} \subset \mathbb{R}^2,$$

that is, the projection to the  $x$ -axis along the  $y$ -axis. Evidently for this  $f : \mathbb{R}^2 \rightarrow \mathbb{R}^2$  we have  $f \circ f = f$  and thus the restriction  $f|_V$  of the given mapping on its codomain is the identity mapping. The kernel of  $f$  is exactly the subspace  $W$ .

The matrix  $B$  has the property  $B^2 = 0$ , therefore the same holds for the corresponding mapping  $f$ . We can envision this as the differentiation of polynomials  $\mathbb{R}_1[x]$  of degree at most one in the basis  $(1, x)$  (we shall come to differentiation in chapter five, see 5.1.6).

The matrix  $C$  gives a mapping  $f$ , which rescales the first vector of the basis  $a$ -times, and the second one  $b$ -times. Therefore the whole plane divides into two subspaces, which are preserved under the mapping and where it is only a *homothety*, that is, scaling by a scalar multiple (the first case was a special case with  $a = 1, b = 0$ ). For instance the choice  $a = 1, b = -1$  corresponds to axial symmetry (mirror symmetry) under the  $x$ -axis, which is the same as complex conjugation  $x+iy \mapsto x-iy$  on the two-dimensional real space  $\mathbb{R}^2 \simeq \mathbb{C}$  in basis  $(1, i)$ . This is a linear mapping of the two-dimensional real vector space  $\mathbb{C}$ , but not of the one-dimensional complex space  $\mathbb{C}$ .

The matrix  $D$  is the matrix of rotation by 90 degrees (the angle  $\pi/2$ ) centered at the origin in the standard basis. We can see at first glance that none of the one-dimensional subspaces is preserved under this mapping.

Such a rotation is a bijection of the plane onto itself, therefore we can surely find distinct bases in the domain and codomain, where its matrix will be the unit matrix  $E$ . We simply take any basis of the domain and its image in the codomain. But we are not able to do this with the same basis for both the domain and the codomain.

Consider the matrix  $D$  as a matrix of the mapping  $g : \mathbb{C}^2 \rightarrow \mathbb{C}^2$  with the standard basis of the complex vector space  $\mathbb{C}^2$ . Then we can find vectors  $u = (i, 1), v = (-i, 1)$ , for which we have

$$g(u) = \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix} \cdot \begin{pmatrix} i \\ 1 \end{pmatrix} = \begin{pmatrix} -1 \\ i \end{pmatrix} = i \cdot u,$$

$$g(v) = \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix} \cdot \begin{pmatrix} -i \\ 1 \end{pmatrix} = \begin{pmatrix} -1 \\ -i \end{pmatrix} = -i \cdot v.$$

That means that in the basis  $(u, v)$  on  $\mathbb{C}^2$ , the mapping  $g$  has the matrix

$$K = \begin{pmatrix} i & 0 \\ 0 & -i \end{pmatrix}.$$

**Solution.** The set of solutions of the given homogeneous linear equation is clearly a vector space with the basis

$$u_1 = \begin{pmatrix} -1 \\ 1 \\ 0 \\ 0 \end{pmatrix}, \quad u_2 = \begin{pmatrix} -1 \\ 0 \\ 1 \\ 0 \end{pmatrix}, \quad u_3 = \begin{pmatrix} -1 \\ 0 \\ 0 \\ 1 \end{pmatrix}.$$

shall be denoted Denote by  $v_1, v_2, v_3$ , vectors of the orthogonal basis obtained using the Gram-Schmidt orthogonalisation process.

First set  $v_1 = u_1$ . Then let

$$v_2 = u_2 - \frac{u_2^T \cdot v_1}{\|v_1\|^2} v_1 = u_2 - \frac{1}{2} v_1 = \left(-\frac{1}{2}, -\frac{1}{2}, 1, 0\right)^T,$$

that is, choose a multiple  $v_2 = (-1, -1, 2, 0)^T$ . Then let

$$v_3 = u_3 - \frac{u_3^T \cdot v_1}{\|v_1\|^2} v_1 - \frac{u_3^T \cdot v_2}{\|v_2\|^2} v_2 = u_3 - \frac{1}{2} v_1 - \frac{1}{6} v_2 = \left(-\frac{1}{3}, -\frac{1}{3}, -\frac{1}{3}, 1\right)^T.$$

Altogether we have

$$v_1 = \begin{pmatrix} -1 \\ 1 \\ 0 \\ 0 \end{pmatrix}, \quad v_2 = \begin{pmatrix} -1 \\ -1 \\ 2 \\ 0 \end{pmatrix}, \quad v_3 = \begin{pmatrix} -1 \\ -1 \\ -1 \\ 3 \end{pmatrix}.$$

Due to the simplicity of the exercise we can immediately give an orthogonal basis of the vectors

$$(1, -1, 0, 0)^T, \quad (0, 0, 1, -1)^T, \quad (1, 1, -1, -1)^T$$

or

$$(-1, 1, 1, -1)^T, \quad (1, -1, 1, -1)^T, \quad (-1, -1, 1, 1)^T.$$

□

**2.D.7.** Write down a basis of the real vector space of the matrices  $3 \times 3$  over  $\mathbb{R}$  with zero trace. (The trace of a matrix is the sum of the elements on the diagonal). Write the coordinates of the matrix

$$\begin{pmatrix} 1 & 2 & 0 \\ 0 & 2 & 0 \\ 1 & -2 & -3 \end{pmatrix}$$

in this basis.

**2.D.8.** Find the orthogonal complement  $U^\perp$  of the subspace

$$U = \{(x_1, x_2, x_3, x_4); x_1 = x_3, x_2 = x_3 + 6x_4\} \subset \mathbb{R}^4.$$

**Solution.** The orthogonal complement  $U^\perp$  consists of just those vectors that are perpendicular to every solution of the system

$$\begin{aligned} x_1 & - x_3 & & = 0, \\ x_2 & - x_3 & - 6x_4 & = 0. \end{aligned}$$

Notice that by extending the scalars to  $\mathbb{C}$ , we arrive at an analogy to the matrix  $C$  with diagonal elements  $a = \cos(\frac{1}{2}\pi) + i \sin(\frac{1}{2}\pi)$  and its complex conjugate  $\bar{a}$ . In other words, the argument of the number  $a$  in polar form provides the angle of the rotation.

This is easy to understand, if we denote the real and imaginary part of the vector  $u$  as follows

$$u = x_u + iy_u = \operatorname{Re} u + i \operatorname{Im} u = \begin{pmatrix} 0 \\ 1 \end{pmatrix} + i \cdot \begin{pmatrix} 1 \\ 0 \end{pmatrix}.$$

The vector  $v$  is the complex conjugate of  $u$ . We are interested in the restriction of the mapping  $g$  to the real vector subspace  $V = \mathbb{R}^2 \cap \operatorname{span}_{\mathbb{C}}\{u, v\} \subset \mathbb{C}^2$ . Evidently,

$$V = \operatorname{span}_{\mathbb{R}}\{u + \bar{u}, i(u - \bar{u})\} = \operatorname{span}_{\mathbb{R}}\{x_u, -y_u\}$$

is the whole plane  $\mathbb{R}^2$ . The restriction of  $g$  to this plane is exactly the original mapping given by the matrix  $D$  (notice this matrix is real, thus it preserves this real subspace). It is immediately seen that this is the rotation through the angle  $\frac{1}{2}\pi$  in the positive sense with respect to the chosen basis  $x_u, -y_u$ . Work it by yourself with a direct calculation. Note also why exchanging the order of the vectors  $u$  and  $v$  leads to the same result, although in a different real basis!

### 2.4.2. Eigenvalues and eigenvectors of mappings.

A key to the description of mappings in the previous examples was the answer to the question “what are the vectors satisfying the equation  $f(u) = a \cdot u$  for some suitable scalars  $a$ ?”

We consider this question for any linear mapping  $f : V \rightarrow V$  on a vector space of dimension  $n$  over scalars  $\mathbb{K}$ . If we imagine such an equality written in coordinates, i.e. using the matrix of the mapping  $A$  in some bases, we obtain a system of linear equations

$$A \cdot x - a \cdot x = (A - a \cdot E) \cdot x = 0$$

with an unknown parameter  $a$ . We know already that such a system of equations has only the solution  $x = 0$  if the matrix  $A - aE$  is invertible. Thus we want to find such values  $a \in \mathbb{K}$  for which  $A - aE$  is not invertible, and for that, the necessary and sufficient condition reads (see Theorem 2.2.11)

$$(1) \quad \det(A - a \cdot E) = 0.$$

If we consider  $\lambda = a$  as a variable in the previous scalar equation, we are actually looking for the roots of a polynomial of degree  $n$ . As we have seen in the case of the matrix  $D$ , the roots may exist in an extension of our field of scalars, if they are not in  $\mathbb{K}$ .

#### EIGENVALUES AND EIGENVECTORS

Scalars  $\lambda \in \mathbb{K}$  satisfying the equation  $f(u) = \lambda \cdot u$  for some nonzero vector  $u \in V$  are called the *eigenvalues of the mapping  $f$* . The corresponding nonzero vectors  $u$  are called the *eigenvectors of the mapping  $f$* .

A vector is a solution of this system if and only if it is perpendicular to both vectors  $(1, 0, -1, 0)$ ,  $(0, 1, -1, -6)$ . Thus we have

$$U^\perp = \{a \cdot (1, 0, -1, 0) + b \cdot (0, 1, -1, -6); a, b \in \mathbb{R}\}.$$

□

**2.D.9.** Find an orthonormal basis of the subspace  $V \subset \mathbb{R}^4$ , where  $V = \{(x_1, x_2, x_3, x_4) \in \mathbb{R}^4 \mid x_1 + 2x_2 + x_3 = 0\}$ .

**Solution.** The fourth coordinate does not appear in the restriction for the subspace, thus it seems reasonable to select  $(0, 0, 0, 1)$  as one of the vectors of the orthonormal basis and reduce the problem into the subspace  $\mathbb{R}^3$ . If we set the second coordinate equal to zero, then in the investigated space there are vectors with reverse first and third coordinate, notably, the unit vector  $(\frac{1}{\sqrt{2}}, 0, -\frac{1}{\sqrt{2}}, 0)$ . This vector is perpendicular to any vector which has first coordinate equal to the third coordinate. In order to get into the investigated subspace, we choose the second coordinate equal to the negative of the sum of the first and the third coordinate, and then normalise. Thus we choose the vector  $(\frac{1}{\sqrt{6}}, -\frac{2}{\sqrt{6}}, \frac{1}{\sqrt{6}}, 0)$  and we are finished. □

**2.D.10.** Find the eigenvalues and the associated subspaces

of eigenvectors of the matrix

$$A = \begin{pmatrix} -1 & 1 & 0 \\ -1 & 3 & 0 \\ 2 & -2 & 2 \end{pmatrix}.$$

**Solution.** First we find the characteristic polynomial of the matrix:

$$\begin{vmatrix} -1 - \lambda & 1 & 0 \\ -1 & 3 - \lambda & 0 \\ 2 & -2 & 2 - \lambda \end{vmatrix} = \lambda^3 - 4\lambda^2 + 2\lambda + 4.$$

This polynomial has roots  $2, 1 + \sqrt{3}, 1 - \sqrt{3}$ , which are then the eigenvalues of the matrix. Their algebraic multiplicity is one (they are simple roots of the polynomial), thus each has associated only one (up to a non-zero multiple) eigenvector. Otherwise stated, the geometric multiplicity of the eigenvalue is one, see 3.4.10).

We determine the eigenvector associated with the eigenvalue 2. It is a solution of the homogeneous linear system with the matrix  $A - 2E$ :

$$\begin{aligned} -3x_1 + x_2 &= 0 \\ -1x_1 + x_2 &= 0 \\ 2x_1 - 2x_2 &= 0. \end{aligned}$$

If  $u, v$  are eigenvectors associated with the same eigenvalue  $\lambda$ , then for every linear combination of  $u$  and  $v$ ,

$$f(au + bv) = af(u) + bf(v) = \lambda(au + bv).$$

Therefore the eigenvectors associated with the same eigenvalue  $\lambda$ , together with the zero vector, form a nontrivial vector subspace  $V_\lambda \subset V$ . We call it the *eigenspace associated with*  $\lambda$ . For instance, if  $\lambda = 0$  is an eigenvalue, the kernel  $\text{Ker } f$  is the eigenspace  $V_0$ .

We have seen how to compute the eigenvalues in coordinates. The independence of the eigenvalues from the choice of coordinates is clear from their definition. But let us look explicitly what happens if we change the basis. As a direct corollary of the transformation properties from the paragraph 2.3.16 and the Cauchy theorem 2.2.7 for calculation of the determinant of product, the matrix  $A'$  in the new coordinates will be  $A' = P^{-1}AP$  with an invertible matrix  $P$ . Thus

$$\begin{aligned} |P^{-1}AP - \lambda E| &= |P^{-1}AP - P^{-1}\lambda EP| \\ &= |P^{-1}(A - \lambda E)P| \\ &= |P^{-1}| |(A - \lambda E)| |P| \\ &= |A - \lambda E|, \end{aligned}$$

because the scalar multiplication is commutative and we know that  $|P^{-1}| = |P|^{-1}$ .

For these reasons we use the same terminology for matrices and mappings:

#### CHARACTERISTIC POLYNOMIALS

For a matrix  $A$  of dimension  $n$  over  $\mathbb{K}$  we call the polynomial  $|A - \lambda E| \in \mathbb{K}_n[\lambda]$  the *characteristic polynomial of the matrix*  $A$ .

Roots of this polynomial are the *eigenvalues of the matrix*  $A$ . If  $A$  is the matrix of the mapping  $f : V \rightarrow V$  in a certain basis, then  $|A - \lambda E|$  is also called the *characteristic polynomial of the mapping*  $f$ .

Because the characteristic polynomial of a linear mapping  $f : V \rightarrow V$  is independent of the choice of the basis of  $V$ , the coefficients of individual powers of the variable  $\lambda$  are scalars expressing some properties of  $f$ . In particular, they too cannot depend on the choice of the basis. Suppose  $\dim V = n$  and  $A = (a_{ij})$  is the matrix of the mapping in some basis. Then

$$\begin{aligned} |A - \lambda \cdot E| &= (-1)^n \lambda^n + (-1)^{n-1} (a_{11} + \dots + a_{nn}) \lambda^{n-1} \\ &\quad + \dots + |A| \lambda^0. \end{aligned}$$

The coefficient at the highest power says whether the dimension of the space  $V$  is even or odd.

The most interesting coefficient is the sum of the diagonal elements of the matrix. We have just proved that it does not depend on the choice of the basis and we call it the *trace of the matrix*  $A$  and denote it by  $\text{Tr } A$ . The *trace of the mapping*  $f$  is defined as a trace of the matrix in an arbitrary basis.

The system has solution  $x_1 = x_2 = 0, x_3 \in \mathbb{R}$  arbitrary. So the eigenvector associated with the value 2 is then the vector  $(0, 0, 1)$  (or any multiple of it).

Similarly we determine the remaining two eigenvectors – as solutions of the system  $[A - (1 + \sqrt{3})E]x = 0$ . The solution of the system

$$\begin{aligned} (-2 - \sqrt{3})x_1 + x_2 &= 0 \\ -1x_1 + (2 - \sqrt{3})x_2 &= 0 \\ 2x_1 - 2x_2 + (1 - \sqrt{3})x_3 &= 0 \end{aligned}$$

is the space  $\{(2 - \sqrt{3}, 1, 2)t, t \in \mathbb{R}\}$ .

That is the space of eigenvectors associated with the eigenvalue  $1 + \sqrt{3}$ .

Similarly we obtain that the space of eigenvectors associated with the eigenvalue  $1 - \sqrt{3}$  is  $\{(2 + \sqrt{3}, 1, -2)t, t \in \mathbb{R}\}$ .  $\square$

**2.D.11.** Determine the eigenvalues and eigenvectors of the matrix

$$A = \begin{pmatrix} 1 & 1 & 0 \\ 1 & 2 & 1 \\ 1 & 2 & 1 \end{pmatrix}.$$

Describe the geometric interpretation of this mapping and write down its matrix in the basis:

$$\begin{aligned} e_1 &= (1, -1, 1) \\ e_2 &= (1, 2, 0) \\ e_3 &= (0, 1, 1) \end{aligned}$$

**Solution.** The characteristic polynomial of the matrix  $A$  is

$$\begin{vmatrix} 1-\lambda & 1 & 0 \\ 1 & 2-\lambda & 1 \\ 1 & 2 & 1-\lambda \end{vmatrix} = -\lambda^3 + 4\lambda^2 - 2\lambda = -\lambda(\lambda^2 - 4\lambda + 2).$$

The roots of this polynomial are the eigenvalues, thus the eigenvalues are  $0, 2 + \sqrt{2}, 2 - \sqrt{2}$ . Thus eigenvalues are  $0, 2 + \sqrt{2}, 2 - \sqrt{2}$ . We compute the eigenvectors associated with the particular eigenvalues:

- 0: We solve the system

$$\begin{pmatrix} 1 & 1 & 0 \\ 1 & 2 & 1 \\ 1 & 2 & 1 \end{pmatrix} \begin{pmatrix} x_1 \\ x_2 \\ x_3 \end{pmatrix} = 0$$

Its solutions form a one-dimensional vector space of eigenvectors:  $\text{span}\{(1, -1, 1)\}$ .

In fact, this is not so surprising once we notice that the trace is actually the linear approximation of the determinant in the neighbourhood of the unit matrix in the direction  $A$ . We shall deal with such concepts in Chapter 8 only. But since the determinant is a polynomial, we may see easily that the only terms in  $\det(E + tA)$  which are linear in the real parameter  $t$  are just the trace. We shall see relation to matrix exponential later in Chapter 8.

The coefficient at  $\lambda^0$  is the determinant  $|A|$  and we shall see later that it describes the rescaling of volumes by the mapping.

**2.4.3. Basis of eigenvectors.** We discuss a few important properties of eigenspaces now.

**Theorem.** *Eigenvectors of linear mappings  $f : V \rightarrow V$  associated to different eigenvalues are linearly independent.*

**PROOF.** Let  $a_1, \dots, a_k$  be distinct eigenvalues of the mapping  $f$  and  $u_1, \dots, u_k$  eigenvectors with these eigenvalues. The proof is by induction on the number of linearly independent vectors among the chosen ones.

Assume that  $u_1, \dots, u_\ell$  are linearly independent and  $u_{\ell+1} = \sum_i c_i u_i$  is their linear combination. We can choose  $\ell = 1$ , because the eigenvectors are nonzero. But then  $f(u_{\ell+1}) = a_{\ell+1} \cdot u_{\ell+1} = \sum_{i=1}^{\ell} a_{\ell+1} \cdot c_i \cdot u_i$ , that is,

$$f(u_{\ell+1}) = \sum_{i=1}^{\ell} a_{\ell+1} \cdot c_i \cdot u_i = \sum_{i=1}^{\ell} c_i \cdot f(u_i) = \sum_{i=1}^{\ell} c_i \cdot a_i \cdot u_i.$$

By subtracting the second and the fourth expression in the equalities we obtain  $0 = \sum_{i=1}^{\ell} (a_{\ell+1} - a_i) \cdot c_i \cdot u_i$ . All the differences between the eigenvalues are nonzero and at least one coefficient  $c_i$  is nonzero. This is a contradiction with the assumed linear independence  $u_1, \dots, u_\ell$ , therefore also the vector  $u_{\ell+1}$  must be linearly independent of the others.  $\square$

The latter theorem can be seen as a decomposition of a linear mapping  $f$  into a sum of much simpler mappings. If there are  $n = \dim V$  distinct eigenvalues  $\lambda_i$ , we obtain the entire  $V$  as a direct sum of one-dimensional eigenspaces  $V_{\lambda_i}$ . Each of them then describes a projection on this invariant one-dimensional subspace, where the mapping is given just as multiplication by the eigenvalue  $\lambda_i$ .

Furthermore, this decomposition can be easily calculated:

- $2 + \sqrt{2}$ : We solve the system

$$\begin{pmatrix} -(1 + \sqrt{2}) & 1 & 0 \\ 1 & -\sqrt{2} & 1 \\ 1 & 2 & -(1 + \sqrt{2}) \end{pmatrix} \begin{pmatrix} x_1 \\ x_2 \\ x_3 \end{pmatrix} = 0.$$

The solutions form a one-dimensional space  $\text{span}\{(1, 1 + \sqrt{2}, 1 + \sqrt{2})\}$ .

- $2 - \sqrt{2}$ : We solve the system

$$\begin{pmatrix} (\sqrt{2} - 1) & 1 & 0 \\ 1 & \sqrt{2} & 1 \\ 1 & 2 & (\sqrt{2} - 1) \end{pmatrix} \begin{pmatrix} x_1 \\ x_2 \\ x_3 \end{pmatrix} = 0.$$

Its solutions form a space of eigenvectors  $\text{span}\{(1, 1 - \sqrt{2}, 1 - \sqrt{2})\}$ .

Hence the given matrix has eigenvalues  $0, 2 + \sqrt{2}$  and  $2 - \sqrt{2}$ , with the associated one-dimensional spaces of eigenvectors  $\text{span}\{(1, -1, 1)\}, \text{span}\{(1, 1 + \sqrt{2}, 1 + \sqrt{2})\}$  and  $\text{span}\{(1, 1 - \sqrt{2}, 1 - \sqrt{2})\}$  respectively.

The mapping can thus be interpreted as a projection along the vector  $(1, -1, 1)$  into the plane given by the vectors  $(1, 1 + \sqrt{2}, 1 + \sqrt{2})$  and  $(1, 1 - \sqrt{2}, 1 - \sqrt{2})$  composed with the linear mapping given by “stretching” by the factor corresponding to the eigenvalues in the directions of the associated eigenvectors.

Now we express it in the given basis. For this we need the matrix  $T$  for changing the basis from the standard basis to the new basis. This can be obtained by writing the coordinates of the vectors of the original basis under the new basis into the columns of the matrix  $T$ . But we shall do it in a different way – we obtain first the matrix for changing the basis from the new one to the original one, that is, the matrix  $T^{-1}$ . We just write the coordinates of the vectors of the new basis into the columns:

$$T^{-1} = \begin{pmatrix} 1 & 1 & 0 \\ -1 & 2 & 1 \\ 1 & 0 & 1 \end{pmatrix}.$$

Then

$$T = T^{-1^{-1}} = \begin{pmatrix} 0 & 0 & 1 \\ 1 & 0 & -1 \\ -2 & 1 & 3 \end{pmatrix},$$

and for the matrix  $B$  of a mapping under new basis we have (see 2.3.16)

$$B = TAT^{-1} = \begin{pmatrix} 0 & 5 & 2 \\ 0 & -2 & -1 \\ 0 & 14 & 6 \end{pmatrix}.$$

□

You can find more exercises on computing with eigenvalues and eigenvectors on the page 133.

**Corollary.** *If there exist  $n$  mutually distinct roots  $\lambda_i$  of the characteristic polynomial of the mapping  $f : V \rightarrow V$  on the  $n$ -dimensional space  $V$ , then there exists a decomposition of  $V$  into a direct sum of eigenspaces each of dimension one. This means that there exists a basis for  $V$  consisting only of eigenvectors and in this basis the matrix for  $f$  is the diagonal matrix with the eigenvalues on the diagonal. This basis is uniquely determined up to the order of the elements and scale of the vectors.*

*The corresponding basis (expressed in the coordinates in an arbitrary basis of  $V$ ) is obtained by solving  $n$  systems of homogeneous linear equations of  $n$  variables with matrices  $(A - \lambda_i \cdot E)$ , where  $A$  is the matrix of  $f$  in a chosen basis.*

**2.4.4. Invariant subspaces.** We have seen that every eigenvector  $v$  of the mapping  $f : V \rightarrow V$  generates a subspace  $\text{span}\{v\} \subset V$ , which is preserved by the mapping  $f$ .

More generally, we say that a vector subspace  $W \subset V$  is an *invariant subspace* for a linear mapping  $f$ , if  $f(W) \subset W$ .

If  $V$  is a finite dimensional vector space and we choose some basis  $(u_1, \dots, u_k)$  of a subspace  $W$ , we can always extend it to a basis  $(u_1, \dots, u_k, u_{k+1}, \dots, u_n)$  for the whole space  $V$ . For every such basis,  $f(W) \subset W$  implies the mapping  $f$  will have the matrix  $A$  of the form

$$(1) \quad A = \begin{pmatrix} B & C \\ 0 & D \end{pmatrix}$$

where  $B$  is a square matrix of dimension  $k$ ,  $D$  is a square matrix of dimension  $n - k$  and  $C$  is a matrix of the type  $n/(n - k)$ . On the other hand, if for some basis  $(u_1, \dots, u_n)$  the matrix of the mapping  $f$  is of the form (1), then  $W = \text{span}\{u_1, \dots, u_k\}$  is invariant under the mapping  $f$ .

By the same arguments, the mapping with the matrix  $A$  as in (1) leaves the subspace  $\text{span}\{u_{k+1}, \dots, u_n\}$  invariant, if and only if the submatrix  $C$  is zero.

From this point of view the eigenspaces of the mapping are special cases of invariant subspaces. Our next task is to find some conditions under which there are invariant complements of invariant subspaces.

**2.4.5.** We illustrate some typical properties of mappings on the spaces  $\mathbb{R}^3$  and  $\mathbb{R}^2$  in terms of eigenvalues and eigenvectors.

(1) Consider the mapping given in the standard basis by the matrix  $A$

$$f : \mathbb{R}^3 \rightarrow \mathbb{R}^3, A = \begin{pmatrix} 0 & 0 & 1 \\ 0 & 1 & 0 \\ 1 & 0 & 0 \end{pmatrix}.$$

In the case of a  $3 \times 3$  matrix, you can use this special formula to find its characteristic polynomial:

**2.D.12.** For any  $n \times n$  matrix  $A$  its characteristic polynomial  $|A - \lambda E|$  is of degree  $n$ , that is, it is of the form

$$|A - \lambda E| = c_n \lambda^n + c_{n-1} \lambda^{n-1} + \dots + c_1 \lambda + c_0, \quad c_n \neq 0,$$

while we have

$$c_n = (-1)^n, \quad c_{n-1} = (-1)^{n-1} \operatorname{tr} A, \quad c_0 = |A|.$$

If the matrix  $A$  is three-dimensional, we obtain

$$|A - \lambda E| = -\lambda^3 + (\operatorname{tr} A) \lambda^2 + c_1 \lambda + |A|.$$

By choosing  $\lambda = 1$  we obtain

$$|A - E| = -1 + \operatorname{tr} A + c_1 + |A|.$$

From there we obtain

$$|A - \lambda E| = -\lambda^3 + (\operatorname{tr} A) \lambda^2 + (|A - E| + 1 - \operatorname{tr} A - |A|) \lambda + |A|.$$

Use this expression for determining the characteristic polynomial and the eigenvalues of the matrix

$$A = \begin{pmatrix} 32 & -67 & 47 \\ 7 & -14 & 13 \\ -7 & 15 & -6 \end{pmatrix}.$$

○

**2.D.13.** Find the orthonormal complement of the vectorspace spanned by the vectors  $(2, 1, 3)$ ,  $(3, 16, 7)$ ,  $(3, 5, 4)$ ,  $(-7, 7, -10)$ .

**Solution.** In fact the task consists of solving the system 2.A.3, which we have done already. □

**2.D.14. Pauli matrices.** In physics, the state of a particle with spin  $\frac{1}{2}$  is described with Pauli matrices. They are the  $2 \times 2$  matrices over complex numbers:

$$\sigma_1 = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}, \sigma_2 = \begin{pmatrix} 0 & -i \\ i & 0 \end{pmatrix}, \sigma_3 = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}$$

For square matrices we define their *commutator* (denoted by square brackets) as  $[\sigma_1, \sigma_2] := \sigma_1 \sigma_2 - \sigma_2 \sigma_1$

Show that  $[\sigma_1, \sigma_2] = 2i\sigma_3$  and similarly  $[\sigma_1, \sigma_3] = 2i\sigma_2$  and  $[\sigma_2, \sigma_3] = 2i\sigma_1$ . Furthermore, show that  $\sigma_1^2 = \sigma_2^2 = \sigma_3^2 = 1$  and that the eigenvalues of the matrices  $\sigma_1, \sigma_2, \sigma_3$  are  $\pm 1$ .

Show that for matrices describing the state of the particle with spin 1, namely

$$\frac{1}{\sqrt{2}} \begin{pmatrix} 0 & 1 & 0 \\ 1 & 0 & 1 \\ 0 & 1 & 0 \end{pmatrix}, \frac{1}{\sqrt{2}} \begin{pmatrix} 0 & -i & 0 \\ i & 0 & -i \\ 0 & i & 0 \end{pmatrix}, \begin{pmatrix} 1 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & -1 \end{pmatrix}$$

We compute

$$|A - \lambda E| = \begin{vmatrix} -\lambda & 0 & 1 \\ 0 & 1 - \lambda & 0 \\ 1 & 0 & -\lambda \end{vmatrix} = -\lambda^3 + \lambda^2 + \lambda - 1,$$

with roots  $\lambda_1 = 1, \lambda_2 = 1, \lambda_3 = -1$ . The eigenvectors with eigenvalue  $\lambda = 1$  can be computed:

$$\begin{pmatrix} -1 & 0 & 1 \\ 0 & 0 & 0 \\ 1 & 0 & -1 \end{pmatrix} \sim \begin{pmatrix} 1 & 0 & -1 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix};$$

with the basis of the space of solutions, that is, of all eigenvectors with this eigenvalue

$$u_1 = (0, 1, 0), \quad u_2 = (1, 0, 1).$$

Similarly for  $\lambda = -1$  we obtain the third independent eigenvector

$$\begin{pmatrix} 1 & 0 & 1 \\ 0 & 2 & 0 \\ 1 & 0 & 1 \end{pmatrix} \sim \begin{pmatrix} 1 & 0 & 1 \\ 0 & 2 & 0 \\ 0 & 0 & 0 \end{pmatrix} \Rightarrow u_3 = (-1, 0, 1).$$

Under the basis  $u_1, u_2, u_3$  (note that  $u_3$  must be linearly independent of the remaining two because of the previous theorem and  $u_1, u_2$  were obtained as two independent solutions)  $f$  has the diagonal matrix

$$A = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & -1 \end{pmatrix}.$$

The whole space  $\mathbb{R}^3$  is a direct sum of eigenspaces,  $\mathbb{R}^3 = V_1 \oplus V_2$ , with  $\dim V_1 = 2$ , and  $\dim V_2 = 1$ . This decomposition is uniquely determined and says much about the geometric properties of the mapping  $f$ . The eigenspace  $V_1$  is furthermore a direct sum of one-dimensional eigenspaces, which can be selected in other ways (thus such a decomposition has no further geometrical meaning).

(2) Consider the linear mapping  $f : \mathbb{R}_2[x] \rightarrow \mathbb{R}_2[x]$  defined by polynomial differentiation, that is,  $f(1) = 0, f(x) = 1, f(x^2) = 2x$ . The mapping  $f$  thus has in the usual basis  $(1, x, x^2)$  the matrix

$$A = \begin{pmatrix} 0 & 1 & 0 \\ 0 & 0 & 2 \\ 0 & 0 & 0 \end{pmatrix}.$$

The characteristic polynomial is  $|A - \lambda \cdot E| = -\lambda^3$ , thus it has only one eigenvalue,  $\lambda = 0$ . We compute the eigenvectors:

$$\begin{pmatrix} 0 & 1 & 0 \\ 0 & 0 & 2 \\ 0 & 0 & 0 \end{pmatrix} \sim \begin{pmatrix} 0 & 1 & 0 \\ 0 & 0 & 1 \\ 0 & 0 & 0 \end{pmatrix}.$$

The space of the eigenvectors is thus one-dimensional, generated by the constant polynomial 1.

The striking property of this mapping is that there is no basis for which the matrix would be diagonal. There is the “chain” of vectors mapping the independent generators as follows:  $\frac{1}{2}x^2 \mapsto x \mapsto 1 \mapsto 0$ . This builds a sequence of invariant subspaces without invariant complements.

, the commuting relations are the same as in the case of Pauli matrices.

Equivalently it can be shown that under the notation  $I := \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}, J := i\sigma_3, K := i\sigma_2, L := i\sigma_1$  forms the vector space with basis  $(1, I, J, K)$  of an algebra of quaternions (the algebra is a vector space with binary bilinear operation of multiplication, in this case the multiplication is given by matrix multiplication). In order for the vector space to be an algebra of quaternions it is necessary and sufficient to show the following properties:  $I^2 = J^2 = K^2 = -1$  and  $IJ = -JI = K, JK = -KJ = I$  and  $KI = -IK = J$ .

**2.D.15.** Can the matrix

$$B = \begin{pmatrix} 5 & 6 \\ 6 & 5 \end{pmatrix}$$

be expressed in the form of the product  $B = P^{-1} \cdot D \cdot P$  for some diagonal matrix  $D$  and invertible matrix  $P$ ? If possible, give an example of such matrices  $D, P$ , and find out how many such pairs there are.

**Solution.** The matrix  $B$  has two distinct eigenvalues, and thus such an expression exists. For instance it holds that

$$\begin{pmatrix} 5 & 6 \\ 6 & 5 \end{pmatrix} = \frac{1}{2} \begin{pmatrix} \sqrt{2} & -\sqrt{2} \\ \sqrt{2} & \sqrt{2} \end{pmatrix} \cdot \begin{pmatrix} 11 & 0 \\ 0 & -1 \end{pmatrix} \cdot \frac{1}{2} \begin{pmatrix} \sqrt{2} & \sqrt{2} \\ -\sqrt{2} & \sqrt{2} \end{pmatrix}.$$

There exist exactly two diagonal matrices  $D$ :

$$\begin{pmatrix} 11 & 0 \\ 0 & -1 \end{pmatrix}, \quad \begin{pmatrix} -1 & 0 \\ 0 & 11 \end{pmatrix},$$

but the columns of the matrix  $P^{-1}$  can be substituted with their arbitrary non-zero scalar multiples, thus there are infinitely many pairs  $D, P$ .  $\square$

As we have already seen in 2.D.11, based on the eigenvalues and eigenvectors of the given  $3 \times 3$  matrix, we can often interpret geometrically the mapping it induces in  $\mathbb{R}^3$ . In particular, we notice that can do so in the following situations: If the matrix has 0 as eigenvalue and 1 as an eigenvalue with geometric multiplicity 2, then it is a projection in the direction of the eigenvector associated with the eigenvalue 0 on the plane given by the eigenspace of the eigenvalue 1. If the eigenvector associated with 0 is perpendicular to that plane, then the mapping is an orthogonal projection.

If the matrix has eigenvalue  $-1$  with the eigenvector perpendicular to the plane of the eigenvectors associated with the eigenvalue 1, then it is a mirror symmetry through the plane of the eigenvectors associated with 1.

**2.4.6. Orthogonal mappings.** We consider the special case of the mapping  $f : V \rightarrow W$  between spaces with scalar products, which preserve lengths for all vectors  $u \in V$ .

ORTHOGONAL MAPPINGS

A linear mapping  $f : V \rightarrow W$  between spaces with scalar product is called an *orthogonal mapping*, if for all  $u \in V$

$$\langle f(u), f(u) \rangle = \langle u, u \rangle.$$

The linearity of  $f$  and the symmetry of the scalar product imply that for all pairs of vectors the following equality holds:

$$\langle f(u+v), f(u+v) \rangle = \langle f(u), f(u) \rangle + \langle f(v), f(v) \rangle + 2\langle f(u), f(v) \rangle.$$

Therefore all orthogonal mappings satisfy also the seemingly stronger condition for all vectors  $u, v \in V$ :

$$\langle f(u), f(v) \rangle = \langle u, v \rangle,$$

i.e. the mapping  $f$  leaves the scalar product invariant if and only if it leaves invariant the length of the vectors. (We should have noticed that this is true for all fields of scalars, where  $1 + 1 \neq 0$ , but it does not hold true for  $\mathbb{Z}_2$ .)

In the initial discussion about the geometry in the plane we proved in the Theorem 1.5.10 that a linear mapping  $\mathbb{R}^2 \rightarrow \mathbb{R}^2$  preserves lengths of the vectors if and only if its matrix in the standard basis (which is orthonormal with respect to the standard scalar product) satisfies  $A^T \cdot A = E$ , that is,  $A^{-1} = A^T$ .

In general, orthogonal mappings  $f : V \rightarrow W$  must be always injective, because the condition  $\langle f(u), f(u) \rangle = 0$  implies  $\langle u, u \rangle = 0$  and thus  $u = 0$ . In such a case, the dimension of the range is always at least as large as the dimension of the domain of  $f$ . But then both dimensions are equal and  $f : V \rightarrow \text{Im } f$  is a bijection. If  $\text{Im } f \neq W$ , we extend the orthonormal basis of the image of  $f$  to an orthonormal basis of the range space and the matrix of the mapping then contains a square regular submatrix  $A$  along with zero rows so that it has the required number of rows. Without loss of generality we can assume that  $W = V$ .

Our condition for the matrix of an orthogonal mapping in any orthonormal basis requires that for all vectors  $x$  and  $y$  in the space  $\mathbb{K}^n$ :

$$(A \cdot x)^T \cdot (A \cdot y) = x^T \cdot (A^T \cdot A) \cdot y = x^T \cdot y.$$

Special choice of the standard basis vectors for  $x$  and  $y$  yields directly  $A^T \cdot A = E$ , that is, the same result as for dimension two. Thus we have proved the following theorem:

MATRIX OF ORTHOGONAL MAPPINGS

**Theorem.** Let  $V$  be a real vector space with scalar product and let  $f : V \rightarrow V$  be a linear mapping. Then  $f$  is orthogonal if and only if in some orthogonal basis (and then consequently in all of them) its matrix  $A$  satisfies  $A^T = A^{-1}$ .

If the matrix has eigenvalue 1 with an eigenvector perpendicular to plane of the eigenvectors associated with the eigenvalue  $-1$ , then it is an axial symmetry (in space) through the axis given by the eigenvector associated with 1.

**2.D.16.** Determine what linear mapping  $\mathbb{R}^3 \rightarrow \mathbb{R}^3$  is given by the matrix

$$\begin{pmatrix} -\frac{2}{3} & -\frac{1}{3} & -\frac{2}{3} \\ \frac{4}{3} & -\frac{7}{3} & -\frac{8}{3} \\ -1 & 1 & 1 \end{pmatrix}$$

**Solution.** The matrix has a double eigenvalue  $-1$ , its associated eigenspace is  $\text{span}\{(2, 0, 1), (1, 1, 0)\}$ . Further, the matrix has 0 as the eigenvalue, with eigenvector  $(1, 4, -3)$ . The mapping given by this matrix under the standard basis is then an axial symmetry through the line given by the last vector composed with the projection on the plane perpendicular to the last vector, that is, given by the equation  $x + 4y - 3z = 0$ .  $\square$

**2.D.17.** The theorem 2.4.7 gives us tools for recognising a matrix of a rotation in  $\mathbb{R}^3$ . It is orthogonal (rows orthogonal to each other equivalently the same for the columns). It has three distinct eigenvalues with absolute value 1. One of them is the number 1 (its associated eigenvector is the axis of the rotation). The argument of the remaining two, which are necessarily complex conjugates, gives the angle of the rotation in the positive sense in the plane given by the basis  $u_\lambda + \overline{u_\lambda}$ ,  $i(u_\lambda - \overline{u_\lambda})$ .

**2.D.18.** Determine what linear mapping is given by the matrix

$$\begin{pmatrix} \frac{3}{5} & \frac{16}{25} & -\frac{12}{25} \\ -\frac{16}{25} & \frac{93}{125} & \frac{24}{125} \\ \frac{12}{25} & \frac{24}{125} & \frac{107}{125} \end{pmatrix}.$$

**Solution.** First we notice, that the matrix is orthogonal (rows are mutually orthogonal, and equivalently the same with columns). The matrix has the following eigenvalues and corresponding eigenvectors: 1,  $v_1 = (0, 1, \frac{4}{3})$ ;  $\frac{3}{5} + \frac{4}{5}i$ ,  $v_2 = (1, \frac{4}{5}i, -\frac{3}{5}i)$ ;  $\frac{3}{5} - \frac{4}{5}i$ ,  $v_3 = (1, -\frac{4}{5}i, \frac{3}{5}i)$ . All three eigenvalues have absolute value one, which together with the observation of orthogonality tells us that the matrix is a matrix of rotation. Its axis is given by the eigenvector corresponding to the eigenvalue 1, that is the vector  $(0, 1, \frac{4}{3})$ . The plane of rotation is the real plane in  $\mathbb{R}^3$ , which is given by the intersection of two dimensional complex space in  $\mathbb{C}^3$  generated by the remaining eigenvectors with  $\mathbb{R}^3$ . It is the plane

**PROOF.** Indeed, if  $f$  preserves lengths, it must have the claimed property in every orthonormal basis. On the other hand, the previous calculations show that this property for the matrix in one such basis ensures length preservation.  $\square$

Square matrices which satisfy the equality  $A^T = A^{-1}$  are called *orthogonal matrices*.

The shape of the coordinate transition matrices between orthonormal bases is a direct corollary of the above theorem. Each such matrix must provide a mapping  $\mathbb{K}^n \rightarrow \mathbb{K}^n$  which preserves lengths and thus satisfies the condition  $S^{-1} = S^T$ . When changing from one orthonormal basis to another one, the matrix of any linear mapping changes according to the relation

$$A' = S^T A S.$$

**2.4.7. Decomposition of an orthogonal mapping.** We take a more detailed look at eigenvectors and eigenvalues of orthogonal mappings on a real vector space  $V$  with scalar product.

Consider a fixed orthogonal mapping  $f : V \rightarrow V$  with the matrix  $A$  in some orthonormal basis. We continue as with the matrix  $D$  of rotation in 2.4.1.

We think first about invariant subspaces of orthogonal mappings and their orthogonal complements. Namely, given any subspace  $W \subset V$  invariant with respect to an orthogonal mapping  $f : V \rightarrow V$ , then for all  $v \in W^\perp$  and  $w \in W$  we immediately see

$$\langle f(v), w \rangle = \langle f(v), f \circ f^{-1}(w) \rangle = \langle v, f^{-1}(w) \rangle = 0$$

since  $f^{-1}(w) \in W$ , too. But this means that also  $f(W^\perp) \subset W^\perp$  and we have proved a simple but very important proposition:

**Proposition.** *The orthogonal complement of a subspace invariant with respect to an orthogonal mapping is also invariant.*

If all eigenvalues of an orthogonal mapping are real, this claim ensures that there always exists a basis of  $V$  composed of eigenvectors. Indeed, the restriction of  $f$  to the orthogonal complement of an invariant subspace is again an orthogonal mapping, therefore we can add one eigenvector to the basis after another, until we obtain the whole decomposition of  $V$ . However, mostly the eigenvalues of orthogonal mappings are not real. We need to deviate into complex vector spaces. We formulate the result right away:

$\text{span}\{(1, 0, 0), (0, -4, 3)\}$  (the first generator is the (real multiple of)  $v_2 + v_3$ , the other one is the (real multiple of)  $i(v_2 - v_3)$ , see 2.4.7). We can determine the rotation angle in this plane. It is a rotation by the angle  $\arccos(\frac{3}{5}) \doteq 0, 295\pi$ , which is the argument of the eigenvalue  $\frac{3}{5} + \frac{4}{5}i$  (or minus that number, if we would choose the other eigenvalue).

It remains to determine the direction of the rotation. First, recall that the meaning of the direction of the rotation changes when we change the orientation of the axis (it has no meaning to speak of the direction of the rotation if we do not have an orientation of the axis). Using the ideas from the proof of the theorem 2.4.7, we see that the given matrix acts by rotating by  $\arccos(\frac{3}{5})$  in the positive sense in the plane given by the basis  $((1, 0, 0), (0, -\frac{4}{5}, \frac{3}{5}))$ . The first vector of the basis is the imaginary part of the eigenvector associated with the eigenvalue  $\frac{3}{5} + \frac{4}{5}i$ , the second is then the (common) real part of the eigenvectors associated with the complex eigenvalues. The order of the vectors in the basis is important (by changing their order the meaning of the direction changes). The axis of rotation is perpendicular to the plane. If we orient using the right-hand rule (the perpendicular direction is obtained by taking the product of the vectors in the basis) then the direction of the rotation agrees with the direction of rotation in the plane with the given basis. In our case we obtain by the vector product  $(0, 1, -1) \times (1, 1, -1) = (0, -1, -1)$ . It is thus a rotation through  $\arccos(\frac{3}{5})$  in the positive sense about the vector  $(0, -1, -1)$ , that is, a rotation through  $\arccos(\frac{3}{5})$  in the negative sense about the vector  $(0, 1, 1)$ .  $\square$

**2.D.19.** Determine what linear mapping is given by the matrix

$$\begin{pmatrix} -\frac{1}{5} & \frac{3}{5} & -\frac{1}{5} \\ -\frac{8}{5} & \frac{9}{5} & \frac{2}{5} \\ \frac{8}{5} & -\frac{4}{5} & \frac{3}{5} \end{pmatrix}.$$

**Solution.** By already known method we find out that the matrix has the following eigenvalues and corresponding eigenvectors:  $1, (1, 2, 0)$ ;  $\frac{3}{5} + \frac{4}{5}i, (1, 1 + i, -1 - i)$ ;  $\frac{3}{5} - \frac{4}{5}i, (1, 1 - i, -1 + i)$ . Though all three eigenvectors have absolute value 1, they are not orthogonal to each other, thus the matrix is not orthogonal. Consequently it is not a matrix of rotation. Nevertheless, it is a linear mapping which is "close" to a rotation. It is a rotation in the plane given by two complex eigenvectors (but this plane is not orthogonal to the vector  $(1, 2, 0)$ , but it is preserved by the map). It remains to

ORTHOGONAL MAPPING DECOMPOSITION

**Theorem.** Let  $f : V \rightarrow V$  be an orthogonal mapping on a real vector space  $V$  with scalar product. Then all the (in general complex) roots of the characteristic polynomial  $f$  have length one. There exists the decomposition of  $V$  into one-dimensional eigenspaces corresponding to the real eigenvalues  $\lambda = \pm 1$  and two-dimensional subspaces  $P_{\lambda, \bar{\lambda}}$  with  $\lambda \in \mathbb{C} \setminus \mathbb{R}$ , where  $f$  acts by the rotation by the angle equal to the argument of the complex number  $\lambda$  in the positive sense. All these subspaces are mutually orthogonal.

**PROOF.** Without loss of generality we can work with the space  $V = \mathbb{R}^m$  with the standard scalar product. The mapping is thus given by an orthogonal matrix  $A$  which can be equally well seen as the matrix of a (complex) linear mapping on the complex space  $\mathbb{C}^m$  (which just happens to have all of its coefficients real).

There exist exactly  $m$  (complex) roots of the characteristic polynomial of  $A$ , counting their algebraic multiplicities (see the fundamental theorem of algebra, 12.2.8). Furthermore, because the characteristic polynomial of the mapping has only real coefficients, the roots are either real or there are pairs of roots which are complex conjugates  $\lambda$  and  $\bar{\lambda}$ . The associated eigenvectors in  $\mathbb{C}^m$  for such pairs of complex conjugates are actually solutions of two systems of linear homogeneous equations which are also complex conjugate to each other – the corresponding matrices of the systems have real components, except for the eigenvalues  $\lambda$ . Therefore the solutions of this systems are also complex conjugates (check this!).

Next, we exploit the fact that for every invariant subspace its orthogonal complement is also invariant. First we find the eigenspaces  $V_{\pm 1}$  associated with the real eigenvalues, and restrict the mapping to the orthogonal complement of their sum. Without loss of generality we can thus assume that our orthogonal mapping has no real eigenvalues and that  $\dim V = 2n > 0$ .

Now choose an eigenvalue  $\lambda$  and let  $u_\lambda$  be the eigenvector in  $\mathbb{C}^{2n}$  associated to the eigenvalue  $\lambda = \alpha + i\beta, \beta \neq 0$ . Analogously to the case of rotation in the plane discussed in paragraph 2.4.1 in terms of the matrix  $D$ , we are interested in the real part of the sum of two one-dimensional (complex) subspaces  $W = \text{span}\{u_\lambda\} \oplus \text{span}\{\bar{u}_\lambda\}$ , where  $\bar{u}_\lambda$  is the eigenvector associated to the conjugated eigenvalue  $\bar{\lambda}$ .

Now we want the intersection of the 2-dimensional complex subspace  $W$  with the real subspace  $\mathbb{R}^{2n} \subset \mathbb{C}^{2n}$ , which is clearly generated (over  $\mathbb{R}$ ) by the vectors  $u_\lambda + \bar{u}_\lambda$  and  $i(u_\lambda - \bar{u}_\lambda)$ . We call this real 2-dimensional subspace  $P_{\lambda, \bar{\lambda}} \subset \mathbb{R}^{2n}$  and notice, this subspace is generated by the basis given by the real and imaginary part of  $u_\lambda$

$$x_\lambda = \text{Re } u_\lambda, \quad -y_\lambda = -\text{Im } u_\lambda.$$

determine the direction of the rotation. First, we should recall that the meaning of the direction of the rotation changes when we change the orientation of the axis (it has no meaning to speak of the direction of the rotation if we do not have an orientation of the axis).

Using the same ideas as in the previous example, we see that the given matrix acts by rotating by  $\arccos(\frac{3}{5})$  in the positive sense in the plane given by the basis  $((1, 1, -1), (0, 1, 1))$ . The first vector of the basis is the imaginary part of the eigenvector associated with the eigenvalue  $\frac{3}{5} + \frac{4}{5}i$ , the second is then the (common) real part of the eigenvectors associated with the complex eigenvalues. The order of the vectors in the basis is important (by changing their order the meaning of the direction changes). The "axis" of rotation is not perpendicular to the plane, but we can orient the vectors lying in the whole half-plane using the right-hand rule (the perpendicular direction is obtained by taking the product of the vectors in the basis) then the direction of the rotation agrees with the direction of rotation in the plane with the given basis. In our case we obtain by the vector product  $(0, 1, -1) \times (1, 1, -1) = (0, -1, -1)$ . It is thus a rotation through  $\arccos(\frac{3}{5})$  in the positive sense about the vector  $(0, -1, -1)$ , that is, a rotation through  $\arccos(\frac{3}{5})$  in the negative sense about the vector  $(0, 1, 1)$ .  $\square$

**2.D.20.** Without any written computation determine the spectrum of the linear mapping  $f : \mathbb{R}^3 \rightarrow \mathbb{R}^3$  given by  $(x_1, x_2, x_3) \mapsto (x_1 + x_3, x_2, x_1 + x_3)$ .  $\circ$

**2.D.21.** Find the dimension of the eigenspaces of the eigenvalues  $\lambda_i$  of the matrix

$$\begin{pmatrix} 4 & 0 & 0 & 0 \\ 1 & 4 & 0 & 0 \\ 5 & 2 & 3 & 0 \\ 0 & 4 & 0 & 3 \end{pmatrix}.$$

$\circ$

Because  $A \cdot (u_\lambda + \bar{u}_\lambda) = \lambda u_\lambda + \bar{\lambda} \bar{u}_\lambda$  and similarly with the second basis vector, it is clearly an invariant subspace with respect to multiplication by the matrix  $A$  and we obtain

$$A \cdot x_\lambda = \alpha x_\lambda + \beta y_\lambda, \quad A \cdot y_\lambda = -\alpha y_\lambda + \beta x_\lambda.$$

Because our mapping preserves lengths, the absolute value of the eigenvalue  $\lambda$  must equal one. But that means that the restriction of our mapping to  $P_{\lambda, \bar{\lambda}}$  is the rotation by the argument of the eigenvalue  $\lambda$ . Note that the choice of the eigenvalue  $\bar{\lambda}$  instead of  $\lambda$  leads to the same subspace with the same rotation, we would just have expressed it in the basis  $x_\lambda, y_\lambda$ , that is, the same rotation will in these coordinates go by the same angle, but with the opposite sign, as expected.

The proof of the whole theorem is completed by restricting the mapping to the orthogonal complement and finding another 2-dimensional subspace, until we get the required decomposition.  $\square$

We return to the ideas in this proof once again in chapter three, where we study complex extensions of the Euclidean vector spaces, see 3.4.4.

**Remark.** The previous theorem is very powerful in dimension three. Here at least one eigenvalue must be real  $\pm 1$ , since three is odd. But then the associated eigenspace is an axis of the rotation of the three-dimensional space through the angle given by the argument of the other eigenvalues. Try to think how to detect in which direction the space is rotated. Note also that the eigenvalue  $-1$  means an additional reflection through the plane perpendicular to the axis of the rotation.

We shall return to the discussion of such properties of matrices and linear mappings in more details at the end of the next chapter, after illustrating the power of the matrix calculus in several practical applications. We close this section with a general quite widely used definition:

## SPECTRUM OF LINEAR MAPPING

**2.4.8. Definition.** The *spectrum of a linear mapping*  $f : V \rightarrow V$ , or the spectrum of a square matrix  $A$ , is a sequence of roots of the characteristic polynomial  $f$  or  $A$ , along with their multiplicities, respectively. The *algebraic multiplicity* of an eigenvalue means the multiplicity of the root of the characteristic polynomial, while the *geometric multiplicity* of the eigenvalue is the dimension of the associated subspace of eigenvectors.

The *spectral diameter* of a linear mapping (or matrix) is the greatest of the absolute values of the eigenvalues.

In this terminology, our results about orthogonal mappings can be formulated as follows: the spectrum of an orthogonal mapping is always a subset of the unit circle in the complex plane. Thus only the values  $\pm 1$  may appear in the real part of the spectrum and their algebraic and geometric multiplicities are always the same. Complex values of the spectrum then correspond to rotations in suitable two-dimensional subspaces which are mutually perpendicular.

E. Additional exercises for the whole chapter

**2.E.1. Kirchhoff's Circuit Laws.** We consider an application of Linear Algebra to analysis of electric circuits, using Ohm's law and Kirchhoff's voltage and current laws.

Consider an electric circuit as in the figure and write down the values of the currents there if you know the values  $V_1 = 20$ ,  $V_2 = 120$ ,  $V_3 = 50$ ,  $R_1 = 10$ ,  $R_2 = 30$ ,  $R_3 = 4$ ,  $R_4 = 5$ ,  $R_5 = 10$ ,

Notice that the quantities  $I_i$  denote the electric currents, while  $R_j$  are resistances, and  $V_k$  are voltages.

**Solution.** There are two closed loops, namely  $ABEF$  and  $EBCD$  and two branching vertices  $B$  and  $E$  of degree no less than 3. On every segment of the circuit, bounded by branching points, the electric current is constant. Set it to be  $I_1$  on the segment  $EFAB$ ,  $I_2$  on  $EB$ , and  $I_3$  on  $BCDE$ .

Applying Kirchhoff's current law to branching points  $B$  and  $E$  we obtain:  $I_1 + I_2 = I_3$  and  $I_3 - I_1 = I_2$ , which are, of course the same equations. In case there are many branching vertices, we write all Kirchhoff's Current Law equations to the system, having at least one of those equations redundant.

Choose the counter clockwise orientations of the loops  $ABEF$  and  $EBCD$ . Applying Kirchhoff Voltage Law and Ohm's Law to the loop  $ABEF$  we obtain the equation:

$$V_1 + I_1 R_3 - I_2 R_5 + V_3 + I_1 R_1 + I_1 R_4 = 0.$$

Similarly, the loop  $EBCD$  implies

$$-V_2 + I_3 R_2 - V_3 + R_5 I_2 = 0.$$

By combining all equations, we obtain the system

$$\begin{aligned} I_1 + I_2 - I_3 &= 0, \\ (R_3 + R_1 + R_4)I_1 - R_5 I_2 + I_3 &= -V_1 - V_3, \\ R_5 I_2 + R_2 I_3 &= V_2 + V_3. \end{aligned}$$

Substituting the prescribed values we obtain the linear system

$$\begin{aligned} I_1 + I_2 - I_3 &= 0, \\ 19I_1 - 10I_2 + I_3 &= -70, \\ 10I_2 + 30I_3 &= 170. \end{aligned}$$

This has solutions  $I_1 = -\frac{80}{53} \approx -1.509$ ,  $I_2 = \frac{219}{53} \approx 4.132$ ,  $I_3 = \frac{139}{53} \approx 2.623$ . □

**2.E.2. The general case.** In general, the method for electrical circuit analysis can be formulated along the following steps:

- i) Identify all branching vertices of the circuit, i.e vertices of degree no less than 3;
- ii) Identify all closed loops of the circuit;
- iii) Introduce variables  $I_k$ , denoting oriented currents on each segment of the circuit between two branching vertices;

- iv) Write down Kirchhoff's current conservation law for each branching vertex. The total incoming current equals the total outgoing current;
- v) Choose an orientation on every closed loop of the circuit and write down Kirchhoff's voltage conservation law according to the chosen orientation. If you find an electric charge of voltage  $V_j$  and you go from the short bar to the long bar, the contribution of this charge is  $V_j$ . It is  $-V_j$  if you go from the long bar to the short one. If you go in the positive direction of a current  $I$  and find a resistor with resistance  $R_j$ , the contribution is  $-R_j I$ , and it is  $R_j I$  if the orientation of the loop is opposite to the direction of the current  $I$ . The total voltage change along each closed loop must be zero.
- vi) Compose the system of linear equations collecting all equations, representing Kirchhoff's current and voltage laws and solve it with respect to the variables, representing currents. Notice that some equations may be redundant, however, the solution should be unique.

To illustrate this general approach, consider the circuit example in the diagram.

**Solution.**

- i) The set of branching vertices is  $\{B, C, F, G, H\}$ .
- ii) The set of closed loops is  $\{ABHG, FHBC, GHF, CDEF\}$ .
- iii) Let  $I_1$  be the current on the segment  $GAB$ ,  $I_2$  on the segment  $GH$ ,  $I_3$  on the segment  $HB$ ,  $I_4$  on the segment  $BC$ ,  $I_5$  on the segment  $FC$ ,  $I_6$  on the segment  $FH$ ,  $I_7$  on  $GF$ , and  $I_8$  on  $CDEF$ .
- iv) Write Kirchhoff's current conservation laws for the branching vertices:
- vertex B:  $I_1 + I_3 = I_4$
  - vertex C:  $I_4 + I_5 = I_8$
  - vertex F:  $I_8 = I_5 + I_6 - I_7$
  - vertex G:  $-I_7 = I_1 + I_2$
  - vertex H:  $I_2 + I_6 = I_3$
- v) Write Kirchhoff's voltage conservation for each of the closed loops traversed counter-clockwise:
- loop  $ABHG$ :  $-R_1 I_2 + V_3 + R_2 I_1 - V_2 = 0$
  - loop  $FHBC$ :  $V_4 + R_3 I_4 - V_3 = 0$
  - loop  $GHF$ :  $R_1 I_2 - V_1 = 0$
  - loop  $CDEF$ :  $R_4 I_8 - V_4 = 0$

Set the parameters:  $R_1 = 4$ ,  $R_2 = 7$ ,  $R_3 = 9$ ,  $R_4 = 12$ ,  $V_1 = 10$ ,  $V_2 = 20$ ,  $V_3 = 60$ ,  $V_4 = 120$ , to obtain the system

$$\begin{aligned} I_1 + I_3 - I_4 &= 0 \\ I_4 + I_5 - I_8 &= 0 \\ I_5 + I_6 - I_7 - I_8 &= 0 \\ I_1 + I_2 + I_7 &= 0 \end{aligned}$$

$$\begin{aligned} I_2 - I_3 + I_6 &= 0 \\ 7I_1 - 4I_2 &= -40 \\ 9I_4 &= -60 \\ 4I_2 &= 10 \\ 12I_8 &= 120 \end{aligned}$$

with the solution set  $I_1 = \frac{-30}{7}$ ,  $I_2 = \frac{5}{2}$ ,  $I_3 = \frac{-50}{21}$ ,  $I_4 = \frac{-20}{3}$ ,  $I_5 = \frac{50}{3}$ ,  $I_6 = \frac{-205}{42}$ ,  $I_7 = \frac{25}{14}$ ,  $I_8 = 10$ .

□

**2.E.3.** Solve the system of equations

$$\begin{aligned} x_1 + x_2 + x_3 + x_4 - 2x_5 &= 3, \\ 2x_2 + 2x_3 + 2x_4 - 4x_5 &= 5, \\ -x_1 - x_2 - x_3 + x_4 + 2x_5 &= 0, \\ -2x_1 + 3x_2 + 3x_3 - 6x_5 &= 2. \end{aligned}$$

**Solution.** The extended matrix of the system is

$$\left( \begin{array}{ccccc|c} 1 & 1 & 1 & 1 & -2 & 3 \\ 0 & 2 & 2 & 2 & -4 & 5 \\ -1 & -1 & -1 & 1 & 2 & 0 \\ -2 & 3 & 3 & 0 & -6 & 2 \end{array} \right).$$

Adding the first row to the third, adding its 2-multiple to the fourth, and adding the  $(-5/2)$ -multiple of the second to the fourth we obtain

$$\left( \begin{array}{ccccc|c} 1 & 1 & 1 & 1 & -2 & 3 \\ 0 & 2 & 2 & 2 & -4 & 5 \\ 0 & 0 & 0 & 2 & 0 & 3 \\ 0 & 5 & 5 & 2 & -10 & 8 \end{array} \right) \sim \left( \begin{array}{ccccc|c} 1 & 1 & 1 & 1 & -2 & 3 \\ 0 & 2 & 2 & 2 & -4 & 5 \\ 0 & 0 & 0 & 2 & 0 & 3 \\ 0 & 0 & 0 & -3 & 0 & -9/2 \end{array} \right).$$

The last row is clearly a multiple of the previous, and thus we can omit it. The pivots are located in the first, second and fourth.

Thus the free variables are  $x_3$  and  $x_5$  which we substitute by the real parameters  $t$  and  $s$ . Thus we consider the system

$$\begin{aligned} x_1 + x_2 + t + x_4 - 2s &= 3, \\ 2x_2 + 2t + 2x_4 - 4s &= 5, \\ 2x_4 &= 3. \end{aligned}$$

We see that  $x_4 = 3/2$ . The second equation gives

$$2x_2 + 2t + 3 - 4s = 5, \quad \text{that is,} \quad x_2 = 1 - t + 2s.$$

From the first we have

$$x_1 + 1 - t + 2s + t + 3/2 - 2s = 3, \quad \text{tj.} \quad x_1 = 1/2.$$

Altogether,

$$(x_1, x_2, x_3, x_4, x_5) = (1/2, 1-t+2s, t, 3/2, s), \quad t, s \in \mathbb{R}.$$

Alternatively, we can consider the extended matrix and transform it using the row transformations into the row echelon form. We arrange it so that the first non-zero number in every row is 1, and the remaining numbers in the column containing this 1 are 0. We omit the fourth equation, which is a combination of the first three. Sequentially, multiplying the second and

the third row by the number  $1/2$ , subtracting the third row from the second and from the first and by subtracting the second row from the first we obtain

$$\begin{pmatrix} 1 & 1 & 1 & 1 & -2 & | & 3 \\ 0 & 2 & 2 & 2 & -4 & | & 5 \\ 0 & 0 & 0 & 2 & 0 & | & 3 \end{pmatrix} \sim \begin{pmatrix} 1 & 1 & 1 & 1 & -2 & | & 3 \\ 0 & 1 & 1 & 1 & -2 & | & 5/2 \\ 0 & 0 & 0 & 1 & 0 & | & 3/2 \end{pmatrix} \sim$$

$$\begin{pmatrix} 1 & 1 & 1 & 0 & -2 & | & 3/2 \\ 0 & 1 & 1 & 0 & -2 & | & 1 \\ 0 & 0 & 0 & 1 & 0 & | & 3/2 \end{pmatrix} \sim \begin{pmatrix} 1 & 0 & 0 & 0 & 0 & | & 1/2 \\ 0 & 1 & 1 & 0 & -2 & | & 1 \\ 0 & 0 & 0 & 1 & 0 & | & 3/2 \end{pmatrix}.$$

If we choose again  $x_3 = t$ ,  $x_5 = s$  ( $t, s \in \mathbb{R}$ ), we obtain the general solution (2.E.3) as above.  $\square$

**2.E.4.** Find the solution of the system of linear equations given by the extended matrix

$$\left( \begin{array}{cccc|c} 3 & 3 & 2 & 1 & 3 \\ 2 & 1 & 1 & 0 & 4 \\ 0 & 5 & -4 & 3 & 1 \\ 5 & 3 & 3 & -3 & 5 \end{array} \right).$$

**Solution.** We transform the given extended matrix into the row echelon form. We first copy the first three rows and into the last row we write the sum of the (2)-multiple of the first and of the (-3)-multiple of the last row. By this we obtain

$$\left( \begin{array}{cccc|c} 3 & 3 & 2 & 1 & 3 \\ 2 & 1 & 1 & 0 & 4 \\ 0 & 5 & -4 & 3 & 1 \\ 5 & 3 & 3 & -3 & 5 \end{array} \right) \sim \left( \begin{array}{cccc|c} 3 & 3 & 2 & 1 & 3 \\ 0 & -3 & -1 & -2 & 6 \\ 0 & 5 & -4 & 3 & 1 \\ 0 & 6 & 1 & 14 & 0 \end{array} \right).$$

Copying the first two rows and adding a 5-multiple of the second row to the 3-multiple of the third and its 2-multiple to the fourth gives

$$\left( \begin{array}{cccc|c} 3 & 3 & 2 & 1 & 3 \\ 0 & -3 & -1 & -2 & 6 \\ 0 & 5 & -4 & 3 & 1 \\ 0 & 6 & 1 & 14 & 0 \end{array} \right) \sim \left( \begin{array}{cccc|c} 3 & 3 & 2 & 1 & 3 \\ 0 & -3 & -1 & -2 & 6 \\ 0 & 0 & -17 & -1 & 33 \\ 0 & 0 & -1 & 10 & 12 \end{array} \right).$$

Copying the first, second and fourth row, and adding the fourth to the third, yields

$$\left( \begin{array}{cccc|c} 3 & 3 & 2 & 1 & 3 \\ 0 & -3 & -1 & -2 & 6 \\ 0 & 0 & -17 & -1 & 33 \\ 0 & 0 & -1 & 10 & 12 \end{array} \right) \sim \left( \begin{array}{cccc|c} 3 & 3 & 2 & 1 & 3 \\ 0 & -3 & -1 & -2 & 6 \\ 0 & 0 & -18 & 9 & 45 \\ 0 & 0 & -1 & 10 & 12 \end{array} \right).$$

With three more row transformations, we arrive at

$$\left( \begin{array}{cccc|c} 3 & 3 & 2 & 1 & 3 \\ 0 & -3 & -1 & -2 & 6 \\ 0 & 0 & -18 & 9 & 45 \\ 0 & 0 & -1 & 10 & 12 \end{array} \right) \sim \left( \begin{array}{cccc|c} 3 & 3 & 2 & 1 & 3 \\ 0 & -3 & -1 & -2 & 6 \\ 0 & 0 & 2 & -1 & -5 \\ 0 & 0 & 1 & -10 & -12 \end{array} \right) \sim$$

$$\left( \begin{array}{cccc|c} 3 & 3 & 2 & 1 & 3 \\ 0 & -3 & -1 & -2 & 6 \\ 0 & 0 & 1 & -10 & -12 \\ 0 & 0 & 2 & -1 & -5 \end{array} \right) \sim \left( \begin{array}{cccc|c} 3 & 3 & 2 & 1 & 3 \\ 0 & -3 & -1 & -2 & 6 \\ 0 & 0 & 1 & -10 & -12 \\ 0 & 0 & 0 & 19 & 19 \end{array} \right).$$

The system has exactly 1 solution. We determine it by backwards elimination

$$\left( \begin{array}{cccc|c} 3 & 3 & 2 & 1 & 3 \\ 0 & -3 & -1 & -2 & 6 \\ 0 & 0 & 1 & -10 & -12 \\ 0 & 0 & 0 & 1 & 1 \end{array} \right) \sim \left( \begin{array}{cccc|c} 3 & 3 & 2 & 0 & 2 \\ 0 & -3 & -1 & 0 & 8 \\ 0 & 0 & 1 & 0 & -2 \\ 0 & 0 & 0 & 1 & 1 \end{array} \right) \sim$$

$$\left( \begin{array}{cccc|c} 3 & 3 & 0 & 0 & 6 \\ 0 & -3 & 0 & 0 & 6 \\ 0 & 0 & 1 & 0 & -2 \\ 0 & 0 & 0 & 1 & 1 \end{array} \right) \sim \left( \begin{array}{cccc|c} 1 & 1 & 0 & 0 & 2 \\ 0 & 1 & 0 & 0 & -2 \\ 0 & 0 & 1 & 0 & -2 \\ 0 & 0 & 0 & 1 & 1 \end{array} \right) \sim \left( \begin{array}{cccc|c} 1 & 0 & 0 & 0 & 4 \\ 0 & 1 & 0 & 0 & -2 \\ 0 & 0 & 1 & 0 & -2 \\ 0 & 0 & 0 & 1 & 1 \end{array} \right).$$

The solution is

$$x_1 = 4, \quad x_2 = -2, \quad x_3 = -2, \quad x_4 = 1.$$

□

**2.E.5.** Find all the solutions of the homogeneous system

$$x + y = 2z + v, \quad z + 4u + v = 0, \quad -3u = 0, \quad z = -v$$

of four linear equations with 5 variables  $x, y, z, u, v$ .

**Solution.** We rewrite the system into a matrix such that in the first column there are coefficients of  $x$ , in the second there are coefficients of  $y$ , and so on. We put all the variables in equations to the left side. By this, we obtain the matrix

$$\begin{pmatrix} 1 & 1 & -2 & 0 & -1 \\ 0 & 0 & 1 & 4 & 1 \\ 0 & 0 & 0 & -3 & 0 \\ 0 & 0 & 1 & 0 & 1 \end{pmatrix}.$$

We add  $(4/3)$ -multiple of the third row to the second and subtract then the second row from the fourth to obtain

$$\begin{pmatrix} 1 & 1 & -2 & 0 & -1 \\ 0 & 0 & 1 & 4 & 1 \\ 0 & 0 & 0 & -3 & 0 \\ 0 & 0 & 1 & 0 & 1 \end{pmatrix} \sim \begin{pmatrix} 1 & 1 & -2 & 0 & -1 \\ 0 & 0 & 1 & 0 & 1 \\ 0 & 0 & 0 & -3 & 0 \\ 0 & 0 & 0 & 0 & 0 \end{pmatrix}.$$

We multiply the third row by the number  $-1/3$  and add the 2-multiple of the second row to the first, which gives

$$\begin{pmatrix} 1 & 1 & -2 & 0 & -1 \\ 0 & 0 & 1 & 0 & 1 \\ 0 & 0 & 0 & -3 & 0 \\ 0 & 0 & 0 & 0 & 0 \end{pmatrix} \sim \begin{pmatrix} 1 & 1 & 0 & 0 & 1 \\ 0 & 0 & 1 & 0 & 1 \\ 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & 0 \end{pmatrix}.$$

From the last matrix, we get immediately (reading from bottom to top)  $u = 0$ ,  $z + v = 0$ ,  $x + y + v = 0$ . Letting  $v = s$  and  $y = t$ , the complete solution is

$$(x, y, z, u, v) = (-t - s, t, -s, 0, s), \quad t, s \in \mathbb{R}.$$

which can be rewritten as

$$\begin{pmatrix} x \\ y \\ z \\ u \\ v \end{pmatrix} = t \begin{pmatrix} -1 \\ 1 \\ 0 \\ 0 \\ 0 \end{pmatrix} + s \begin{pmatrix} -1 \\ 0 \\ -1 \\ 0 \\ 1 \end{pmatrix}, \quad t, s \in \mathbb{R},$$

Notice that the second and the fifth column of the matrix together form a basis for the solutions. These are the columns which do not contain a leading 1 in any of its entries. □

**2.E.6.** Determine the number of solutions for the systems

(a)

$$\begin{aligned} 12x_1 + \sqrt{5}x_2 + 11x_3 &= -9, \\ x_1 &- 5x_3 = -9, \\ x_1 &+ 2x_3 = -7; \end{aligned}$$

(b)

$$\begin{aligned} 4x_1 + 2x_2 - 12x_3 &= 0, \\ 5x_1 + 2x_2 - x_3 &= 0, \\ -2x_1 - x_2 + 6x_3 &= 4; \end{aligned}$$

(c)

$$\begin{aligned} 4x_1 + 2x_2 - 12x_3 &= 0, \\ 5x_1 + 2x_2 - x_3 &= 1, \\ -2x_1 - x_2 + 6x_3 &= 0. \end{aligned}$$

**Solution.** The vectors  $(1, 0, -5)$ ,  $(1, 0, 2)$  are clearly linearly independent, (they are not multiples of each other) and the vector  $(12, \sqrt{5}, 11)$  cannot be their linear combination (its second coordinate is non-zero). Therefore the matrix whose rows are these three linearly independent vectors (from the left side) is invertible. Thus the system for case (a) has exactly one solution.

For cases (b) and (c), it is enough to note that

$$(4, 2, -12) = -2(-2, -1, 6).$$

In case (b) adding the first equation to the third multiplied by two gives  $0 = 8$ , hence there is no solution for the system. In case (c) the third equation is a multiple of the first, so the system has infinitely many distinct solutions.  $\square$

**2.E.7.** Find a linear system, whose set of solutions is exactly

$$\{(t + 1, 2t, 3t, 4t); t \in \mathbb{R}\}.$$

**Solution.** Such a system is for instance

$$2x_1 - x_2 = 2, \quad 2x_2 - x_4 = 0, \quad 4x_3 - 3x_4 = 0.$$

These solutions are satisfied for every  $t \in \mathbb{R}$ . The vectors

$$(2, -1, 0, 0), \quad (0, 2, 0, -1), \quad (0, 0, 4, -3)$$

giving the left-hand sides of the equations are linearly independent (the set of solutions contains a single parameter).  $\square$

**2.E.8.** Solve the system of homogeneous linear equations given by the matrix

$$\begin{pmatrix} 0 & \sqrt{2} & \sqrt{3} & \sqrt{6} & 0 \\ 2 & 2 & \sqrt{3} & -2 & -\sqrt{5} \\ 0 & 2 & \sqrt{5} & 2\sqrt{3} & -\sqrt{3} \\ 3 & 3 & \sqrt{3} & -3 & 0 \end{pmatrix}.$$

**2.E.9.** Determine all solutions of the system

$$\begin{aligned} & x_2 + x_4 = 1, \\ 3x_1 - 2x_2 - 3x_3 + 4x_4 &= -2, \\ x_1 + x_2 - x_3 + x_4 &= 2, \\ x_1 - x_3 &= 1. \end{aligned}$$

**2.E.10.** Solve

$$\begin{aligned} 3x - 5y + 2u + 4z &= 2, \\ 5x + 7y - 4u - 6z &= 3, \\ 7x - 4y + \quad + 3z &= 4, \\ x + 6y - 2u - 5z &= 2 \end{aligned}$$

**2.E.11.** Determine whether or not the system of linear equations

$$\begin{aligned} 3x_1 + 3x_2 + x_3 &= 1, \\ 2x_1 + 3x_2 - x_3 &= 8, \\ 2x_1 - 3x_2 + x_3 &= 4, \\ 3x_1 - 2x_2 + x_3 &= 6 \end{aligned}$$

of three variables  $x_1, x_2, x_3$  has a solution.

**2.E.12.** Determine the number of solutions of the system of 5 linear equations

$$A^T \cdot x = (1, 2, 3, 4, 5)^T,$$

where

$$x = (x_1, x_2, x_3)^T \quad \text{and} \quad A = \begin{pmatrix} 3 & 1 & 7 & 5 & 0 \\ 0 & 0 & 0 & 0 & 1 \\ 2 & 1 & 4 & 3 & 0 \end{pmatrix}.$$

Repeat the question for the system

$$A^T \cdot x = (1, 1, 1, 1, 1)^T$$

**2.E.13.** Depending on the parameter  $a \in \mathbb{R}$ , determine the solution of the system of linear equations

$$\begin{aligned} ax_1 + 4x_2 + 2x_3 &= 0, \\ 2x_1 + 3x_2 - x_3 &= 0. \end{aligned}$$

**2.E.14.** Depending on the parameter  $a \in \mathbb{R}$ , determine the number of solutions of the system

$$\begin{pmatrix} 4 & 1 & 4 & a \\ 2 & 3 & 6 & 8 \\ 3 & 2 & 5 & 4 \\ 6 & -1 & 2 & -8 \end{pmatrix} \begin{pmatrix} x_1 \\ x_2 \\ x_3 \\ x_4 \end{pmatrix} = \begin{pmatrix} 2 \\ 5 \\ 3 \\ -3 \end{pmatrix}.$$

**2.E.15.** Decide whether or not there is a system of homogeneous linear equations of three variables whose set of solutions is exactly

- (a)  $\{(0, 0, 0)\}$ ;
- (b)  $\{(0, 1, 0), (0, 0, 0), (1, 1, 0)\}$ ;
- (c)  $\{(x, 1, 0); x \in \mathbb{R}\}$ ;
- (d)  $\{(x, y, 2y); x, y \in \mathbb{R}\}$ .

**2.E.16.** Solve the system of linear equations, depending on the real parameters  $a, b$ .

$$\begin{aligned} x + 2y + bz &= a \\ x - y + 2z &= 1 \\ 3x - y &= 1. \end{aligned}$$

**2.E.17.** Using the inverse matrix, compute the solution of the system

$$\begin{aligned} x_1 + x_2 + x_3 + x_4 &= 2, \\ x_1 + x_2 - x_3 - x_4 &= 3, \\ x_1 - x_2 + x_3 - x_4 &= 3, \\ x_1 - x_2 - x_3 + x_4 &= 5. \end{aligned}$$

**2.E.18.** For what values of parameters  $a, b \in \mathbb{R}$  has the system of linear equations

$$\begin{aligned} x_1 - ax_2 - 2x_3 &= b, \\ x_1 + (1-a)x_2 &= b-3, \\ x_1 + (1-a)x_2 + ax_3 &= 2b-1 \end{aligned}$$

- (a) exactly one solution;  
 (b) no solution;  
 (c) at least 2 solutions? (i.e. infinitely many solutions)

**Solution.** We rewrite it, as usual, in the extended matrix, and transform:

$$\begin{aligned} \begin{pmatrix} 1 & -a & -2 & b \\ 1 & 1-a & 0 & b-3 \\ 1 & 1-a & a & 2b-1 \end{pmatrix} &\sim \begin{pmatrix} 1 & -a & -2 & b \\ 0 & 1 & 2 & -3 \\ 0 & 1 & a+2 & b-1 \end{pmatrix} \\ &\sim \begin{pmatrix} 1 & -a & -2 & b \\ 0 & 1 & 2 & -3 \\ 0 & 0 & a & b+2 \end{pmatrix}. \end{aligned}$$

At the first step we subtract the first row from the second and the third; and at the second step we subtract the second from the third. We see that the system has a unique solution (determined by backward elimination) if and only if  $a \neq 0$ . If  $a = 0$  and  $b = -2$ , we have a zero row in the extended matrix. Choosing  $x_3 \in \mathbb{R}$  as a parameter then gives infinitely many distinct solutions. For  $a = 0$  and  $b \neq -2$  the last equation  $a = b + 2$  cannot be satisfied and the system has no solution.

Note that for  $a = 0, b = -2$  the solutions are

$$(x_1, x_2, x_3) = (-2 + 2t, -3 - 2t, t), \quad t \in \mathbb{R}$$

and for  $a \neq 0$  the unique solution is the triple

$$\left( \frac{-3a^2 - ab - 4a + 2b + 4}{a}, -\frac{2b + 3a + 4}{a}, \frac{b + 2}{a} \right).$$

□

**2.E.19.** Let

$$A = \begin{pmatrix} 4 & 5 & 1 \\ 3 & 4 & 0 \\ 1 & 1 & 1 \end{pmatrix}, \quad x = \begin{pmatrix} x_1 \\ x_2 \\ x_3 \end{pmatrix}, \quad b = \begin{pmatrix} b_1 \\ b_2 \\ b_3 \end{pmatrix}.$$

Find real numbers  $b_1, b_2, b_3$  such that the system of linear equations  $A \cdot x = b$  has:

- (a) infinitely many solutions;  
 (b) unique solution;  
 (c) no solution;  
 (d) exactly four solutions.

**Solution.** Since the first row is the sum of the other two, it is enough to choose  $b_1 = b_2 + b_3$  in case a) and  $b_1 \neq b_2 + b_3$  in case c). Variant b) cannot occur, since the matrix  $A$  is not invertible. As long as we work over reals, there cannot be any finite number of solutions, except zero or one. Thus d) is impossible. □

**2.E.20.** Factor the following permutations into a product of transpositions:

- i)  $\begin{pmatrix} 1 & 2 & 3 & 4 & 5 & 6 & 7 \\ 7 & 6 & 5 & 4 & 3 & 2 & 1 \end{pmatrix}$ ,  
 ii)  $\begin{pmatrix} 1 & 2 & 3 & 4 & 5 & 6 & 7 & 8 \\ 6 & 4 & 1 & 2 & 5 & 8 & 3 & 7 \end{pmatrix}$ ,  
 iii)  $\begin{pmatrix} 1 & 2 & 3 & 4 & 5 & 6 & 7 & 8 & 9 & 10 \\ 4 & 6 & 1 & 10 & 2 & 5 & 9 & 8 & 3 & 7 \end{pmatrix}$ .

2.E.21. Determine the parity of the given permutations:

i)  $\begin{pmatrix} 1 & 2 & 3 & 4 & 5 & 6 & 7 \\ 7 & 5 & 6 & 4 & 1 & 2 & 3 \end{pmatrix}$ ,

ii)  $\begin{pmatrix} 1 & 2 & 3 & 4 & 5 & 6 & 7 & 8 \\ 6 & 7 & 1 & 2 & 3 & 8 & 4 & 5 \end{pmatrix}$ ,

iii)  $\begin{pmatrix} 1 & 2 & 3 & 4 & 5 & 6 & 7 & 8 & 9 & 10 \\ 9 & 7 & 1 & 10 & 2 & 5 & 4 & 9 & 3 & 6 \end{pmatrix}$ .

2.E.22. Find the algebraically adjoint matrix  $F^*$  for

$$F = \begin{pmatrix} \alpha & \beta & 0 \\ \gamma & \delta & 0 \\ 0 & 0 & 1 \end{pmatrix}, \quad \alpha, \beta, \gamma, \delta \in \mathbb{R}.$$

2.E.23. Calculate the algebraically adjoint matrix for the matrices

(a)  $\begin{pmatrix} 3 & -2 & 0 & -1 \\ 0 & 2 & 2 & 1 \\ 1 & -2 & -3 & -2 \\ 0 & 1 & 2 & 1 \end{pmatrix}$ , (b)  $\begin{pmatrix} 1+i & 2i \\ 3-2i & 6 \end{pmatrix}$ ,

where  $i$  denotes the imaginary unit.

2.E.24. Is the set  $V = \{(1, x); x \in \mathbb{R}\}$  with operations

$$\oplus : V \times V \rightarrow V, \quad (1, y) \oplus (1, z) = (1, z + y) \quad \text{for all } z, y \in \mathbb{R}$$

$$\odot : \mathbb{R} \times V \rightarrow V, \quad z \odot (1, y) = (1, y \cdot z) \quad \text{for all } z, y \in \mathbb{R}$$

a vector space?

2.E.25. Express the vector  $(5, 1, 11)$  as a linear combination of the vectors  $(3, 2, 2)$ ,  $(2, 3, 1)$ ,  $(1, 1, 3)$ , that is, find numbers  $p, q, r \in \mathbb{R}$ , for which

$$(5, 1, 11) = p(3, 2, 2) + q(2, 3, 1) + r(1, 1, 3).$$

2.E.26. In  $\mathbb{R}^3$ , determine the matrix of rotation through the angle  $120^\circ$  in the positive sense about the vector  $(1, 0, 1)$

2.E.27. In the vector space  $\mathbb{R}^3$ , determine the matrix of the orthogonal projection onto the plane  $x + y - 2z = 0$ .

2.E.28. In the vector space  $\mathbb{R}^3$ , determine the matrix of the orthogonal projection on the plane  $2x - y + 2z = 0$ .

2.E.29. Determine whether the subspaces  $U = \langle(2, 1, 2, 2)\rangle$  and  $V = \langle(-1, 0, -1, 2), (-1, 0, 1, 0), (0, 0, 1, -1)\rangle$  of the space  $\mathbb{R}^4$  are orthogonal. If they are, is  $\mathbb{R}^4 = U \oplus V$ , that is, is  $U^\perp = V$ ?

2.E.30. Let  $p$  be a given line:

$$p : [1, 1] + (4, 1)t, \quad t \in \mathbb{R}$$

Determine the parametric expression of all lines  $q$  that pass through the origin and have deflection  $60^\circ$  with the line  $p$ .

**2.E.31.** Depending on the parameter  $t \in \mathbb{R}$ , determine the dimension of the subspace  $U$  of the vector space  $\mathbb{R}^3$ , if  $U$  is generated by the vectors

- (a)  $u_1 = (1, 1, 1)$ ,  $u_2 = (1, t, 1)$ ,  $u_3 = (2, 2, t)$ ;  
 (b)  $u_1 = (t, t, t)$ ,  $u_2 = (-4t, -4t, 4t)$ ,  $u_3 = (-2, -2, -2)$ .

○

**2.E.32.** Construct an orthogonal basis of the subspace

$$\langle (1, 1, 1, 1), (1, 1, 1, -1), (-1, 1, 1, 1) \rangle$$

of the space  $\mathbb{R}^4$ .

○

**2.E.33.** In the space  $\mathbb{R}^4$ , find an orthogonal basis of the subspace of all linear combinations of the vectors  $(1, 0, 1, 0)$ ,  $(0, 1, 0, -7)$ ,  $(4, -2, 4, 14)$ .

Find an orthogonal basis of the subspace generated by the vectors  $(1, 2, 2, -1)$ ,  $(1, 1, -5, 3)$ ,  $(3, 2, 8, -7)$ .

○

**2.E.34.** For what values of the parameters  $a, b \in \mathbb{R}$  are the vectors

$$(1, 1, 2, 0, 0), (1, -1, 0, 1, a), (1, b, 2, 3, -2)$$

in the space  $\mathbb{R}^5$  pairwise orthogonal?

○

**2.E.35.** In the space  $\mathbb{R}^5$ , consider the subspace generated by the vectors

$(1, 1, -1, -1, 0)$ ,  $(1, -1, -1, 0, -1)$ ,  $(1, 1, 0, 1, 1)$ ,  $(-1, 0, -1, 1, 1)$ . Find a basis for its orthogonal complement.

○

**2.E.36.** Describe the orthogonal complement of the subspace  $V$  of the space  $\mathbb{R}^4$ , if  $V$  is generated by the vectors  $(-1, 2, 0, 1)$ ,  $(3, 1, -2, 4)$ ,  $(-4, 1, 2, -4)$ ,  $(2, 3, -2, 5)$ .

○

**2.E.37.** In the space  $\mathbb{R}^5$ , determine the orthogonal complement  $W^\perp$  of the subspace  $W$ , if

- (a)  $W = \{(r + s + t, -r + t, r + s, -t, s + t); r, s, t \in \mathbb{R}\}$ ;  
 (b)  $W$  is the set of the solutions of the system of equations  $x_1 - x_3 = 0$ ,  $x_1 - x_2 + x_3 - x_4 + x_5 = 0$ .

○

**2.E.38.** In the space  $\mathbb{R}^4$ , let

$$(1, -2, 2, 1), (1, 3, 2, 1)$$

be given vectors. Extend these two vectors into an orthogonal basis of the whole  $\mathbb{R}^4$ . (You can do this in any way you wish, for instance by using the Gram-Schmidt orthogonalization process.)

○

**2.E.39.** Define an inner product on the vector space of the matrices from the previous exercise. Compute the norm of the matrix from the previous exercise, induced by the product you have defined.

○

**2.E.40.** Find a basis for the vector space of all antisymmetric real square matrices of the type  $4 \times 4$ . Consider the standard inner product in this basis and using this inner product, express the size of the matrix

$$\begin{pmatrix} 0 & 3 & 1 & 0 \\ -3 & 0 & 1 & 2 \\ -1 & -1 & 0 & 2 \\ 0 & -2 & -2 & 0 \end{pmatrix}$$

○

**2.E.41.** Find the eigenvalues and the associated eigenspaces of eigenvectors of the matrix:

$$A = \begin{pmatrix} 1 & 1 & 0 \\ -1 & 3 & 0 \\ 2 & -2 & 2 \end{pmatrix}.$$

**Solution.** The characteristic polynomial of the matrix is  $\lambda^3 - 6\lambda^2 + 12\lambda - 8$ , which is  $(\lambda - 2)^3$ . The number 2 is thus an eigenvalue with algebraic multiplicity three. Its geometric multiplicity is either one, two or three. We determine the vectors associated to this eigenvalue as the solutions of the system

$$\begin{aligned} -x_1 + x_2 &= 0, \\ (A - 2E)\mathbf{x} = -x_1 + x_2 &= 0, \\ 2x_1 - 2x_2 &= 0. \end{aligned}$$

Its solutions form the two-dimensional space  $\langle (1, -1, 0), (0, 0, 1) \rangle$ . Thus the eigenvalue 2 has algebraic multiplicity 3 and geometric multiplicity 2.

□

**2.E.42.** Determine the eigenvalues of the matrix

$$\begin{pmatrix} -13 & 5 & 4 & 2 \\ 0 & -1 & 0 & 0 \\ -30 & 12 & 9 & 5 \\ -12 & 6 & 4 & 1 \end{pmatrix}.$$

○

**2.E.43.** Given that the numbers 1, -1 are eigenvalues of the matrix

$$A = \begin{pmatrix} -11 & 5 & 4 & 1 \\ -3 & 0 & 1 & 0 \\ -21 & 11 & 8 & 2 \\ -9 & 5 & 3 & 1 \end{pmatrix},$$

find all solutions of the characteristic equation  $|A - \lambda E| = 0$ . Hint: if you denote all the roots of the polynomial  $|A - \lambda E|$  by  $\lambda_1, \lambda_2, \lambda_3, \lambda_4$ , then

$$|A| = \lambda_1 \cdot \lambda_2 \cdot \lambda_3 \cdot \lambda_4, \quad \text{and} \quad \text{tr } A = \lambda_1 + \lambda_2 + \lambda_3 + \lambda_4.$$

○

**2.E.44.** Find a four-dimensional matrix with eigenvalues  $\lambda_1 = 6$  and  $\lambda_2 = 7$  such that the multiplicity of  $\lambda_2$  as a root of the characteristic polynomial is three, and that

- (a) the dimension of the subspace of eigenvectors of  $\lambda_2$  is 3;
- (b) the dimension of the subspace of eigenvectors of  $\lambda_2$  is 2;
- (c) the dimension of the subspace of eigenvectors of  $\lambda_2$  is 1;

○

**2.E.45.** Find the eigenvalues and the eigenvectors of the matrix:

$$\begin{pmatrix} -1 & -\frac{5}{6} & \frac{5}{3} \\ 0 & -\frac{2}{3} & -\frac{2}{3} \\ 0 & \frac{1}{6} & -\frac{1}{3} \end{pmatrix}.$$

**2.E.46.** Determine the characteristic polynomial  $|A - \lambda E|$ , eigenvalues and eigenvectors of the matrix

$$\begin{pmatrix} 4 & -1 & 6 \\ 2 & 1 & 6 \\ 2 & -1 & 8 \end{pmatrix}.$$

respectively.

## Solutions to the exercises

2.A.11. There is only one such matrix  $X$ , and it is

$$\begin{pmatrix} 18 & -32 \\ 5 & -8 \end{pmatrix}.$$

2.A.13.  $A^{-1} = \begin{pmatrix} 1 & 10 & -4 \\ 1 & 12 & -5 \\ 0 & 5 & -2 \end{pmatrix}.$

2.A.14.

$$A^5 = \begin{pmatrix} 122 & -121 & 121 \\ -121 & 122 & -121 \\ 0 & 0 & 1 \end{pmatrix}, \quad A^{-3} = \frac{1}{27} \begin{pmatrix} 14 & 13 & -13 \\ 13 & 14 & 13 \\ 0 & 0 & 27 \end{pmatrix}.$$

2.A.15.  $\begin{pmatrix} 2 & -3 & 0 & 0 & 0 \\ -5 & 8 & 0 & 0 & 0 \\ 0 & 0 & -1 & 0 & 0 \\ 0 & 0 & 0 & -5 & 2 \\ 0 & 0 & 0 & 3 & -1 \end{pmatrix}.$

2.A.16.  $C^{-1} = \frac{1}{2} \begin{pmatrix} 0 & 1 & 1 & 0 \\ 0 & 1 & 0 & -1 \\ 1 & -1 & 0 & 0 \\ 1 & -1 & -1 & 1 \end{pmatrix}.$

2.A.17. In the first case we have

$$A^{-1} = \frac{1}{2} \cdot \begin{pmatrix} 3 & -i \\ i & 1 \end{pmatrix};$$

in the second

$$A^{-1} = \begin{pmatrix} 14 & 8 & 5 \\ 2 & 1 & 1 \\ 1 & 1 & 0 \end{pmatrix}.$$

2.C.9.  $(2 + \frac{1}{\sqrt{3}}, 2 - \frac{1}{\sqrt{3}}).$

2.C.10. The vectors are dependent whenever at least one of the conditions

$$a = b = 1, \quad a = c = 1, \quad b = c = 1$$

is satisfied.

2.C.11. Vectors are linearly independent.

2.C.12. It suffices to add for instance the polynomial  $x$ .

2.D.5.  $\cos = \frac{\sqrt{2}}{\sqrt{3}}.$

2.D.12. Je  $|A - \lambda E| = -\lambda^3 + 12\lambda^2 - 47\lambda + 60, \lambda_1 = 3, \lambda_2 = 4, \lambda_3 = 5.$

2.D.20. The solution is the sequence 0, 1, 2.

2.D.21. The dimension is 1 for  $\lambda_1 = 4$  and 2 for  $\lambda_2 = 3$ .

2.E.8. The solutions are all scalar multiples of the vector

$$(1 + \sqrt{3}, -\sqrt{3}, 0, 1, 0).$$

2.E.9.  $x_1 = 1 + t, \quad x_2 = \frac{3}{2}, \quad x_3 = t, \quad x_4 = -\frac{1}{2}, \quad t \in \mathbb{R}.$

2.E.10. The system has no solution.

2.E.11. The system has a solution, because

$$3 \cdot \begin{pmatrix} 3 \\ 2 \\ 2 \\ 3 \end{pmatrix} - \begin{pmatrix} 3 \\ 3 \\ -3 \\ -2 \end{pmatrix} - 5 \cdot \begin{pmatrix} 1 \\ -1 \\ 1 \\ 1 \end{pmatrix} = \begin{pmatrix} 1 \\ 8 \\ 4 \\ 6 \end{pmatrix}.$$

**2.E.12.** The system of linear equations

$$\begin{array}{rcl} 3x_1 & + & 2x_3 = 1, \\ x_1 & + & x_3 = 2, \\ 7x_1 & + & 4x_3 = 3, \\ 5x_1 & + & 3x_3 = 4, \\ & x_2 & = 5 \end{array}$$

has no solution, while the system

$$\begin{array}{rcl} 3x_1 & + & 2x_3 = 1, \\ x_1 & + & x_3 = 1, \\ 7x_1 & + & 4x_3 = 1, \\ 5x_1 & + & 3x_3 = 1, \\ & x_2 & = 1 \end{array}$$

has a unique solution  $x_1 = -1, x_2 = 1, x_3 = 2$ .

**2.E.13.** The set of all solutions is given by

$$\{(-10t, (a+4)t, (3a-8)t); t \in \mathbb{R}\}.$$

**2.E.14.** For  $a = 0$ , the system has no solution. For  $a \neq 0$  the system has infinitely many solutions.

**2.E.15.** The correct answers are „yes“, „no“, „no“ and „yes“ respectively.

**2.E.16.** i) If  $b \neq -7$ , then  $x = z = (2+a)/(b+7), y = (3a-b-1)/(b+7)$ . ii) If  $b = -7$  and  $a \neq -2$ , then there is no solution. iii)

If  $a = -2$  and  $b = -7$  then the solution is  $x = z = t, y = 3t - 1$ , for any  $t$ .

**2.E.17.**

$$\begin{pmatrix} 1 & 1 & 1 & 1 \\ 1 & 1 & -1 & -1 \\ 1 & -1 & 1 & -1 \\ 1 & -1 & -1 & 1 \end{pmatrix}^{-1} = \frac{1}{4} \begin{pmatrix} 1 & 1 & 1 & 1 \\ 1 & 1 & -1 & -1 \\ 1 & -1 & 1 & -1 \\ 1 & -1 & -1 & 1 \end{pmatrix}.$$

We can then easily obtain

$$x_1 = \frac{13}{4}, \quad x_2 = -\frac{3}{4}, \quad x_3 = -\frac{3}{4}, \quad x_4 = \frac{1}{4}.$$

**2.E.20.** i) (1, 7)(2, 6)(5, 3), ii) (1, 6)(6, 8)(8, 7)(7, 3)(2, 4), iii) (1, 4)(4, 10)(10, 7)(7, 9)(9, 3)(2, 6)(6, 5)

**2.E.21.** i) 17 inversions, odd, ii) 12 inversions, even iii) 25 inversions, odd

**2.E.22.** From the knowledge of the inverse matrix  $F^{-1}$  we obtain

$$F^* = (\alpha\delta - \beta\gamma) F^{-1} = \begin{pmatrix} \delta & -\beta & 0 \\ -\gamma & \alpha & 0 \\ 0 & 0 & \alpha\delta - \beta\gamma \end{pmatrix},$$

for any  $\alpha, \beta, \gamma, \delta \in \mathbb{R}$ .

**2.E.23.** The matrices are

$$(a) \begin{pmatrix} 1 & 1 & -2 & -4 \\ 0 & 1 & 0 & -1 \\ -1 & -1 & 3 & 6 \\ 2 & 1 & -6 & -10 \end{pmatrix}, \quad (b) \begin{pmatrix} 6 & -2i \\ -3+2i & 1+i \end{pmatrix}.$$

**2.E.24.** It is easy to check that it is a vector space. The first coordinate does not affect the results of the operations – it is just the vector space  $(\mathbb{R}, +, \cdot)$  written in a different way.

**2.E.25.** There is a unique solution

$$p = 2, \quad q = -2, \quad r = 3.$$

**2.E.26.**

$$\begin{pmatrix} 1/4 & -\sqrt{6}/4 & 3/4 \\ \sqrt{6}/4 & -1/2 & -\sqrt{6}/4 \\ 3/4 & \sqrt{6}/4 & 1/4 \end{pmatrix}$$

**2.E.27.**

$$\begin{pmatrix} 5/6 & -1/6 & 1/3 \\ -1/6 & 5/6 & 1/3 \\ 1/3 & 1/3 & 1/3 \end{pmatrix}.$$

2.E.28.

$$\begin{pmatrix} 5/9 & 2/9 & -4/9 \\ 2/9 & 8/9 & 2/9 \\ -4/9 & 2/9 & 5/9 \end{pmatrix}$$

2.E.29. The vector that determines the subspace  $U$  is perpendicular to each of the three vectors that generate  $V$ . The subspaces are thus orthogonal. But it is not true that  $\mathbb{R}^4 = U \oplus V$ . The subspace  $V$  is only two-dimensional, because

$$(-1, 0, -1, 2) = (-1, 0, 1, 0) - 2(0, 0, 1, -1).$$

2.E.30.

$$q_1 : (2 - \frac{\sqrt{3}}{2}, 2\sqrt{3} + \frac{1}{2})t, \quad q_2 : (2 + \frac{\sqrt{3}}{2}, -2\sqrt{3} + \frac{1}{2})t.$$

2.E.31. In the first case we have  $\dim U = 2$  for  $t \in \{1, 2\}$ , otherwise we have  $\dim U = 3$ . In the second case we have  $\dim U = 2$  for  $t \neq 0$  and  $\dim U = 1$  for  $t = 0$ .

2.E.32. Using the Gram-Schmidt orthogonalization process we can obtain the result

$$((1, 1, 1, 1), (1, 1, 1, -3), (-2, 1, 1, 0)).$$

2.E.33. We have for instance the orthogonal bases

$$((1, 0, 1, 0), (0, 1, 0, -7))$$

for the first part, and

$$((1, 2, 2, -1), (2, 3, -3, 2), (2, -1, -1, -2)).$$

for the second part.

2.E.34. The solution is  $a = 9/2$ ,  $b = -5$ , because

$$1 + b + 4 + 0 + 0 = 0, \quad 1 - b + 0 + 3 - 2a = 0.$$

2.E.35. The basis must contain a single vector. It is

$$(3, -7, 1, -5, 9).$$

(or any non-zero scalar multiple thereof)

2.E.36. The orthogonal complement  $V^\perp$  is the set of all scalar multiples of the vector  $(4, 2, 7, 0)$ .

2.E.37.

$$(a) W^\perp = \langle (1, 0, -1, 1, 0), (1, 3, 2, 1, -3) \rangle;$$

$$(b) W^\perp = \langle (1, 0, -1, 0, 0), (1, -1, 1, -1, 1) \rangle.$$

2.E.38. There are infinitely many possible extensions, of course. A very simple one is

$$(1, -2, 2, 1), \quad (1, 3, 2, 1), \quad (1, 0, 0, -1), \quad (1, 0, -1, 1).$$

2.E.39. For instance, one can use the inner product that follows from the isomorphism of the space of all real  $3 \times 3$  matrices with the space  $\mathbb{R}^9$ . If we use the product from  $\mathbb{R}^9$ , we obtain an inner product that assigns to two matrices the sum of products of two corresponding elements. For the given matrix we obtain

$$\left\| \begin{pmatrix} 1 & 2 & 0 \\ 0 & 2 & 0 \\ 1 & -2 & -3 \end{pmatrix} \right\| = \left\langle \begin{pmatrix} 1 & 2 & 0 \\ 0 & 2 & 0 \\ 1 & -2 & -3 \end{pmatrix}, \begin{pmatrix} 1 & 2 & 0 \\ 0 & 2 & 0 \\ 1 & -2 & -3 \end{pmatrix} \right\rangle = \sqrt{1^2 + 2^2 + 0^2 + 0^2 + 2^2 + 0^2 + 1^2 + (-2)^2 + (-3)^2} = \sqrt{23}.$$

2.E.40.

2.E.42. The matrix has only one eigenvalue, namely  $-1$ , since the characteristic polynomial is  $(\lambda + 1)^4$ .

2.E.43. The root  $-1$  of the polynomial  $|A - \lambda E|$  has multiplicity three.

2.E.44. Possible examples are,

$$(a) \begin{pmatrix} 6 & 0 & 0 & 0 \\ 0 & 7 & 0 & 0 \\ 0 & 0 & 7 & 0 \\ 0 & 0 & 0 & 7 \end{pmatrix}; \quad (b) \begin{pmatrix} 6 & 0 & 0 & 0 \\ 0 & 7 & 1 & 0 \\ 0 & 0 & 7 & 0 \\ 0 & 0 & 0 & 7 \end{pmatrix};$$

$$(c) \begin{pmatrix} 6 & 0 & 0 & 0 \\ 0 & 7 & 1 & 0 \\ 0 & 0 & 7 & 1 \\ 0 & 0 & 0 & 7 \end{pmatrix}.$$

**2.E.45.** There is a triple eigenvalue  $-1$ . The corresponding eigenspace is  $\langle (1, 0, 0), (0, 2, 1) \rangle$ .

**2.E.46.** The characteristic polynomial is  $-(\lambda - 2)^2(\lambda - 9)$ , that is, the eigenvalues are 2 and 9 with associated eigenvectors  $(1, 2, 0), (-3, 0, 1)$  a  $(1, 1, 1)$

## Linear models and matrix calculus

where are the matrices useful?  
– basically almost everywhere...

### A. Linear optimization

Let us start with an example of a very simple problem:

**3.A.1.** A company manufactures bolts and nuts. Nuts and bolts are moulded – moulding a box of bolts takes one minute, a box of nuts is moulded for 2 minutes. Preparing the box itself takes one minute for bolts, 4 minutes for nuts. The company has at its disposal two hours for moulding and three hours for box preparation. Demand says that it is necessary to manufacture at least 90 boxes of bolts more than boxes of nuts. Due to technical reasons it is not possible to manufacture more than 110 boxes of bolts. The profit from one box of bolts is \$4 and the profit from one box of nuts is \$6. The company has no trouble with selling. How many boxes of nuts and bolts should be manufactured in order to have maximal profit?

**Solution.** Write the given data into a table:

	Bolts 1 box	Nuts 1 box	Capacity
Mould	1 min./box	2 min./box	2 hours
Box	1 min./box	4 min./box	3 hours
Profit	\$4/box	\$6/box	

We have already developed a useful package of tools and it is time to show some applications of matrix calculus. The first three parts of this chapter are independent and the readers more interested in the theory might skip any of them and continue with the fourth part straight ahead.

It might seem that the assumption of linearity of relations between quantities is too restrictive. But this is often not so. In real problems, linear relations may appear directly. A problem may be solved as a result of an iteration of many linear steps. If this is not the case, we may still use this approach at least to approximate real non-linear processes.

We should also like to compute with matrices (and linear mappings) as easily as we can compute with scalars. In order to do that, we prepare the necessary tools in the second part of this chapter. We also present a useful application of matrix decompositions to the pseudoinverse matrices, which are needed for numerical mastery of matrix calculus.

We try to illustrate all the phenomena with rather easy problems. Still some parts of this chapter are perhaps difficult for first reading. This in particular concerns the very first part providing some glimpses towards the linear optimization (linear programming), and the third part devoted to iterated processes (the Frobenius-Perron theory).

The rest of the chapter comes back to some more advanced parts of the matrix calculus (the Jordan canonical form, decompositions, and pseudo-inverses of matrices). The reader should feel free to move forward if getting lost.

### 1. Linear optimization

The simplest linear processes are given by linear mappings  $\varphi : V \rightarrow W$  on vector spaces. As we can surely imagine, the vector  $v \in V$  can represent the state of some system we are observing, while  $\varphi(v)$  gives the result after some process is realized.

If we want to reach a given result  $b \in W$  of such a process, we solve the problem

$$\varphi(x) = b$$

for some unknown vector  $x$  and a known vector  $b$ .

In fixed coordinates we then have the matrix  $A$  of a mapping  $\varphi$  and coordinate expression of the vector  $b$ . We have mastered such problems in the previous chapter. Now we

Denote by  $x_1$  the number of manufactured boxes of bolts and by  $x_2$  the number of manufactured boxes of nuts. From the restriction on moulding time and from the restriction on the box preparation we obtain the following restrictive conditions:

$$\begin{aligned} x_1 + 2x_2 &\leq 120 \\ x_1 + 4x_2 &\leq 180 \\ x_1 &\geq x_2 + 90 \\ x_1 &\leq 110 \end{aligned}$$

The objective function (the function that gives the profit for given number of manufactured nuts and bolts) is  $4x_1 + 6x_2$ . The previous system of inequalities defines a region in  $\mathbb{R}^2$ . Optimisation of the profit means finding in this region the point (points) in which the objective function has the maximum value, that is, to find the largest  $k$  such that the line  $4x_1 + 6x_2 = k$  has a non-empty intersection with the given region. Graphically, we can find the solution for example by placing the line  $p$  into the plane such that it satisfies the equation  $4x_1 + 6x_2 = 0$  and start moving it "upwards" as long as it has some intersection with the area. It is clear that the last intersection is either a point or a line parallel to  $p$  forming a border of the region. Thus we obtain (see the figure) the point  $x_1 = 110$  and  $x_2 = 5$ . Maximum possible income is thus  $4 \cdot 110 + 6 \cdot 5 = \$470$ .

□

**3.A.2. Minimisation of costs for feeding.** A stable in Nišovice u Volyně buys fodder for winter: hay and oats. The

draw more interesting conclusions in the setup of *linear optimization models* (called also *linear programming*).

**3.1.1. Linear optimization.** In the practical column, the previous chapter started with a painting problem, and we shall continue here in a similar way. Imagine that our very specialized painter in a black&white world is willing to paint facades of either small family houses or of large public buildings, and that he (of course) uses only black and white colours. He can arbitrarily choose proportions between  $x_1$  units of area for the small houses or  $x_2$  units for the large buildings. Assume that his maximal workload in a given interval is  $L$  units of area, his net income (that is, after subtracting the costs) is  $c_1$  per unit of area for small houses and  $c_2$  per unit of area for large buildings. Furthermore, he has only  $W$  kg of white colour and  $B$  kg of black colour at his disposal. Finally, a unit of area for small houses requires  $w_1$  kg of white colour and  $b_1$  kg of black colour. For large buildings the corresponding values are  $w_2$  and  $b_2$ .

If we write all this information as inequalities, we obtain the conditions

- (1)  $x_1 + x_2 \leq L$
- (2)  $w_1x_1 + w_2x_2 \leq W$
- (3)  $b_1x_1 + b_2x_2 \leq B$ .

The total net income of the painter, which is the following linear form  $h$ ,

$$h(x_1, x_2) = c_1x_1 + c_2x_2,$$

is to be maximized.

Each of the given inequalities clearly determines a half-plane in the plane of the variables  $(x_1, x_2)$ , bounded by a line given by the corresponding equality, and we must also assume that both  $x_1$  and  $x_2$  are non-negative real numbers (because the painter cannot paint negative areas). Thus we have constraints for the values  $(x_1, x_2)$  – either the constraints are unsatisfiable, or they allow points inside a polygon with at most five vertices. See the diagram.

the axis in the diagram should be called  $x_1$  and  $x_2$ ! Add the line of constant value for  $h$ , best through one of the vertices with hand-written description "optimal constant value of  $h$ "

nutritional values of the fodder and required daily portions for one foal are given in the table:

g/kg	Hay	Oats	Requirements
Dry basis	841	860	$\geq 6300$ g
Digestible nitrogen stuff	53	123	$\geq 1150$ g
Starch	0.348	0.868	$\leq 5.35$ g
Calcium	6	1.6	$\geq 30$ g
Phosphate	2.8	3.5	$\leq 44$ g
Natrium	0.2	1.4	$\simeq 7$ g
Cost	1.80	1.60	

Every foal must obtain in its daily meal at least 2 kg of oats. The average cost (counting the payment for the transportation) is €1.80 per 1 kg of hay and €1.60 per 1 kg of oats. Compose a daily diet for one foal which has minimum costs. ○

The previous three examples could be solved by drawing the diagram and checking all the vertices on the boundary of the polygonal area  $M \subset \mathbb{R}^2$ . Moreover, we know that the maximum will be at one of the extremes in the direction of the normal to the defining line from the linear cost function  $h$ .

But the principle works in higher dimensions as well. If there is a function  $f : \mathbb{R}^n \rightarrow \mathbb{R}$ ,  $f(x_1, \dots, x_n) = c_0 + c_1x_1 + \dots + c_nx_n$  (we call it the objective function), its values in the points  $A = (a_1, \dots, a_n)$  and  $B = A + u = (a_1 + u_1, \dots, a_n + u_n)$  differ by  $f(B) - f(A) = f(u) = f(u_1, \dots, u_n) = c_1u_1 + \dots + c_nu_n$ , which is the scalar product of the vectors  $(c_1, \dots, c_n)$  and  $(u_1, \dots, u_n)$ . The relation between the scalar product and the cosine of the angle between vectors ensures that the given function  $f$  defines a hypersurface in  $\mathbb{R}^n$  with normal  $(c_1, \dots, c_n)$ . This hypersurface splits the space  $\mathbb{R}^n$  into two half-spaces. Clearly the given function grows if moving towards one of those half-spaces and declines in the other one. This is essentially the same principle as we saw when discussing the visibility of segments in dimension 2 (we checked whether the observer is to the left or to the right from the oriented segment, cf. 1.5.12).

This observation leads to an algorithm for finding the extremal values of the linear objective function  $f$  on the set  $M$  of admissible points defined by linear inequalities.

We shall deal with the standard problem of linear programming. That is, we want to maximize the linear function  $h = c_1x_1 + \dots + c_nx_n$  on the set  $M$  given by  $Ax \leq b$  and  $x \geq 0$  (here the inequality between vectors means the inequality between all their individual components). As explained in 3.1.6 we may add slack variables  $x_s$ , one for each equation.

How to solve such a problem? We seek the maximum value of a linear form  $h$  over subsets  $M$  of a vector space which are defined by linear inequalities. In the plane,  $M$  is given by the intersection of half planes.

Next, note that every linear form over real vector space  $h : V \rightarrow \mathbb{R}$  (that is, arbitrary linear scalar function) is monotone in every chosen direction. More precisely, if we choose a fixed starting vector  $u \in V$  and “directional” vector  $v \in V$ , then composition of our form  $h$  with parametrization yields

$$t \mapsto h(u + tv) = h(u) + th(v).$$

This expression is indeed either increasing or decreasing, or constant (depending on whether  $h(v)$  is positive, negative or zero), as a function of  $t$ .

Thus, if the set  $M$  is bounded as at our picture above, we easily find the solution by testing the value of  $h$  at the vertices of the boundary polygon. In general, we must expect that problems similar to the one with the painter are either unsatisfiable (if the given set with constraints is empty), or the profit is unbounded (if the constraints allow for unbounded directions in the space and the form  $h$  is non-zero in some of the unbounded directions) or they attain a maximal solution in at least one of the “vertices” of the set  $M$ . Normally the maximum is attained at a single point of  $M$ , but sometimes it is attained on a part of the boundary of the set  $M$ .

Try to choose explicit values for the parameters  $w_1, w_2, b_1, b_2, c_1, c_2$ , draw the above picture for these parameters and find the explicit solution to the problem (if it exists)!

**3.1.2. Terminology.** In general we speak of a *linear programming problem* whenever we seek either the maximum or minimum value of a linear form  $h$  over  $\mathbb{R}^n$  on a set bounded by a system of linear inequalities which we call *linear constraints*. The vector on the right side is then called the *vector of constraints*. The linear form  $h$  is also called the *objective function*.<sup>1</sup> In real practice we meet hundreds or thousands of constraints for dozens of variables.

The *standard maximization problem* is defined by seeking a maximum of the objective function while the restrictive inequalities are  $\leq$  and the variables are non-negative. On the other hand, the *standard minimization problem* is defined by seeking a minimum of the objective function while the restrictive inequalities are  $\geq$  and the variables are non-negative.

It is easy to see that every general linear programming problem can be transformed into a standard one of either types. Aside from sign changes, we can work with a decomposition of the variables that have no sign restriction into a difference of two non-negative ones. Without loss of generality we will work only with the standard maximization problem.

<sup>1</sup>Leonid Kantorovich and Tjalling Koopmans shared the 1975 Nobel prize in economics for their formulations and solution of economical and logistics problems in a similar way during the second world war. But it was George B. Dantzig who independently developed general linear programming formulation in the period 1946-49, motivated by planning problems in US Air Force. Among others, he invented the simplex method algorithm.

Thus we may restrict ourselves to the problem of maximizing  $h$  on a vector space of solutions of systems of linear equations with the additional condition that all the values of the coordinates must be non-negative.

If there are more general inequalities, we can always change them into our form by multiplying them with  $-1$  and minimization of value of  $h$  corresponds to maximization of  $-h$ .

As explained in more details in 3.1.1 and 3.1.6, we add the first row of coefficients of  $h$  (with minus signs) and use the simplex tableau:

$$\begin{array}{ccc|c} -c_1 & \dots & -c_n & 0 \\ a_{11} & \dots & a_{1n} & b_1 \\ \vdots & & \vdots & \vdots \\ a_{m1} & \dots & a_{mn} & b_n \end{array}$$

We start the algorithm if we find  $m$  columns (here  $m$  is the number of equations in the problem) such that Gauss elimination for these columns leads to a unit submatrix in  $A$  and positive values at the positions of all  $b_i$ . The coordinates corresponding to these columns and values 1 in them are called the basic coordinates. We restrict ourselves to the cases where all  $b_i$  are nonnegative in the original problem and then we choose all the slack variables as the basic ones and the initialization of the algorithm is done.

Next we move in the following iterated steps (compare the more theoretical explanation in 3.1.6):

We choose the first column from the left having a non-positive value in the first row. In this column (let it be the  $j$ -th column), we pick up the positive entry  $a_{ij}$  in  $A$  which provides the minimal relation  $b_i/a_{ij}$  (we call this entry the *pivot*). Finally we eliminate the entire chosen column with the help of the chosen  $a_i$ . This means we achieve by elementary row transformations that the  $j$ -th column contains the value 1 at its  $i$ -th row, with all other values vanishing.

We explain the procedure by an example:

**3.A.3.** Minimize the function  $-3x - y - 2z$  under the conditions  $x, y, z \geq 0$  and

$$\begin{array}{rcll} x & - & y & + & z & \geq & -4, \\ 2x & & & + & z & \leq & 3, \\ x & + & y & + & 3z & \leq & 8. \end{array}$$

**Solution.** First we multiply the objective function and the first inequality by  $-1$ . We get the equivalent task of maximizing

**3.1.3. Formulation using linear equations.** Finding an optimum is not always as simple as in the previous 2-dimensional case. The problem can contain many variables and constraints and even deciding whether the set  $M$  of the feasible points is non-empty can be a problem.

We do not have the ambition to go into detailed theory here. But we mention at least some ideas which show that the solution can be always found, and then we build an effective algorithm solving the problem in the next paragraphs.

We begin by comparison with systems of linear equations – because we understand those well. We write the equations (1)-(3) in 3.1.1 in the general form:

$$A \cdot x \leq b,$$

where  $x$  is now an  $n$ -dimensional vector,  $b$  is an  $m$ -dimensional vector and  $A$  is the corresponding matrix. By an inequality between vectors we mean individual inequalities between all coordinates. We want to maximize the product  $c \cdot x$  for a given row vector of coefficients of the linear form  $h$  a the feasible values of  $x$ . If we add new auxiliary variables  $x_s$ , one for every equation and add another variable  $z$  for the value of the linear form  $h$ , we can rewrite the whole system as a system of linear equations

$$(1) \quad \begin{pmatrix} 1 & -c & 0 \\ 0 & A & E_m \end{pmatrix} \cdot \begin{pmatrix} z \\ x \\ x_s \end{pmatrix} = \begin{pmatrix} z - c \cdot x \\ A \cdot x + x_s \end{pmatrix} = \begin{pmatrix} 0 \\ b \end{pmatrix}$$

where the matrix is composed of the blocks with  $1 + n + m$  columns and  $1 + m$  rows, with corresponding individual components of the vectors. We call the new variables  $x_s$  the *slack variables*. Moreover, we require non-negativity for all coordinates  $x$  and  $x_s$ . If the given system of equations has a solution, we seek values for the variables  $z$ ,  $x$  and  $x_s$ , such that all  $x$  and  $x_s$  are non-negative and  $z$  is maximized.

Specifically, in our problem of the black&white painter from 3.1.1, the system of linear equations looks like this:

$$\begin{pmatrix} 1 & -c_1 & -c_2 & 0 & 0 & 0 \\ 0 & 1 & 1 & 1 & 0 & 0 \\ 0 & w_1 & w_2 & 0 & 1 & 0 \\ 0 & b_1 & b_2 & 0 & 0 & 1 \end{pmatrix} \cdot \begin{pmatrix} z \\ x_1 \\ x_2 \\ x_3 \\ x_4 \\ x_5 \end{pmatrix} = \begin{pmatrix} 0 \\ L \\ W \\ B \end{pmatrix}$$

In paragraph 4.1.11 on page 239 we will discuss this situation from the viewpoint of affine geometry. Now we just notice that being on the boundary of the set of feasible points  $M$  of the problem is equivalent to having some of the slack variables vanishing. Our algorithm will try to move from one such position to another while increasing  $h$ . But we shall need some conceptual preparation first.

**3.1.4. Duality of linear programming.** Consider the real matrix  $A$  with  $m$  rows and  $n$  columns, vector of constraints  $b$  and row vector  $c$  giving the objective function. From this data we can consider two problems of linear programming for  $x \in \mathbb{R}^n$  and  $y \in \mathbb{R}^m$ .

the function  $3x + y + 2z$  under the conditions

$$\begin{aligned} -x + y + z &\leq 4, \\ 2x + z &\leq 3, \\ x + y + 3z &\leq 8. \end{aligned}$$

Introducing the non-negative slack variables  $u, v, w$ , we obtain the tableau with the objective function  $3x + y + 2z + 0 \cdot u + 0 \cdot v + 0 \cdot w$ :

$$\begin{array}{cccccc|c} -3 & -1 & -2 & 0 & 0 & 0 & 0 \\ \hline -1 & 1 & -1 & \boxed{1} & 0 & 0 & 4 \\ \textcircled{2} & 0 & 1 & 0 & \boxed{1} & 0 & 3 \\ 1 & 1 & 3 & 0 & 0 & \boxed{1} & 8 \end{array}$$

Since the right-hand column is non-negative, setting  $u = 4$ ,  $v = 3$ ,  $w = 8$ ,  $x = y = z = 0$  provides an admissible solution to the system which corresponds to the choice of the basic variables  $u, v, w$ , and the algorithm may begin.

The first column is already with a negative entry in the first row, so we choose this one. We have circled the pivot, i.e. the value two there (we compare the relations of the elements and those in the last column, i.e.  $\frac{3}{2}$  and  $\frac{8}{1}$ , and take the minimal one, since we need to keep the last column positive during the elimination). Next we eliminate the first column with the help of the pivot (we multiply the third row by  $\frac{1}{2}$ , and subtract its reasonable multiples from the other rows, not forgetting the first row of the tableau, so that only zero entries remain there):

$$\begin{array}{cccccc|c} 0 & -1 & -\frac{1}{2} & 0 & \frac{3}{2} & 0 & \frac{9}{2} \\ \hline 0 & \textcircled{1} & -\frac{1}{2} & \boxed{1} & \frac{1}{2} & 0 & \frac{11}{2} \\ \boxed{1} & 0 & \frac{1}{2} & 0 & \frac{1}{2} & 0 & \frac{3}{2} \\ 0 & 1 & \frac{5}{2} & 0 & -\frac{1}{2} & \boxed{1} & \frac{13}{2} \end{array}$$

Now the basic variables are  $x = 3/2$ ,  $u = 11/2$ ,  $w = 13/2$ , which reflects the fact that we moved as much from the former slack variable  $v$  to the new basic variable  $x$  as possible. This increased the value of the objective function, which we may read in the right top corner of the tableau.

Next, we choose the pivot from the second column and the above rule yields the first row in  $A$  ( $\frac{11}{2} < \frac{13}{2}$ ). We have already circled the 1 in the tableau above. We eliminate:

$$\begin{array}{cccccc|c} 0 & 0 & -1 & 1 & 2 & 0 & 10 \\ \hline 0 & \boxed{1} & -\frac{1}{2} & 1 & \frac{1}{2} & 0 & \frac{11}{2} \\ \boxed{1} & 0 & \frac{1}{2} & 0 & \frac{1}{2} & 0 & \frac{3}{2} \\ 0 & 0 & \textcircled{3} & -1 & -1 & \boxed{1} & 1 \end{array}$$

DUAL PROBLEMS OF LINEAR PROGRAMMING

**Maximization problem:** Maximize  $c \cdot x$  under the conditions  $A \cdot x \leq b$  and  $x \geq 0$ .

**Minimization problem:** Minimize  $y^T \cdot b$  under the condition  $y^T \cdot A \geq c$  and  $y \geq 0$ .

We say that these two problems are *dual problems of linear programming*. Before deriving further properties of linear programming we need some terminology.

We say that the problem is *solvable* if there is an *admissible vector*  $x$  (or admissible vector  $y^T$ ) which satisfies all constraints. A solvable maximization (minimization) problem is *bounded*, if the objective function is bounded from above (below) over the set of admissible vectors.

**Lemma (Weak duality theorem).** *If  $x \in \mathbb{R}^n$  is an admissible vector for the standard maximization problem, and if  $y \in \mathbb{R}^m$  is an admissible vector for the dual minimization problem, then*

$$c \cdot x \leq y^T \cdot b$$

**PROOF.** It is a simple observation. Since  $x \geq 0$  and  $c \leq y^T \cdot A$ , it follows that  $c \cdot x \leq y^T \cdot A \cdot x$ . But also  $y \geq 0$  and  $A \cdot x \leq b$ , hence

$$c \cdot x \leq y^T \cdot A \cdot x \leq y^T \cdot b,$$

which is what we wanted to prove.  $\square$

We see immediately that if both dual problems are solvable, then they must be bounded. Even more interesting is the following corollary, which is directly implied by the inequality in the previous proof.

**Corollary.** *If there exist admissible vectors  $x$  and  $y$  of dual linear problems such that for the objective functions  $c \cdot x = y^T \cdot b$ , then both are optimal solutions for the corresponding problems.*

**3.1.5. Theorem (Strong duality theorem).** *If a standard problem of linear programming is solvable and bounded, then its dual is also bounded and solvable. There exists an optimal solution for each of the problems, and the optimal values of the corresponding objective functions are equal.*

**PROOF.** As already proved in the latter corollary, once it is established that the values of the objective functions for the dual problems equal, we have the required optimal solutions to both problems. It remains to prove the other implication, i.e. the existence of an optimal solution under the assumptions in the theorem, as well as the fact, that the objective functions share their values in such a case. This will be verified by delivering an efficient algorithm in the next paragraph.  $\square$

We notice yet another corollary of the just formulated duality theorem:

**Corollary (Equilibrium theorem).** *Consider two admissible vectors  $x$  and  $y$  for the standard maximization problem and its dual problem as defined in 3.1.4. Then both vectors are*

Again, we have shifted the new basic variable from  $u$  to  $y$  and the objective function increased. The next pivot will be the circled number 3 in the third column and fourth row:

0	0	0	$\frac{2}{3}$	$\frac{5}{3}$	$\frac{1}{3}$	$\frac{31}{3}$
0	1	0	$\frac{5}{6}$	$\frac{1}{3}$	$\frac{1}{6}$	$\frac{17}{3}$
1	0	0	$\frac{1}{6}$	$\frac{2}{3}$	$-\frac{1}{6}$	$\frac{4}{3}$
0	0	1	$-\frac{1}{3}$	$-\frac{1}{3}$	$\frac{1}{3}$	$\frac{1}{3}$

This is the resulting tableau, where the basic variables are  $x = \frac{4}{3}$ ,  $y = \frac{17}{3}$ ,  $z = \frac{1}{3}$  and their values are read from the last column. Notice that all the original variables are among the basic ones and their values are non-zero. This is not always the case, see the example 3.A.1 above and its explanation via this algorithm in 3.1.6. The maximal value  $\frac{31}{3}$  for the objective function is now in the right top corner.

As mentioned in the theoretical explanation, the final tableau also provides the solution of the dual problem, i.e. the minimization of  $4u + 3v + 8w$  under the condition

$$\begin{aligned} u + 2v + w &\leq 3, \\ -u + w &\geq 1, \\ u + v + 3w &\geq 2. \end{aligned}$$

According to the strong duality theorem (see 3.1.5), the minimal value is again  $\frac{31}{3}$ , while the corresponding values of the variables  $u$ ,  $v$  and  $w$  are read off the first row in the corresponding columns:  $u = \frac{2}{3}$ ,  $v = \frac{5}{3}$ ,  $w = \frac{1}{3}$ .

You may check directly that the numbers  $c_4, c_5, c_6$  in the first row of the tableau and the value  $h$  in the top right corner satisfy  $4c_4 + 3c_5 + 8c_6 = h$ . Indeed, the numbers  $c_i$  tell how many times the appropriate row (the one with original value 1) has been added. Thus we obtain the right linear combination for  $h$ . □

**3.A.4. Some game theory.** Imagine a game played by two players – a billionaire and fate. The billionaire would like to invest into gold, silver, diamonds or stocks of an important IT software company. The wins and losses of such investments are well known for the last four years (for simplicity, we consider only the last four years and write them into the matrix  $A = (a_{ij})$ ):

	gold	silver	diamonds	software
2001	2%	1%	4%	3%
2002	3%	-1%	-2%	6%
2003	1%	2%	3%	-4%
2004	-2%	1%	2%	3%

optimal if and only if  $y_i = 0$  for all coordinates with index  $i$  for which  $\sum_{j=1}^n a_{ij}x_j < b_i$  and simultaneously  $x_j = 0$  for all coordinates with index  $j$  such that  $\sum_{i=1}^m y_i a_{ij} > c_j$ .

**PROOF.** Suppose both relations regarding the zeros among  $x_i$  and  $y_i$  are true. Since the summands with strict inequality have zero coefficients, we have

$$\sum_{i=1}^m y_i b_i = \sum_{i=1}^m y_i \sum_{j=1}^n a_{ij} x_j = \sum_{i=1}^m \sum_{j=1}^n y_i a_{ij} x_j$$

and for the same reason

$$\sum_{i=1}^m \sum_{j=1}^n y_i a_{ij} x_j = \sum_{j=1}^n c_j x_j.$$

This shows one implication, by the duality theorem.

Suppose now that both  $x$  and  $y$  are optimal vectors. Then

$$\sum_{i=1}^m y_i b_i \geq \sum_{i=1}^m \sum_{j=1}^n y_i a_{ij} x_j \geq \sum_{j=1}^n c_j x_j.$$

But the left- and right-hand sides are equal, and hence there is equality everywhere. If we rewrite the first equality as

$$\sum_{i=1}^m y_i \left( b_i - \sum_{j=1}^n a_{ij} x_j \right) = 0,$$

then we see that it can be satisfied only if the relation from the statement holds. But it is a sum of non-negative numbers and equals zero. From the second equality we similarly derive the second part and the proof is finished. □

The duality theorem and equilibrium theorem are useful when solving linear programming problems, because they show us relations between zeros among the additional variables and the fulfillment of the constraints. As usual, it is good to know that the problem is solvable in principle and to have some theory related to that, but we still need some clever ideas to make it all into an efficient algorithmic procedure. The next paragraph will provide some insight to this.

**3.1.6. The algorithm.** As already explained, the linear programming problem of maximizing the linear objective function  $h = cx$  under the conditions  $Ax \leq b$

can be turned into solving the system of equations (1) in 3.1.3, where we added the slack variables  $x_s$ . If all entries in  $b$  are non-negative, then the choice of  $x_s = b$  and  $x = 0$  provides an admissible solution of the system with the value of the objective function  $h = 0$ . This is the choice of the origin  $x = 0$  as one of the vertices of the distinguished region  $M$  of the admissible points. We can understand this as choosing the variables  $x_s$  as the *basic variables*, whose values are given by the right hand sides of the equation, while all the other variables are set to zero.

In the general case (allowing for negative entries in  $b$ ), we shall see in 4.1.11 that we always can find an admissible vertex. That is, the choice of the basic variables in the above

The billionaire would like to invest for one year only. How should he split his investment in order to ensure the maximal win independently of development on the stock market? We assume that next year will be some (unknown) probabilistic mix of the previous four ones. In terms of our game, fate will play some stochastic vector  $(x_1, x_2, x_3, x_4)$  fixing the behaviour of the market (as a probabilistic mixture of the previous ones), while the billionaire will play another stochastic vector  $(y_1, y_2, y_3, y_4)$  describing the split of his investment. The win of the billionaire is  $\sum_{i,j=1}^4 x_i y_j a_{ij}$ .

**Solution.** The task is to find the stochastic vector  $(y_1, y_2, y_3, y_4)$ , which will maximize the minimum of all values  $\sum_{i,j=1}^4 x_i y_j a_{ij}$  for the fixed matrix  $A$  and any stochastic vector  $(x_1, x_2, x_3, x_4)$ .

A very observant reader could imagine that this task is equivalent to the problem of maximizing  $z_1 + z_2 + z_3 + z_4$  under the condition  $A^T z \leq (1, \dots, 1)^T, z \geq 0$  (and the requested stochastic vector  $y$  is then obtained by normalizing the vector  $z$ , the requested optimal value is the inverse of the optimal value obtained).<sup>1</sup>

Thus, we have to solve a linear programming problem. We introduce the slack variables  $w_1, w_2, w_3, w_4$ , and transform the problem to the standard form

$$\max \{z_1 + z_2 + z_3 + z_4 \mid (A^T | E_4)(z, w) = (1, 1, 1, 1)^T\}.$$

We work with the table:

-1	-1	-1	-1	0	0	0	0	0
2	3	1	-2	1	0	0	0	1
<span style="border: 1px solid black; padding: 2px;">1</span>	-1	2	1	0	1	0	0	1
<span style="border: 1px solid black; border-radius: 50%; padding: 2px;">4</span>	-2	3	2	0	0	1	0	1
3	6	-4	3	0	0	0	1	1

0	$-\frac{3}{2}$	$-\frac{1}{4}$	$-\frac{1}{2}$	0	0	$\frac{1}{4}$	0	$\frac{1}{4}$
0	4	$-\frac{1}{2}$	-3	<span style="border: 1px solid black; padding: 2px;">1</span>	0	$-\frac{1}{2}$	0	$\frac{1}{2}$
0	$-\frac{1}{2}$	$\frac{5}{4}$	$\frac{1}{2}$	0	<span style="border: 1px solid black; padding: 2px;">1</span>	$-\frac{1}{4}$	0	$\frac{3}{4}$
<span style="border: 1px solid black; padding: 2px;">1</span>	$-\frac{1}{2}$	$\frac{3}{4}$	$\frac{1}{2}$	0	0	$\frac{1}{4}$	0	$\frac{1}{4}$
0	<span style="border: 1px solid black; border-radius: 50%; padding: 2px;"><math>\frac{15}{2}</math></span>	$-\frac{25}{4}$	$\frac{3}{2}$	0	0	$-\frac{3}{4}$	<span style="border: 1px solid black; padding: 2px;">1</span>	$\frac{1}{4}$

sense, describing an admissible solution. Next, we shall assume to have such a vertex already.

The idea of the algorithm is to perform equivalent row transformations of the entire system in such a way, that we move to other vertices of the region  $M$  and the function  $h$  increases. In order to move to more interesting vertices in  $M$ , we must bring some of the slack variables to zero while the appropriate column for the unit matrix would move to one of those columns corresponding to the variables  $x$ . A simple check reveals that in order to do this, we must choose some of the negative entries in the first line of the matrix 3.1.3(1), pick up this column and choose a line in such a way that using the Gaussian elimination to push the other entries in this particular column to zero, the right hand sides of the equations remain non-negative. The latter condition means that we have to choose the index  $i$  such that  $b_i/a_{ij}$  is minimal. This entry in the matrix is called the *pivot* for the next step in the elimination. Of course, the non-positive coefficients  $a_{ij}$  are not taken into consideration, since they would not lead to any increase in the objective function. When there are no more negative entries in the first row, we are finished, and the claim is that the optimal value of  $h$  appears in the right hand top corner of the matrix.

Before indicating the proof of all the above claims, we show how all this works for the simple problem from 3.A.1. In practice, the very first column of the matrix in question does not change during the procedure at all, so we can omit it completely. Thus we deal with the matrix tableaux:

-4	-6	0	0	0	0	0
1	2	1	0	0	0	120
1	4	0	1	0	0	180
-1	1	0	0	1	0	-90
1	0	0	0	0	1	110

We cannot find an admissible solution by fixing  $x_s$  as the basic variables here, since there are negative values in  $b$ . We try to initiate the above algorithm by changing the sign in the last but one row and performing the Gaussian elimination for the very first column aiming to have only the 1 in the last but one row there. We obtain:

0	-10	0	0	-4	0	360
0	<span style="border: 1px solid black; border-radius: 50%; padding: 2px;">3</span>	<span style="border: 1px solid black; padding: 2px;">1</span>	0	1	0	30
0	5	0	<span style="border: 1px solid black; padding: 2px;">1</span>	1	0	90
<span style="border: 1px solid black; padding: 2px;">1</span>	-1	0	0	-1	0	90
0	1	0	0	1	<span style="border: 1px solid black; padding: 2px;">1</span>	20

We choose the boxed entries for the basic variables, this represents the values  $x_1 = 90, x_2 = 0, x_3 = 30, x_4 = 90, x_5 = 0, x_6 = 20$ , and  $h = 360 = 4 \cdot 90 = -4 \cdot (-90)$  which is an admissible solution. We have also circled the pivot for the next step, i.e. the element in the second column which we want to replace with 1 and eliminate the rest of the column (remember this is the one yielding the smallest ratio with the

<sup>1</sup>The observation comes from the proof of the von Neumann Minimax theorem, 1928. The theorem claims that any probabilistic extension of a matrix game enjoys an equilibrium state.

0	0	$-\frac{3}{2}$	$-\frac{1}{5}$	0	0	$\frac{1}{10}$	$\frac{1}{5}$	$\frac{3}{10}$
0	0	$\frac{17}{6}$	$-\frac{19}{5}$	1	0	$-\frac{1}{10}$	$-\frac{8}{15}$	$\frac{11}{30}$
0	0	$\frac{5}{6}$	$\frac{3}{5}$	0	1	$-\frac{3}{10}$	$\frac{1}{15}$	$\frac{23}{30}$
1	0	$\frac{1}{3}$	$\frac{3}{5}$	0	0	$\frac{1}{5}$	$\frac{1}{15}$	$\frac{4}{15}$
0	1	$-\frac{5}{6}$	$\frac{1}{5}$	0	0	$-\frac{1}{10}$	$\frac{2}{15}$	$\frac{1}{30}$
0	0	0	$-\frac{188}{85}$	$\frac{9}{17}$	0	$\frac{4}{85}$	$-\frac{7}{85}$	$\frac{42}{85}$
0	0	1	$-\frac{114}{85}$	$\frac{6}{17}$	0	$-\frac{3}{85}$	$-\frac{16}{85}$	$\frac{11}{85}$
0	0	0	$\frac{146}{85}$	$-\frac{5}{17}$	1	$-\frac{23}{85}$	$\frac{19}{85}$	$\frac{56}{85}$
1	0	0	$\frac{89}{85}$	$-\frac{2}{17}$	0	$\frac{18}{85}$	$\frac{11}{85}$	$\frac{19}{85}$
0	1	0	$-\frac{78}{85}$	$\frac{5}{17}$	0	$-\frac{11}{85}$	$-\frac{2}{85}$	$\frac{12}{85}$
$\frac{188}{89}$	0	0	0	$\frac{25}{89}$	0	$\frac{44}{89}$	$\frac{17}{89}$	$\frac{86}{89}$
$\frac{114}{89}$	0	1	0	$\frac{18}{89}$	0	$\frac{21}{89}$	$-\frac{2}{89}$	$\frac{37}{89}$
$-\frac{146}{89}$	0	0	0	$-\frac{9}{89}$	1	$-\frac{55}{89}$	$\frac{1}{89}$	$\frac{26}{89}$
$-\frac{85}{89}$	0	0	1	$-\frac{10}{89}$	0	$\frac{18}{89}$	$\frac{11}{89}$	$\frac{19}{89}$
$\frac{78}{89}$	1	0	0	$\frac{17}{89}$	0	$\frac{5}{89}$	$\frac{8}{89}$	$\frac{30}{89}$

The last table is already the optimal one, since there are no negative values in the first row. We can read off the optimal solution:  $z_2 = \frac{30}{89}$ ,  $z_3 = \frac{37}{89}$ ,  $z_4 = \frac{19}{89}$ ,  $z_1 = 0$ . The optimal value (upper right corner) is  $z_1 + z_2 + z_3 + z_4 = \frac{86}{89}$ . After rescaling to a stochastic vector (multiplying with  $\frac{89}{86}$ ) we get the solution of the original problem:  $y_1 = 0$ ,  $y_2 = \frac{30}{86}$ ,  $y_3 = \frac{37}{86}$ ,  $y_4 = \frac{19}{86}$ . with the optimal value  $\frac{89}{86}$ .  $\square$

### B. Difference equations

Distinct linear dependences can be an excellent tool for describing various models of growth. We begin with a very popular population model that uses a linear difference equation of second order:

**3.B.1. Fibonacci sequence.** In the beginning of spring, a stork brought two newborn rabbits, male and female, to a meadow. The female, after being two months old, is able to deliver two newborns, male and female. The newborns can then start delivering after one month and then every month. Every female is pregnant for one month and then she delivers. How many pairs of rabbits

last right hand column entry among the positive elements –  $30/3 = 10$  which is less than  $90/5 = 18$  and  $20/1 = 20$ ). This leads to the next admissible vertex in our region  $M$  and, of course the value for  $h$  will increase:

0	0	$\frac{10}{3}$	0	$-\frac{2}{3}$	0	460
0	1	$\frac{1}{3}$	0	$\frac{1}{3}$	0	10
0	0	$-\frac{5}{3}$	1	$-\frac{2}{3}$	0	40
1	0	$\frac{1}{3}$	0	$-\frac{2}{3}$	0	100
0	0	$-\frac{1}{3}$	0	$\frac{2}{3}$	1	10

with  $x_1 = 100$ ,  $x_2 = 10$ ,  $x_3 = x_5 = 0$ ,  $x_4 = 40$ ,  $x_6 = 10$ , and  $h = 460 = 4 \cdot 100 + 6 \cdot 10 = \frac{10}{3} \cdot 120 - \frac{2}{3} \cdot (-90)$ . We still have one of the entries in the first line negative. We circled the next pivot leading to

0	0	$\frac{9}{3}$	0	0	1	470
0	1	$\frac{1}{2}$	0	0	$-\frac{1}{2}$	5
0	0	-2	1	0	1	50
1	0	0	0	0	1	110
0	0	$-\frac{1}{2}$	0	1	$\frac{3}{2}$	15

with the final values  $x_1 = 110$ ,  $x_2 = 5$ ,  $x_3 = 0$ ,  $x_4 = 50$ ,  $x_5 = 15$ ,  $x_6 = 0$ , and

$$h = 470 = 4 \cdot 110 + 6 \cdot 5 = \frac{9}{3} \cdot 120 + 1 \cdot 110.$$

Let us remind why we can be sure that this is the optimal solution. Thanks to fact that the first line is exclusively non-negative, we have got admissible solution of the dual problem which leads to the same value as the solution of the original one. Thus the equilibrium theorem claims we are done!

**CORRECTNESS OF THE ALGORITHM.** Let us come back to the above claims in some detail. We should check whether the algorithm provides the right answer when it terminates, but we should also check under which conditions it terminates.

We start with the first part. The special feature of the above algorithm reshuffling the basic variables is that the slack variables parts of the matrix are closely linked to the dual linear programming problem. Moreover, there is an invariant of the entire procedure:

**Claim.** Writing  $(-\hat{c}, \hat{c}_s, \hat{h})$  for the current first line in the matrix and  $(\hat{x}, \hat{x}_s)$  for the current values of the variables, we obtain  $\hat{c} \cdot \hat{x} = \hat{c}_s \cdot \hat{x}_s = \hat{h}$  at each step.

In particular at the moment of the termination of the above algorithm, the coefficients  $y = \hat{c}_s$  in the first row represent admissible values of the dual problem (while the values  $\hat{c}$  stay for the slack variables in the dual problem), and the right hand top corner provides the value of the corresponding objective function  $y^T \cdot b$ . Since the two objective functions are equal, we know that the algorithm provides the optimal solution.

will be there after nine months (if none of them dies and none “move in”)?

**Solution.** After one month, there is still one pair, but the female is already pregnant. After two months, first newborns are delivered, thus there are two pairs. Every next month, there are that many new pairs as there were pregnant females one month before, which equals to the number of at least one month-old pairs, which equals the number of pairs that were there two months ago. The total number of pairs  $p_n$  after  $n$  months is thus the sum of the number of pairs in the previous two months. For the number of pairs we thus have the following *homogeneous linear recurrent formula*

$$(1) \quad p_{n+2} = p_{n+1} + p_n, \quad n = 1, \dots,$$

which, along with the initial conditions  $p_1 = 1$  and  $p_2 = 1$ , uniquely determines the number of pairs of rabbits at the meadow in individual months. Linearity of the formula means that all members of the sequence  $(p_n)$  appear to the first power. Hopefully the meaning of the word recurrence is clear. For the value of the  $n$ -th member we can derive an explicit formula. In searching for the formula we can use the observation that for certain  $r$  the function  $r^n$  is a solution of the difference equation without initial conditions. This  $r$  can be obtained by substitution into the recurrent relation:

$$\begin{aligned} r^{n+2} &= r^{n+1} + r^n \quad \text{and after dividing by } r^n \text{ we obtain} \\ r^2 &= r + 1. \end{aligned}$$

This is the *characteristic equation* of the given recurrent formula. Thus our equation has roots  $\frac{1-\sqrt{5}}{2}$  and  $\frac{1+\sqrt{5}}{2}$  and the sequences  $a_n = (\frac{1-\sqrt{5}}{2})^n$  and  $b_n = (\frac{1+\sqrt{5}}{2})^n$ ,  $n \geq 1$  satisfy the given relation. The relation is also satisfied by any linear combination, that is, any sequence  $c_n = sa_n + tb_n$ ,  $s, t \in \mathbb{R}$ . The numbers  $s$  and  $t$  can be chosen so that the resulting combination satisfies the initial conditions, in our case  $c_1 = 1$ ,  $c_2 = 1$ . For simplicity, it is convenient to define the zero-th member of the sequence as  $c_0 = 0$  and compute  $s$  and  $t$  from the equations for  $c_0$  and  $c_1$ . We find that  $s = -\frac{1}{\sqrt{5}}$ ,  $t = \frac{1}{\sqrt{5}}$  and thus

$$(2) \quad p_n = \frac{(1 + \sqrt{5})^n - (1 - \sqrt{5})^n}{2^n(\sqrt{5})}.$$

Such a sequence satisfies the given recurrent formula and also the initial conditions  $c_0 = 0$ ,  $c_1 = 1$ . Hence it is the unique sequence given by these requirements. Note that the value of  $p_n$  in the formula (2) is an integer for any natural  $n$  (all terms

**PROOF OF THE CLAIM.** As we know, the Gaussian elimination can be expressed as multiplication by a suitable transition matrix  $T$  from the left. Our “pivoting” corresponds always to a (block wise) matrix

$$T = \begin{pmatrix} 1 & y^T \\ 0 & R \end{pmatrix},$$

with an invertible matrix  $R$ . Thus (dealing with the standard problem)

$$T \cdot \begin{pmatrix} 1 & -c & 0 & 0 \\ 0 & A & E_m & 0 \end{pmatrix} = \begin{pmatrix} 1 & -c + y^T A & y^T & y^T b \\ 0 & RA & R & Rb \end{pmatrix}$$

and the second line corresponds to the equality  $A\hat{x} + \hat{x}_s = b$ . Consequently, we arrive at

$$-\hat{c}\hat{x} = (-c + y^T A)\hat{x} = -c\hat{x} + y^T(b - \hat{x}_s).$$

Now, notice the components  $\hat{x}_s$  vanish whenever the corresponding components of  $y^T \neq 0$ , i.e.,  $y^T \hat{x}_s = 0$ . Similarly,  $\hat{c}\hat{x} = 0$  and so we read from the latter displayed equality  $\hat{c}\hat{x} = y^T b$ , as claimed.  $\square$

The termination of the algorithm is a more subtle question. While it terminates nearly always, it might happen that the algorithm cycles without enlarging the objective function. We shall not go into more details here, a simple example is given in ??.

$\square$  Put a cycling simple example to the practice column, maybe in the end of the chapter.

**3.1.7. Notes about linear models in economy.** Our simple scheme of the black&white painter from the paragraph 3.1.1 can be used to illustrate one of the typical economical models, the *model of production planning*. The model tries to capture the problem completely, that is, to capture both external and internal relations. The left-hand sides of the equations (1), (2), (3) in 3.1.1, and the objective function  $h(x_1, x_2)$  express various production relations. Depending on the character of the problem, we have on the right-hand sides either exact values (and so we solve equations) or capacity constraints and goal optimization (then we obtain linear programming problems).

Thus in general we can solve the problem of source allocation with supplier constraints and either minimize costs or maximize income.

Among economical models, we can find many modifications. One of them is the problem of *financial planning*, which is connected to the optimization of portfolio. We are setting up a volume of investment into individual investment possibilities with the goal to meet the given constraints for risk factors while maximizing the profit, or dually minimize the risk under the given volume.

Another common model is *marketing application*, for instance allocation of costs for advertisement in various media or placing advertisement into time intervals. Restrictions are in this case determined by budget, target population, etc.

Very common are models of *nutrition*, that is, setting up how much of different kinds of food should be eaten in order to meet total volume of specific components, e.g. minerals and vitamins.

in the Fibonacci sequence are integers), although it might not seem so at the first glance.  $\square$

We do some exercises about solving linear difference equation of the second order with constant coefficients. The sequence satisfying the given recurrence equation of the second order is uniquely determined whenever we prescribe any two neighbouring members. Note a further use of complex numbers: to determine the explicit formula for the  $n$ -th member of the sequence of real numbers we might require calculations with complex numbers. This happens when the characteristic polynomial of the difference equation has complex roots.

**3.B.2.** Find an explicit formula for the sequence satisfying the following linear difference equation with the initial conditions:

$$x_{n+2} = 2x_n + n, \quad x_1 = 2, \quad x_2 = 2.$$

**Solution.** The homogeneous equation is

$$x_{n+2} = 2x_n.$$

Its characteristic polynomial is  $x^2 - 2$ , its roots are  $\pm\sqrt{2}$ . The solution of the homogeneous equation is of the form

$$a(\sqrt{2})^n + b(-\sqrt{2})^n, \quad \text{for any } a, b \in \mathbb{R}.$$

We look for the particular solution using the method of indeterminate coefficients. The non-homogeneous part of the equation is a linear polynomial  $n$ . Thus a particular solution will be of the form of a linear polynomial in the variable  $n$ . That is,  $kn + l$ , where  $k, l \in \mathbb{R}$ . By substituting into the original equation we obtain

$$k(n+2) + l = 2(kn + l) + n.$$

By comparing the coefficients of the variable  $n$  on both sides of the equation, we obtain the relation  $k = 2k+1$ , that is,  $k = -1$ . By comparing the absolute terms we obtain  $2k + l = 2l$ , that is,  $l = -2$ . Thus the particular solution is the sequence  $-n - 2$ .

Thus the solution of the non-homogeneous difference equation of the second order without initial condition is of the form

$$a(\sqrt{2})^n + b(-\sqrt{2})^n - n - 2, \quad a, b \in \mathbb{R}$$

Problems of linear programming arise with personal tasks, where workers with specific qualifications and other properties are distributed into working shifts. Common are also problems of *merging*, problems of *splitting* and problems of *goods distribution*.

## 2. Difference equations

We have already met difference equations in the first chapter, albeit briefly and of first order only. Now we consider a more general theory for linear equations with constant coefficients. This not only provides very practical tools but also represents a good illustration for the concepts of vector spaces and linear mappings.

### HOMOGENEOUS LINEAR DIFFERENCE EQUATION OF ORDER $k$

**3.2.1. Definition.** A homogeneous linear difference equation (or homogeneous linear recurrence) of order  $k$  is given by the expression

$$a_0x_n + a_1x_{n-1} + \dots + a_kx_{n-k} = 0, \quad a_0 \neq 0, \quad a_k \neq 0,$$

where the coefficients  $a_i$  are scalars, which can possibly depend on  $n$ .

A solution of this equation is a sequence of scalars  $x_i$ , for all  $i \in \mathbb{N}$  (or  $i \in \mathbb{Z}$ ), which satisfy the equation with any  $n$ .

We often understand the sequence in question as a function

$$x_n = f(n) = -\frac{a_1}{a_0}f(n-1) - \dots - \frac{a_k}{a_0}f(n-k).$$

By giving any  $k$  consecutive values  $x_i$  in the sequence, all other values of  $x_i$  are determined uniquely. Indeed, we work over a field of scalars, thus the values  $a_0$  and  $a_k$  are invertible and hence, using the recurrent definition, any  $x_n$  can be computed uniquely from the preceding  $k$  values, and similarly for  $x_{n-k}$ . Induction thus immediately proves that all remaining values are uniquely determined.

The space of all infinite sequences  $x_i$  forms a vector space, where addition and multiplication by scalars work coordinate-wise. The definition immediately implies that a sum of two solutions of a homogeneous linear difference equation or a multiple of a solution is again a solution. Analogously as with homogeneous linear systems we see that the set of all solutions forms a subspace.

Initial conditions on the values  $x_0, \dots, x_{k-1}$  of the solution represent a  $k$ -dimensional vector in  $\mathbb{K}^k$ . The sum of initial conditions determines the sum of the corresponding solutions, similarly for scalar multiples. Note also that substituting zeros and ones into initial  $k$  values immediately yields  $k$  linearly independent solutions of the difference equation. Thus, although the vectors are infinite sequences, the set of all solutions has finite dimension. The dimension equals the order of the equation  $k$ . Moreover, we can easily obtain a basis of all those solutions. Again we speak of the *fundamental*

Now, by substitution in the initial conditions, we determine the indeterminate  $a, b \in \mathbb{R}$ . To simplify the calculation, we use a little trick: from the initial conditions and the given recurrence relation we compute the member  $x_0 : x_0 = \frac{1}{2}(x_2 - 0) = 1$ . The given recurrence formula along with the conditions  $x_0 = 1$  and  $x_1 = 1$  is then clearly satisfied by the same formula that satisfies the original initial conditions. Thus we have the following relations for  $a, b$ :

$$\begin{aligned} x_0 : \quad & a(\sqrt{2})^0 + b(-\sqrt{2})^0 - 2 = 1, \quad \text{thus } a + b = 3, \\ x_1 : \quad & \sqrt{2}a - \sqrt{2}b = 5, \end{aligned}$$

whose solution gives us  $a = \frac{6+5\sqrt{2}}{4}, b = \frac{6-5\sqrt{2}}{4}$ . The solution is thus the sequence

$$x_n = \frac{6 + 5\sqrt{2}}{4}(\sqrt{2})^n + \frac{6 - 5\sqrt{2}}{4}(-\sqrt{2})^n - n - 2.$$

□

**3.B.3.** Determine the basis of the space of all solutions of the homogeneous difference equation

$$x_{n+4} = x_{n+3} + x_{n+1} - x_n,$$

Express your solution in terms of real valued functions.

**Solution.** The characteristic polynomial of the given equation is  $x^4 - x^3 - x + 1$ . If we are looking for its roots, we solve the equation

$$x^4 - x^3 - x + 1 = 0$$

The left side factors as

$$(x - 1)^2(x^2 + x + 1)$$

with two complex roots  $x_1 = -\frac{1}{2} + i\frac{\sqrt{3}}{2} = \cos(2\pi/3) + i\sin(2\pi/3)$  and  $x_2 = -\frac{1}{2} - i\frac{\sqrt{3}}{2} = \cos(2\pi/3) - i\sin(2\pi/3)$  and a double root 1. Thus the basis of the vector space of the sequences that are a solution of the difference equation in question is the following quadruple of sequences:  $\{(-\frac{1}{2} + i\sqrt{3})^n\}_{n=1}^\infty, \{(-\frac{1}{2} - i\sqrt{3})^n\}_{n=1}^\infty, \{1\}_{n=1}^\infty$  (constant sequence) and  $\{n\}_{n=1}^\infty$ . If we are looking for a basis of real valued functions, we must replace two of the generators (sequences) from this basis by some sequences that are real only. As these generators are power series whose members are complex conjugates, it suffices to take as suitable generators the sequences given by the half of the sum and by the half of the  $i$ -th multiple of the difference of that complex generators. This yields the following real

system of solutions and all other solutions are its linear combinations.

As we have just checked, if we choose  $k$  indices  $i, i + 1, \dots, i + k - 1$  in sequence, the homogeneous linear difference equation gives a linear mapping  $\mathbb{K}^k \rightarrow \mathbb{K}^\infty$  of  $k$ -dimensional vectors of initial values into infinitely-dimensional sequences of the same scalars. The independence of such solutions is equivalent to the independence of the initial values – which can be easily checked by a determinant: If we have a  $k$ -tuple of solutions  $(x_n^{[1]}, \dots, x_n^{[k]})$ , it is independent if and only if the following determinant, sometimes called the *Casoratian*, is non-zero for one  $n$

$$C_n = \begin{vmatrix} x_n^{[1]} & \cdots & x_n^{[k]} \\ x_{n+1}^{[1]} & \cdots & x_{n+1}^{[k]} \\ \vdots & \ddots & \vdots \\ x_{n+k-1}^{[1]} & \cdots & x_{n+k-1}^{[k]} \end{vmatrix} \neq 0.$$

Notice the determinant  $C_{n+1}$  is obtained from  $C_n$  by replacing the first row in  $C_n$  by the last row in  $C_{n+1}$  expressed as the linear combination of the rows in  $C_n$  given by the difference equation and then putting the first row to position of the last one. Thus  $C_{n+1} = (-1)^k \frac{a_0}{a_k} C_n$ , with values  $a_0, a_k$  corresponding to  $n+k$ . In particular, linearly independent initial conditions lead to independent  $k$ -dimensional vectors for all consecutive  $k$  components of the solution.

**3.2.2. Recurrences with constant coefficients.** It is difficult to find a universal mechanism for finding a solution (that is, a directly computable expression) of general homogeneous linear difference equations. We shall come back to this problem in the end of chapter 13.

In practical models there are very often equations, where the coefficients are constant. In this case it is possible to guess a suitable form for the solution and indeed to find  $k$  linearly independent solutions. This would then be a complete solution of the problem, since all other solutions would be linear combinations of them.

For simplicity we start with equations of second order. Such recurrences are very often encountered in practical problems, where there are relations based on two previous values. A linear difference equation (recurrence) of second order with constant coefficients is thus a formula

$$(1) \quad f(n + 2) = a f(n + 1) + b f(n) + c,$$

where  $a, b, c$  are known scalar coefficients.

Consider a population model. We assume that the individuals in a population mature and start breeding two seasons later (that is, they add to the value  $f(n + 2)$  by a multiple  $b f(n)$  with positive  $b > 1$ ), while immature individuals at the same time weaken and destroy part of the mature population (that is, the coefficient  $a$  at  $f(n+1)$  is negative). Furthermore, it might be that somebody destroys (uses, eats) a fixed amount  $-c$  of individuals every season.

basis of the solution space:  $\{1\}_{n=1}^{\infty}$  (constant sequence),  $\{n\}_{n=1}^{\infty}$ ,  $\{\cos(2n\pi/3)\}_{n=1}^{\infty}$ ,  $\{\sin(2n\pi/3)\}_{n=1}^{\infty}$ .  $\square$

**3.B.4.** Solve the following difference equation:

$$x_{n+4} = x_{n+3} - x_{n+2} + x_{n+1} - x_n.$$

**Solution.** From the theory we know that the space of the solutions of this difference equation is a four-dimensional vector space whose generators can be obtained from the roots of the characteristic polynomial of the given equation. The characteristic polynomial is

$$x^4 - x^3 + x^2 - x + 1 = 0.$$

It is a reciprocal equation (that means that the coefficients at the  $(n-k)$ -th and  $k$ -th power of  $x$ ,  $k = 1, \dots, n$ , are equal). We can use the substitution  $u = x + \frac{1}{x}$ . After dividing the equation by  $x^2$  (zero cannot be a root) and substituting (note that  $x^2 + \frac{1}{x^2} = u^2 - 2$ ) we obtain

$$x^2 - x + 1 - \frac{1}{x} + \frac{1}{x^2} = u^2 - u - 1 = 0.$$

Thus we obtain the indeterminates  $u_{1,2} = \frac{1 \pm \sqrt{5}}{2}$ . From there then by the equation  $x^2 - ux + 1 = 0$  we determine the four roots

$$x_{1,2,3,4} = \frac{1 \pm \sqrt{5} \pm \sqrt{-10 \pm 2\sqrt{5}}}{4}.$$

Note that the roots of the characteristic equation could have been “guessed” right away since

$$x^5 + 1 = (x + 1)(x^4 - x^3 + x^2 - x + 1).$$

Thus the roots of the polynomial  $x^4 - x^3 + x^2 - x + 1$  are also the roots of the polynomial  $x^5 + 1$ , which are exactly the fifth roots of the  $-1$ . By this we obtain that the solutions of the characteristic polynomial are the numbers  $x_{1,2} = \cos(\frac{\pi}{5}) \pm i \sin(\frac{\pi}{5})$  and  $x_{3,4} = \cos(\frac{3\pi}{5}) \pm i \sin(\frac{3\pi}{5})$ . Thus the real basis of the space of the solution of the given difference equation is for instance the basis of the sequences  $\cos(\frac{n\pi}{5})$ ,  $\sin(\frac{n\pi}{5})$ ,  $\cos(\frac{3n\pi}{5})$  and  $\sin(\frac{3n\pi}{5})$ , which are sines and cosines of the arguments of the corresponding powers of the roots of the characteristic polynomial.

Note that we have incidentally derived the algebraic expressions for  $\cos(\frac{\pi}{5}) = \frac{1+\sqrt{5}}{4}$ ,  $\sin(\frac{\pi}{5}) = \frac{\sqrt{10-2\sqrt{5}}}{4}$ ,  $\cos(\frac{3\pi}{5}) = \frac{\sqrt{5}-1}{4}$  and  $\sin(\frac{3\pi}{5}) = \frac{\sqrt{10+2\sqrt{5}}}{4}$ . This is because all the roots of the equation have absolute value 1, they are the real and imaginary parts of the corresponding roots).  $\square$

A similar situation with  $c = 0$  and both other coefficients positive determines the famous Fibonacci sequence of numbers  $y_0, y_1, \dots$ , where  $y_{n+2} = y_{n+1} + y_n$ , see 3.B.1.

If we have no idea how to solve a mathematical problem, we can always blindly try some known solutions of similar problems. Thus, let us substitute into the equation (1) with coefficient  $c = 0$  a similar solution as with the linear equations from the first chapter (cf. 1.2.1), that is, we try  $f(n) = \lambda^n$  for some scalar  $\lambda$ . By substitution into the equation we obtain

$$\lambda^{n+2} - a\lambda^{n+1} - b\lambda^n = \lambda^n(\lambda^2 - a\lambda - b) = 0.$$

This relation will hold either for  $\lambda = 0$  or for the choice of the values

$$\lambda_1 = \frac{1}{2}(a + \sqrt{a^2 + 4b}), \quad \lambda_2 = \frac{1}{2}(a - \sqrt{a^2 + 4b}).$$

It is easy to see that such solutions work. We just had to choose the scalar  $\lambda$  suitably. But we are not finished, since we want to find a solution for any two initial values  $f(0)$  and  $f(1)$ . So far, we have only found two specific sequences satisfying the given equation (or possibly even only one sequence if  $\lambda_2 = \lambda_1$ ).

As we have already derived for linear recurrences, the sum of two solutions  $f_1(n)$  and  $f_2(n)$  of our equation  $f(n+2) - a f(n+1) - b f(n) = 0$  is again a solution of the same equation. The same holds for scalar multiples of the solution. Our two specific solutions thus generate the more general solutions

$$f(n) = C_1 \lambda_1^n + C_2 \lambda_2^n$$

for arbitrary scalars  $C_1$  and  $C_2$ . For a unique solution of the specific problem with given initial values  $f(0)$  and  $f(1)$ , it remains only to find the corresponding scalars  $C_1$  and  $C_2$ .

**3.2.3. The choice of scalars.** We show how this can work with an example. Consider the problem:

$$(1) \quad y_{n+2} = y_{n+1} + \frac{1}{2}y_n, \quad y_0 = 2, \quad y_1 = 0.$$

Here  $\lambda_{1,2} = \frac{1}{2}(1 \pm \sqrt{3})$  and clearly

$$\begin{aligned} y_0 &= C_1 + C_2 = 2 \\ y_1 &= \frac{1}{2}C_1(1 + \sqrt{3}) + \frac{1}{2}C_2(1 - \sqrt{3}) \end{aligned}$$

is satisfied for exactly one choice of these constants. Direct calculation yields  $C_1 = 1 - \frac{1}{3}\sqrt{3}$ ,  $C_2 = 1 + \frac{1}{3}\sqrt{3}$  and our problem has unique solution

$$f(n) = (1 - \frac{1}{3}\sqrt{3})\frac{1}{2^n}(1 + \sqrt{3})^n + (1 + \frac{1}{3}\sqrt{3})\frac{1}{2^n}(1 - \sqrt{3})^n.$$

Note that even if the found solution for our equation with rational coefficients and rational initial values looks complicated and is expressed with irrational numbers, we know a priori that the solution itself is again rational. But without this “step aside” into a larger field of scalars, we would not be able to describe the general solution.

**3.B.5.** Determine the explicit expression of the sequence satisfying the difference equation  $x_{n+2} = 2x_{n+1} - 2x_n$  with initial values  $x_1 = 2, x_2 = 2$ .

**Solution.** The roots of the characteristic polynomial  $x^2 - 2x + 2$  are  $1 + i$  and  $1 - i$ . The basis of the (complex) vector space of the solution is thus formed by the sequences  $y_n = (1 + i)^n$  and  $z_n = (1 - i)^n$ . The sequence in question can thus be expressed as a linear combination of these sequences (with complex coefficients). It is thus  $x_n = a \cdot y_n + b \cdot z_n$ , where  $a = a_1 + ia_2, b = b_1 + ib_2$ . From the recurrent relation we compute  $x_0 = \frac{1}{2}(2x_1 - x_2) = 0$  and by substitution  $n = 0$  and  $n = 1$  into the expression of  $x_n$  we obtain

$$\begin{aligned} 1 = x_0 &= a_1 + ia_2 + b_1 + ib_2 \\ 2 = x_1 &= (a_1 + ia_2)(1 + i) + (b_1 + ib_2)(1 - i). \end{aligned}$$

By comparing the real and the complex part of both equations, we obtain a linear system of four equations with four indeterminates

$$\begin{aligned} a_1 + b_1 &= 1 \\ a_2 + b_2 &= 0 \\ a_1 - a_2 + b_1 + b_2 &= 2 \\ a_1 + a_2 - b_1 + b_2 &= 0. \end{aligned}$$

These equations imply that  $a_1 = b_1 = b_2 = \frac{1}{2}$  and  $a_2 = -1/2$ . Thus we can express the sequence in question as

$$x_n = \left(\frac{1}{2} - \frac{1}{2}i\right)(1 + i)^n + \left(\frac{1}{2} + \frac{1}{2}i\right)(1 - i)^n.$$

The sequence can also be expressed using the real basis of the (complex) vector space of the space of solutions, that is, using the sequences  $u_n = \frac{1}{2}(y_n + z_n) = (\sqrt{2})^n \cos(\frac{n\pi}{4})$  and  $v_n = \frac{1}{2}i(z_n - y_n) = (\sqrt{2})^n \sin(\frac{n\pi}{4})$ . The transition matrix for the changing the basis from the complex one to the real one is

$$T := \begin{pmatrix} \frac{1}{2} & -\frac{1}{2}i \\ \frac{1}{2} & \frac{1}{2}i \end{pmatrix},$$

the inverse matrix is  $T^{-1} = \begin{pmatrix} 1 & 1 \\ i & -i \end{pmatrix}$ , for expressing the sequence  $x_n$  using the real basis, that is, for expressing the coordinates  $(c, d)$  of the sequence  $x_n$  under the basis  $\{u_n, v_n\}$ , we have

$$\begin{pmatrix} c \\ d \end{pmatrix} = T^{-1} \begin{pmatrix} a \\ b \end{pmatrix} = \begin{pmatrix} 1 \\ 1 \end{pmatrix},$$

We will often meet similar phenomena. Moreover, the general solution often allows us to discuss qualitative behaviour of the sequence of numbers  $f(n)$  without direct enumeration of the constants. For example, we may see whether the values approach some fixed value with increasing  $n$  or oscillate in some interval or whether they are unbounded.

**3.2.4. General homogeneous recurrences.** We substitute  $x_n = \lambda^n$  for some (yet unknown) scalar  $\lambda$  into the general homogeneous equation from the definition 3.2.1 (with constant coefficients). For every  $n$  we obtain the condition

$$\lambda^{n-k}(a_0\lambda^k + a_1\lambda^{k-1} \dots + a_k) = 0.$$

This means that either  $\lambda = 0$  or  $\lambda$  is the root of the so-called *characteristic polynomial* in the parentheses. The characteristic polynomial is independent of  $n$ .

Assume that the characteristic polynomial has  $k$  distinct roots  $\lambda_1, \dots, \lambda_k$ . For this purpose, we can extend the field of scalars we are working in, for instance  $\mathbb{Q}$  into  $\mathbb{R}$  or  $\mathbb{C}$ . Of course, if the initial conditions are in the original field then the solutions stay there since the recurrence equation itself does. Each of the roots gives us single possible solution

$$x_n = (\lambda_i)^n.$$

We need  $k$  linearly independent solutions.

Thus we should check the independence by substituting  $k$  values for  $n = 0, \dots, k - 1$  for  $k$  choices of  $\lambda_i$  into the Casoratian (see 3.2.1). Thus we obtain the Vandermonde matrix. It is a good but not entirely trivial exercise to show that for every  $k$  and any  $k$ -tuple of distinct  $\lambda_i$  the determinant of such a matrix non-zero, see 2.B.7 on the page 89. It follows that the chosen solutions are linearly independent.

Thus we have found the fundamental system of solutions of the homogeneous difference equation in the case that all the (possibly complex) roots of its characteristic polynomial are distinct.

Now we suppose  $\lambda$  is a multiple root. We ask whether  $x_n = n\lambda^n$  could be a solution. We arrive at the condition

$$a_0n\lambda^n + \dots + a_k(n - k)\lambda^{n-k} = 0.$$

This condition can be rewritten as

$$\lambda(a_0\lambda^n + \dots + a_k\lambda^{n-k})' = 0$$

where the dash denotes differentiation with respect to  $\lambda$  (cf. the infinitesimal definition in 5.1.6, and 12.2.7 for the purely algebraic treatment).

Moreover, a root  $c$  of a polynomial  $f$  has multiplicity greater than one if and only if it is a root of  $f'$ , see 12.2.7 for the proof. Our condition is thus satisfied.

With greater multiplicity  $\ell$  of the root of the characteristic polynomial we can proceed similarly and use the (now obvious) fact that a root with multiplicity  $\ell$  is a root of all derivatives of the polynomial up to order  $\ell - 1$  (inclusively).

thus we have again an alternative expression of the sequence  $x_n$  where there are no complex numbers (but there are square roots):

$$x_n = (\sqrt{2})^n \cos\left(\frac{n\pi}{4}\right) + (\sqrt{2})^n \sin\left(\frac{n\pi}{4}\right).$$

We could have obtained these by solving two linear equations in two variables  $c, d$ , that is,  $1 = x_0 = c \cdot u_0 + d \cdot v_0 = c$  and  $2 = x_1 = c \cdot u_1 + d \cdot v_1 = c + d$ .  $\square$

**3.B.6. A simplified model for the behaviour of gross domestic product.** Consider the difference equation

$$(1) \quad y_{k+2} - a(1+b)y_{k+1} + aby_k = 1,$$

where  $y_k$  is the gross domestic product at the year  $k$ . The

constant  $a$  is the *consumption tendency*, which is a macro economical factor that gives the fraction of money that the people spend (from what they have at their disposal). The constant  $b$  describes the dependence of the measure of investment of the private sector on the consumption tendency.

Further, we assume that the size of the domestic product is normalised such that the right-hand side of the equation is 1.

Compute the values  $y_n$  for  $a = \frac{3}{4}, b = \frac{1}{3}, y_0 = 1, y_1 = 1$ .

**Solution.** Look first for the solution of the homogeneous equation (the right side being zero) in the form of  $r^k$ . The number  $r$  must be a solution of the characteristic equation

$$x^2 - a(1+b)x + ab = 0, \quad \text{that is, } x^2 - x + \frac{1}{4} = 0,$$

which has a double root  $\frac{1}{2}$ . All the solutions of the homogeneous equation are then of the form  $a(\frac{1}{2})^n + b n(\frac{1}{2})^n$ .

Note also that if we find some solution of the non-homogeneous equation (the particular solution), then we can add to it any solution of the homogeneous solution, to obtain another solution of the non-homogeneous equation. It can be shown that all solutions of the non-homogeneous equation can be found in this way.

In this problem, it is easy to check that the constant function  $y_n = c$  is a solution provided  $c = 4$ . All solutions of the difference equation

$$y_{k+2} - y_{k+1} + \frac{1}{4} \cdot y_k = 1$$

are thus of the form  $4 + a(\frac{1}{2})^n + b n(\frac{1}{2})^n$ . We require that  $y_0 = y_1 = 1$  and these two equations give  $a = b = -3$ .

Derivatives look like this:

$$\begin{aligned} f(\lambda) &= a_0\lambda^n + \dots + a_k\lambda^{n-k} \\ f'(\lambda) &= a_0n\lambda^{n-1} + \dots + a_k(n-k)\lambda^{n-k-1} \\ f''(\lambda) &= a_0n(n-1)\lambda^{n-2} + \dots + a_k(n-k)(n-k-1)\lambda^{n-k-2} \\ &\vdots \\ f^{(\ell)} &= a_0n \dots (n-\ell+1)\lambda^{n-\ell} + \dots \\ &\quad + a_k(n-k) \dots (n-k-\ell+1)\lambda^{n-k-\ell}. \end{aligned}$$

We look at the case of a triple root  $\lambda$  and try to find a solution in the form  $n^2\lambda^n$ . By substitution into the definition, we obtain the equation

$$a_0n^2\lambda^n + \dots + a_k(n-k)^2\lambda^{n-k} = 0.$$

Clearly the left side equals the expression  $\lambda^2 f''(\lambda) + \lambda f'(\lambda)$  and because  $\lambda$  is a root of both derivatives, the condition is satisfied.

Using induction, we prove that even for the general condition of the solution in the form  $x_n = n^\ell \lambda^n$ ,

$$a_0n^\ell \lambda^n + \dots + a_k(n-k)^\ell \lambda^{n-k} = 0,$$

the solution can be obtained as a linear combination of the derivatives of the characteristic polynomial starting with the expression (check the combinatorics!)

$$\lambda^\ell f^{(\ell)} + \binom{\ell}{2} \lambda^{\ell-1} f^{(\ell-1)} + \dots$$

We have thus come close to the complete proof of the following result:

HOMOGENOUS EQUATIONS WITH CONSTANT COEFFICIENTS

**Theorem.** *The solution space of a homogeneous linear difference equation of order  $k$  with constant coefficients, over the field of scalars  $\mathbb{K} = \mathbb{C}$ , is the  $k$ -dimensional vector space generated by the sequences  $x_n = n^\ell \lambda^n$ , where  $\lambda$  are (complex) roots of the characteristic polynomial and the powers  $\ell$  run over all natural numbers  $0, \dots, r_\lambda - 1$ , where  $r_\lambda$  is the multiplicity of the root  $\lambda$ .*

**PROOF.** The relation between the multiplicity of roots and the derivatives of real polynomials will be proved later (cf. 5.3.7), while the fact that every complex polynomial has exactly as many roots (counting multiplicities) as its degree will appear in 10.2.11. It remains to prove that the  $k$ -tuple of solutions thus found is linearly independent. Even in this case we can prove inductively that the corresponding Casoratian is non-zero. We have done this already in the case of the Vandermonde determinant before.

This approach is well illustrated by the calculation in the case of a root  $\lambda_1$  with multiplicity one and a root  $\lambda_2$  with

Thus the solution of this non-homogeneous equation is

$$y_n = 4 - 3 \left(\frac{1}{2}\right)^n - 3n \left(\frac{1}{2}\right)^n.$$

Again, as we know that the sequence given by this formula satisfies the given difference equation and also the given initial conditions, it is indeed the only sequence characterized by these properties.  $\square$

**3.B.7.** Find a sequence which satisfies the given non-homogeneous difference equation with the initial conditions:

$$x_{n+2} = x_{n+1} + 2x_n + 1, \quad x_1 = 2, \quad x_2 = 2.$$

**Solution.** The general solution of the homogeneous equation is of the form  $a(-1)^n + b2^n$ . A particular solution is the constant  $-1/2$ . The general solution of the given non-homogeneous equation without initial conditions is thus

$$a(-1)^n + b2^n - \frac{1}{2}.$$

Substituting in the initial conditions, then gives the constants  $a = -5/6$ ,  $b = 5/6$ . The given difference equation with initial conditions is thus satisfied by the sequence

$$x_n = -\frac{5}{6}(-1)^n + \frac{5}{3}2^{n-1} - \frac{1}{2}.$$

$\square$

**3.B.8.** Determine the sequence of real numbers that satisfies the following non-homogeneous difference equation with initial conditions:

$$2x_{n+2} = -x_{n+1} + x_n + 2, \quad x_1 = 2, \quad x_2 = 3.$$

**Solution.** The general solution of the homogeneous equation is of the form  $a(-1)^n + b(1/2)^n$ . A particular solution is the constant 1. The general solution of the non-homogeneous equation without initial conditions is thus

$$a(-1)^n + b \left(\frac{1}{2}\right)^n + 1.$$

By substitution with the initial conditions, we obtain the constants  $a = 1$ ,  $b = 4$ . The given equation with initial conditions is thus satisfied by the sequence

$$x_n = (-1)^n + 4 \left(\frac{1}{2}\right)^n + 1.$$

$\square$

multiplicity two:

$$\begin{aligned} C(\lambda_1^n, \lambda_2^n, n\lambda_2^n) &= \begin{vmatrix} \lambda_1^n & \lambda_2^n & n\lambda_2^n \\ \lambda_1^{n+1} & \lambda_2^{n+1} & (n+1)\lambda_2^{n+1} \\ \lambda_1^{n+2} & \lambda_2^{n+2} & (n+2)\lambda_2^{n+2} \end{vmatrix} \\ &= \lambda_1^n \lambda_2^{2n} \begin{vmatrix} 1 & 1 & n \\ \lambda_1 & \lambda_2 & (n+1)\lambda_2 \\ \lambda_1^2 & \lambda_2^2 & (n+2)\lambda_2^2 \end{vmatrix} \\ &= \lambda_1^n \lambda_2^{2n} \begin{vmatrix} 1 & 1 & n \\ \lambda_1 - \lambda_2 & 0 & \lambda_2 \\ \lambda_1(\lambda_1 - \lambda_2) & 0 & \lambda_2^2 \end{vmatrix} \\ &= -\lambda_1^n \lambda_2^{2n} \begin{vmatrix} \lambda_1 - \lambda_2 & \lambda_2 \\ \lambda_1(\lambda_1 - \lambda_2) & \lambda_2^2 \end{vmatrix} \\ &= \lambda_1^n \lambda_2^{2n+1} (\lambda_1 - \lambda_2)^2 \neq 0. \end{aligned}$$

In the general case the proof can be carried on inductively in a similar way.  $\square$

**3.2.5. Real basis of the solutions.** For equations with real coefficients, initial real conditions always lead to real solutions (and similarly with scalars  $\mathbb{Z}$  or  $\mathbb{Q}$ ). However, the corresponding fundamental solutions derived using the above theorem might exist only in the complex domain.

We try therefore to find other generators, which will be more convenient. Because the coefficients of the characteristic polynomial are real, each of its roots is either real or the roots are paired as complex conjugates.

If we describe the solution in polar form as

$$\begin{aligned} \lambda^n &= |\lambda|^n (\cos n\varphi + i \sin n\varphi) \\ \bar{\lambda}^n &= |\lambda|^n (\cos n\varphi - i \sin n\varphi), \end{aligned}$$

we see immediately that their sum and difference leads to two linearly independent solutions

$$x_n = |\lambda|^n \cos n\varphi, \quad y_n = |\lambda|^n \sin n\varphi.$$

Difference equations very often appear as a model of dynamics of some system. A nice topic to think about is the connection between the absolute values of individual roots and the stability of the solution. We will not go into details here, because only in the fifth chapter we will speak of convergence of values to some limit value. There is space for some interesting numerical experiments: for instance with oscillations of suitable population or economical models.

**3.2.6. The non-homogeneous case.** As in the case of systems of linear equations we can obtain all solutions of *non-homogeneous linear difference equations*

$$a_0(n)x_n + a_1(n)x_{n-1} + \dots + a_k(n)x_{n-k} = b(n),$$

where the coefficients  $a_i$  and  $b$  are scalars which might depend on  $n$ , with  $a_0(n) \neq 0$ ,  $a_k(n) \neq 0$ . Again, we proceed by finding one solution and adding the complete vector space of dimension  $k$  of solutions to the corresponding homogeneous system. Indeed each such sum yields a solution. Since the difference of two solutions of a non-homogeneous system is

**3.B.9.** Determine sequences satisfying

$$x_{n+2} - 6x_{n+1} + 5x_n = ne^n.$$

**Solution.** Solve first the homogeneous part. We get:

$$x_n^{(h)} = c_1 \cdot (1)^n + c_2 \cdot 5^n.$$

To find the particular solution we can use the method of variation of the constant. The Wronski determinant is

$$W_{j+1} = \det \begin{pmatrix} 1^{j+1} & 5^{j+1} \\ 1^{j+2} & 5^{j+2} \end{pmatrix} = 4 \cdot 5^{j+1}.$$

Thus,

$$x_n = c_1 + c_2 \cdot 5^n - \frac{1}{4} \sum_{j=0}^{n-1} j e^j + \left( \sum_{j=0}^{n-1} \frac{j e^j}{4 \cdot 5^{j+1}} \right) 5^n,$$

$c_1, c_2 \in \mathbb{R}$ . □

**3.B.10.** Determine an explicit expression of the sequence satisfying the difference equation  $x_{n+2} = 3x_{n+1} + 3x_n$  with members  $x_1 = 1$  and  $x_2 = 3$ . ○

**3.B.11.** Determine an explicit formula for the  $n$ -th member of the unique solution  $\{x_n\}_{n=1}^{\infty}$  that satisfies the following conditions:

$$x_{n+2} = x_{n+1} - x_n, x_1 = 1, x_2 = 5.$$

○

**3.B.12.** Determine an explicit formula for the  $n$ -th member of the unique solution  $\{x_n\}_{n=1}^{\infty}$  that satisfies the following conditions:

$$-x_{n+3} = 2x_{n+2} + 2x_{n+1} + x_n, x_1 = 1, x_2 = 1, x_3 = 1.$$

○

**3.B.13.** Determine an explicit formula for the  $n$ -th member of the unique solution  $\{x_n\}_{n=1}^{\infty}$  that satisfies the following conditions:

$$-x_{n+3} = 3x_{n+2} + 3x_{n+1} + x_n, x_1 = 1, x_2 = 1, x_3 = 1.$$

○

### C. Population models

Population models, which we consider now, have recurrence relations in vector spaces. The unknown in this case is not a sequence of numbers but a sequence of vectors. The role of coefficients is played by matrices. We begin with a simple (two-dimensional) case.

a solution of the homogeneous system, we obtain all solutions in this way.

When we were working with systems of linear equations, it was possible that there was no solution. This is not possible with difference equations. But it is not always easy to find that one particular solution of a non-homogeneous system, particularly if the behaviour of the scalar coefficients in the equation is complicated. Even for linear recurrences with constant coefficients it may not be easy to find a solution if the right-hand side is complicated.

But we can always try to find a solution in a form similar to the right hand side. Consider the case when the corresponding homogeneous system has constant coefficients and  $b(n)$  is a polynomial of degree  $s$ . The solution can then be found in the form of the polynomial

$$x_n = \alpha_0 + \alpha_1 n + \dots + \alpha_s n^s$$

with unknown coefficients  $\alpha_i, i = 1, \dots, s$ . By substitution into the difference equation and comparing the coefficients of the individual powers of  $n$  we obtain a system of  $s + 1$  equations for  $s + 1$  variables  $\alpha_i$ . If this system has a solution, then we have found a solution of our original problem. If it has no solution, we can try again with an increase in the degree  $s$  of the polynomial in question.

For instance, the equation  $x_n - x_{n-2} = 2$  cannot have a constant solution, because substitution of the potential solution  $x_n = \alpha_0$  yields the requirement  $\alpha_0 - \alpha_0 = 0 = 2$ . But by setting  $x_n = \alpha_0 + \alpha_1 n$  we obtain a solution  $x_n = \alpha_0 + n$ , with  $\alpha_0$  arbitrary. Thus the general solution of our equation is

$$x_n = C_1 + C_2(-1)^n + n.$$

We use this method, the *method of indeterminate coefficients* for example in 3.B.6.

**3.2.7. Variation of constants.** Another possible way to solve such an equation is the *variation of constants* method. Here we find first a solution

$$y(n) = \sum_{i=1}^k c_i f_i(n)$$

of the homogeneous equation, where we consider the constants  $c_i$  as functions  $c_i(n)$  of the variable  $n$ . Then we look for a particular solution of the given equation in the form

$$y(n) = \sum_{i=1}^k c_i(n) f_i(n).$$

We illustrate the method on second order equations. Suppose that the homogeneous part of the second order non-homogeneous equation

$$x_{n+2} + a_n x_{n+1} + b_n x_n = f_n$$

has  $x_n^{(1)}$  and  $x_n^{(2)}$  as a basis of solutions. We will be looking for a particular solution of the non-homogeneous equation in the form

$$x_n = A_n x_n^{(1)} + B_n x_n^{(2)}$$

**3.C.1. Savings.** A friend and I save for a holiday together by monthly payments in the following way. At the beginning I give 10 € and he gives 20 €. Every consecutive month each of us gives as many as last month plus one half of what the other has given the month before. How much will we have after one year? How much money will I pay in the twelfth month?

**Solution.** Let the amount of money I pay in the  $n$ -th month be denoted by  $x_n$ , and the amount my friend pays is  $y_n$ . Thus in the first month we deposit  $x_1 = 10, y_1 = 20$ . For the following payments we can write down a recurrent relation:

$$\begin{aligned} x_{n+1} &= x_n + \frac{1}{2}y_n \\ y_{n+1} &= y_n + \frac{1}{2}x_n \end{aligned}$$

If we denote the common savings by  $z_n = x_n + y_n$ , then by summing the equations we obtain  $z_{n+1} = z_n + \frac{1}{2}z_n = \frac{3}{2}z_n$ . This is a geometric sequence and we obtain  $z_n = 3 \cdot (\frac{3}{2})^{n-1}$ . In a year we will have  $z_1 + z_2 + \dots + z_{12}$ . This partial sum is easy to compute

$$3 \left( 1 + \frac{3}{2} + \dots + \left( \frac{3}{2} \right)^{11} \right) = 3 \frac{\left( \frac{3}{2} \right)^{12} - 1}{\frac{3}{2} - 1} \doteq 772, 5.$$

In a year we will have saved over 772 €.

The recurrent system of equation describing the savings system can be written by matrices as follows:

$$\begin{pmatrix} x_{n+1} \\ y_{n+1} \end{pmatrix} = \begin{pmatrix} 1 & \frac{1}{2} \\ \frac{1}{2} & 1 \end{pmatrix} \begin{pmatrix} x_n \\ y_n \end{pmatrix}$$

It is thus again a geometric sequence. Its elements are now vectors and the quotient is not a scalar, but a matrix. The solution can be found analogously:

$$\begin{pmatrix} x_n \\ y_n \end{pmatrix} = \begin{pmatrix} 1 & \frac{1}{2} \\ \frac{1}{2} & 1 \end{pmatrix}^{n-1} \begin{pmatrix} x_1 \\ y_1 \end{pmatrix}$$

The power of the matrix acting on the vector  $(x_1, y_1)$  can be found by expressing this vector in the basis of eigenvectors. The characteristic polynomial of the matrix is  $(1-\lambda)^2 - \frac{1}{4} = 0$  and the eigenvalues are thus  $\lambda_{1,2} = \frac{3}{2}, \frac{1}{2}$ . The corresponding eigenvectors are thus  $(1, 1)$  and  $(1, -1)$ . For the initial vector  $(x_1, y_1) = (1, 2)$  we compute

$$\begin{pmatrix} 1 \\ 2 \end{pmatrix} = \frac{3}{2} \begin{pmatrix} 1 \\ 1 \end{pmatrix} - \frac{1}{2} \begin{pmatrix} 1 \\ -1 \end{pmatrix}$$

and thus

$$\begin{pmatrix} x_n \\ y_n \end{pmatrix} = \frac{3}{2} \left( \frac{3}{2} \right)^{n-1} \begin{pmatrix} 1 \\ 1 \end{pmatrix} - \frac{1}{2} \left( \frac{1}{2} \right)^{n-1} \begin{pmatrix} 1 \\ -1 \end{pmatrix}$$

That means that in the 12th month I pay

$$x_{12} = \left( \frac{3}{2} \right)^{12} - \left( \frac{1}{2} \right)^{12} \doteq 130$$

with some conditions on  $A_n$  and  $B_n$  to be imposed. We have

$$\begin{aligned} x_{n+1} &= A_{n+1}x_{n+1}^{(1)} + B_{n+1}x_{n+1}^{(2)} = A_nx_{n+1}^{(1)} + B_nx_{n+1}^{(2)} + \\ &\quad (A_{n+1} - A_n)x_{n+1}^{(1)} + (B_{n+1} - B_n)x_{n+1}^{(2)} \\ &= A_nx_{n+1}^{(1)} + B_nx_{n+1}^{(2)} + \delta A_nx_{n+1}^{(1)} + \delta B_nx_{n+1}^{(2)}, \end{aligned}$$

where  $\delta A_n = A_{n+1} - A_n$  and  $\delta B_n = B_{n+1} - B_n$ .

In order to be able to use the same  $A_n, B_n$  in the expression for  $x_{n+1}$ , we impose for all  $n$  the condition

$$\delta A_nx_{n+1}^{(1)} + \delta B_nx_{n+1}^{(2)} = 0.$$

Thus, for all  $n$

$$x_{n+1} = A_nx_{n+1}^{(1)} + B_nx_{n+1}^{(2)},$$

and in particular

$$\begin{aligned} x_{n+2} &= A_{n+1}x_{n+2}^{(1)} + B_{n+1}x_{n+2}^{(2)} \\ &= A_nx_{n+2}^{(1)} + B_nx_{n+2}^{(2)} + \delta A_nx_{n+2}^{(1)} + \delta B_nx_{n+2}^{(2)}. \end{aligned}$$

Now,

$$\begin{aligned} f_n &= x_{n+2} + a_nx_{n+1} + b_nx_n \\ &= A_n(x_{n+2}^{(1)} + a_nx_{n+1}^{(1)} + b_nx_n^{(1)}) + B_n(x_{n+2}^{(2)} + \\ &\quad a_nx_{n+1}^{(2)} + b_nx_n^{(2)}) + \delta A_nx_{n+2}^{(1)} + \delta B_nx_{n+2}^{(2)} \\ &= \delta A_nx_{n+2}^{(1)} + \delta B_nx_{n+2}^{(2)} \end{aligned}$$

Hence the variations  $\delta A_n$  and  $\delta B_n$  are subject to the systems

$$\begin{aligned} \delta A_nx_{n+1}^{(1)} + \delta B_nx_{n+1}^{(2)} &= 0 \\ \delta A_nx_{n+2}^{(1)} + \delta B_nx_{n+2}^{(2)} &= f_n \end{aligned}$$

with solutions (compute the inverse matrix e.g. by means of the algebraic adjoint and the determinant)

$$\begin{aligned} \delta A_n &= A_{n+1} - A_n = -\frac{f_nx_{n+1}^{(2)}}{W_{n+1}} \\ \delta B_n &= B_{n+1} - B_n = \frac{f_nx_{n+1}^{(1)}}{W_{n+1}} \end{aligned}$$

where  $W_{n+1}$  is the *Wronski determinant*

$$W_{n+1} = \det \begin{pmatrix} x_{n+1}^{(1)} & x_{n+1}^{(2)} \\ x_{n+2}^{(1)} & x_{n+2}^{(2)} \end{pmatrix}.$$

It follows that

$$\begin{aligned} A_n - A_0 &= \sum_{j=0}^{n-1} -\frac{f_jx_{j+1}^{(2)}}{W_{j+1}} \\ B_n - B_0 &= \sum_{j=0}^{n-1} \frac{f_jx_{j+1}^{(1)}}{W_{j+1}}. \end{aligned}$$

€ and my friend pays basically the same amount. □

**Remark.** The previous example can be solved also without matrices by rewriting the recurrent equation:  $x_{n+1} = x_n + \frac{1}{2}y_n = \frac{1}{2}x_n + \frac{1}{2}z_n$ .

The previous example was actually a model of growth (in this case, growth of saved money). We go now to the models of growth describing primarily the growth of a population. The Leslie model of population growth with which we have dealt with in great detail in the theoretical part describes very well not only populations of sheep (according to which it was developed), but can be also applied in modelling of the following populations:

**3.C.2. Rabbits for the second time.** We show how the Leslie model can describe the population of the rabbits on a meadow with which we have worked in exercise (3.B.1). Suppose that the rabbits are dying after reaching the ninth year of age (in the original model the rabbits were immortal). Denote the number of rabbits according to their age in months at time  $t$  (in months) as  $x_1(t), x_2(t), \dots, x_9(t)$ . Then the number of rabbits in individual categories are described after one month by the formula  $x_1(t+1) = x_2(t) + x_3(t) + \dots + x_9(t)$ ,  $x_i(t+1) = x_{i-1}(t)$ , for  $i = 2, 3, \dots, 10$ , or

$$\begin{pmatrix} x_1(t+1) \\ x_2(t+1) \\ x_3(t+1) \\ x_4(t+1) \\ x_5(t+1) \\ x_6(t+1) \\ x_7(t+1) \\ x_8(t+1) \\ x_9(t+1) \end{pmatrix} = \begin{pmatrix} 0 & 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 \\ 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 & 0 \end{pmatrix} \begin{pmatrix} x_1(t) \\ x_2(t) \\ x_3(t) \\ x_4(t) \\ x_5(t) \\ x_6(t) \\ x_7(t) \\ x_8(t) \\ x_9(t) \end{pmatrix}.$$

The characteristic polynomial of the given matrix is  $\lambda^9 - \lambda^7 - \lambda^6 - \lambda^5 - \lambda^4 - \lambda^3 - \lambda^2 - \lambda - 1$ . The roots of this polynomial are hard to explicitly express, but we can estimate one of them very well –  $\lambda_1 \doteq 1.608$  (why must it be smaller than  $(\sqrt{5} + 1)/2$ ?). Thus the population grows according to this model approximately with the geometric sequence  $1.608^t$ .

**3.C.3. Pond.** Suppose we have a simple model of a pond where there lives a population of white fish (roach, bleak, vimba, nase, etc.). Assume that 20 % of babies survive their second year and from that age on they are able to reproduce. For these young fish, approximately 60 % of them survive their third year and in the following years the mortality can be ignored. Furthermore we assume that the birth rate is three times the number of fish that can reproduce.

Such a population would clearly fill the pond very quickly. Thus we want to maintain a balance by using a

Setting  $A_0 = B_0 = 0$  we obtain

$$A_n = \sum_{j=0}^{n-1} -\frac{f_j x_{j+1}^{(2)}}{W_{j+1}}$$

$$B_n = \sum_{j=0}^{n-1} \frac{f_j x_{j+1}^{(1)}}{W_{j+1}}.$$

and the acquired general solution of our recurrence equation is

$$x_n = C_1 x_n^{(1)} + C_2 x_n^{(2)} + \left( \sum_{j=0}^{n-1} -\frac{f_j x_{j+1}^{(2)}}{W_{j+1}} \right) x_n^{(1)} + \left( \sum_{j=0}^{n-1} \frac{f_j x_{j+1}^{(1)}}{W_{j+1}} \right) x_n^{(2)}.$$

This method is used to solve the example 3.B.9.

**3.2.8. Linear filters.** Now we consider infinite sequences

$$x = (\dots, x_{-n}, x_{-n+1}, \dots, x_{-1}, x_0, x_1, \dots, x_n, \dots).$$

As in the case of systems of linear equations, we work with an operation  $T$  that maps the sequence  $x$  to the sequence  $z = Tx$  with elements

$$z_n = a_0 x_n + a_1 x_{n-1} + \dots + a_k x_{n-k}.$$

As already noticed, the sequences  $x = (x_n)$  are vectors with respect to coordinate-wise operations, and the vector space of all such sequences is infinitely-dimensional. The operation  $T$  is clearly a linear mapping on this space.

The sequences can be imagined as discrete values of a signal, often captured in very short time units.  $T$  plays the role of a filter that works with the signal. For example, this is how the sampling of an audio signal looks like. We are interested in estimating the properties such a *linear filter* can have.

Signals are often a linear combination of superimposed parts, which are themselves periodical. From our definition it is clear that *periodic sequences*  $x_n$ , that is, sequences satisfying for some fixed natural number  $p$  and all  $n$

$$x_{n+p} = x_n$$

will also have periodic images  $z = Tx$

$$z_{n+p} = a_0 x_{n+p} + a_1 x_{n-1+p} + \dots + a_k x_{n-k+p}$$

$$= a_0 x_n + a_1 x_{n-1} + \dots + a_k x_{n-k} = z_n$$

with the same period  $p$ .

We are interested in which input periodic sequences  $Tx$  remain roughly the same (up to a scalar multiple), and in which  $Tx$  will be suppressed close to zero values. This means, we are looking for the kernel of our linear mapping  $T$  and other eigen vectors. The kernel is the subspace of sequences given by the homogeneous difference equation

$$a_0 x_n + a_1 x_{n-1} + \dots + a_k x_{n-k} = 0, \quad a_0 \neq 0 \quad a_k \neq 0,$$

which we are able to solve.

predator, for instance esox. Assume that one esox eats per year approximately 500 mature white fish. How many esox should be put into the pond in order for the population to remain constant?

**Solution.** If we denote by  $p$  the number of babies, by  $m$  the number of young fish and by  $r$  the number of adult fish, then the state of the population in the next year is given by:

$$\begin{pmatrix} p \\ m \\ r \end{pmatrix} \mapsto \begin{pmatrix} 3m + 3r \\ 0.2p \\ 0.6m + \tau r \end{pmatrix},$$

where  $1 - \tau$  is the relative mortality of the adult fish caused by the esox. The corresponding matrix describing this model is then

$$\begin{pmatrix} 0 & 3 & 3 \\ 0.2 & 0 & 0 \\ 0 & 0.6 & \tau \end{pmatrix}$$

If the population is to stagnate, (ie. remain constant), then this matrix must have eigenvalue 1. In other words, one must be the root of the characteristic polynomial of this matrix. That is of the form  $\lambda^2(\tau - \lambda) + 0.36 - 0.6(\tau - \lambda) = 0$ . That means that  $\tau$  must satisfy

$$\begin{aligned} \tau - 1 + 0.36 - 0.6(\tau - 1) &= 0 \\ 0.4\tau - 0.04 &= 0 \end{aligned}$$

In the next year only 10 % is allowed to survive and the rest should be eaten by the esox. If we denote the desired number of esox by  $x$ , then together they eat  $500x$  fish, which, according to the previous computation, should be  $0.9r$ . The ratio of the number of white fish to the number of esox should thus be  $\frac{r}{x} = \frac{500}{0.9}$ . That is, one esox for (approximately) 556 white fish.  $\square$

**3.C.4.** In the population model, let the number of predators be  $D_k$  and the number of preys be  $K_k$  in month  $k$ . The relation of these between month  $k$  and month  $k + 1$  is given by one of the three linear systems

(a)

$$\begin{aligned} D_{k+1} &= 0.6 D_k + 0.5 K_k, \\ K_{k+1} &= -0.16 D_k + 1.2 K_k; \end{aligned}$$

(b)

$$\begin{aligned} D_{k+1} &= 0.6 D_k + 0.5 K_k, \\ K_{k+1} &= -0.175 D_k + 1.2 K_k; \end{aligned}$$

(c)

$$\begin{aligned} D_{k+1} &= 0.6 D_k + 0.5 K_k, \\ K_{k+1} &= -0.135 D_k + 1.2 K_k. \end{aligned}$$

Analyse the behaviour of this model for large time values.

**3.2.9. Bad equalizer.** As an example, consider a very simple linear filter given by the equation

$$z_n = (Tx)_n = x_n + x_{n-2}.$$

Clearly, the kernel of  $T$  is generated by  $x_n = \cos(\frac{\pi}{2}n)$  and  $x_n = \sin(\frac{\pi}{2}n)$ , while the solutions to  $x_{n+2} = x_n$  correspond to the requirement  $(Tx)_n = 2x_n$ . The results of such an operation on a signal are illustrated by the two diagrams below. There we use two different frequencies of signals and display their discrete sampling (the solid lines and the points  $x_n$  on them). The dashed line represents the sampling  $z_n$  of the filtered signal.

The first case shows an amplifying of the signal, while the second frequency is close to the kernel which is killed by the filter. Notice that the filtered signal suffers serious shifts in phase, which varies with the frequencies. Cheap equalisers work in such a bad way.

Notice also how badly the original signal is sampled on the second picture. This is due to the fact that the sampling frequency is not much higher than the frequency of the signal.

### 3. Iterated linear processes

**3.3.1. Iterated processes.** In practical models we often encounter the situation where the evolution of a system in a given time interval is given by a linear process, and we are interested in the behaviour of the system after many iterations. The linear process often remains the same, thus from the mathematical point of view we are dealing with an iterated multiplication of the state vector by the same matrix.

While solving the systems of linear equations requires only minimal knowledge of properties of linear mappings, in order to understand the behaviour of an iterated system, we shall exploit the features of eigenvalues, eigenvectors and other structural features.

In fact, the determination of the solution of a linear recurrence equation by a set of initial conditions can be described as an iterated process. Imagine we keep the state vector of the

**Solution.** Note that the individual variants differ from each other only in the value of the coefficients at  $D_k$  in the second equation. Thus we can express all three cases as

$$\begin{pmatrix} D_k \\ K_k \end{pmatrix} = \begin{pmatrix} 0.6 & 0.5 \\ -a & 1.2 \end{pmatrix} \cdot \begin{pmatrix} D_{k-1} \\ K_{k-1} \end{pmatrix}, \quad k \in \mathbb{N},$$

where we set  $a = 0.16$ ,  $a = 0.175$ ,  $a = 0.135$ . The value of the coefficient  $a$  represents here the average number of preys killed by one predator per month. When denoting

$$T = \begin{pmatrix} 0.6 & 0.5 \\ -a & 1.2 \end{pmatrix}$$

we obtain

$$\begin{pmatrix} D_k \\ K_k \end{pmatrix} = T^k \cdot \begin{pmatrix} D_0 \\ K_0 \end{pmatrix}, \quad k \in \mathbb{N}.$$

Using the powers of the matrix  $T$  we can determine the evolution of the populations of predators and prey after a very long time.

We compute the eigenvalues for the matrix  $T$

- (a)  $\lambda_1 = 1, \quad \lambda_2 = 0.8;$
- (b)  $\lambda_1 = 0.95, \quad \lambda_2 = 0.85;$
- (c)  $\lambda_1 = 1.05, \quad \lambda_2 = 0.75.$

The respective eigenvectors are

- (a)  $(5, 4)^T, \quad (5, 2)^T;$
- (b)  $(10, 7)^T, \quad (2, 1)^T;$
- (c)  $(10, 9)^T, \quad (10, 3)^T.$

For  $k \in \mathbb{N}$  we obtain

(a)

$$T^k = \begin{pmatrix} 5 & 5 \\ 4 & 2 \end{pmatrix} \cdot \begin{pmatrix} 1 & 0 \\ 0 & 0.8 \end{pmatrix}^k \cdot \begin{pmatrix} 5 & 5 \\ 4 & 2 \end{pmatrix}^{-1};$$

(b)

$$T^k = \begin{pmatrix} 10 & 2 \\ 7 & 1 \end{pmatrix} \cdot \begin{pmatrix} 0.95 & 0 \\ 0 & 0.85 \end{pmatrix}^k \cdot \begin{pmatrix} 10 & 2 \\ 7 & 1 \end{pmatrix}^{-1};$$

(c)

$$T^k = \begin{pmatrix} 10 & 10 \\ 9 & 3 \end{pmatrix} \cdot \begin{pmatrix} 1.05 & 0 \\ 0 & 0.75 \end{pmatrix}^k \cdot \begin{pmatrix} 10 & 10 \\ 9 & 3 \end{pmatrix}^{-1}.$$

From there we have for large  $k \in \mathbb{N}$  that

(a)

$$\begin{aligned} T^k &\approx \begin{pmatrix} 5 & 5 \\ 4 & 2 \end{pmatrix} \cdot \begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix} \cdot \begin{pmatrix} 5 & 5 \\ 4 & 2 \end{pmatrix}^{-1} \\ &= \frac{1}{10} \begin{pmatrix} -10 & 25 \\ -8 & 20 \end{pmatrix}; \end{aligned}$$

last  $k$  values

$$Y_n = (x_n, \dots, x_{n-k+1})$$

(filled by the initial condition in the beginning of the process). In the next step we update the state vector

$$Y_{n+1} = (x_{n+1}, x_n, \dots, x_{n-k+2}),$$

where the first entry  $x_{n+1} = a_1 x_n + \dots + a_k x_{n-k+1}$  is computed by means of a homogeneous difference equation, while the other entries are just a shift by one position with the last one forgotten. The corresponding square matrix of order  $k$  that satisfies  $Y_{n+1} = A \cdot Y_n$  is as follows:

$$A = \begin{pmatrix} a_1 & a_2 & \dots & a_{k-1} & a_k \\ 1 & 0 & \dots & 0 & 0 \\ 0 & 1 & \dots & 0 & 0 \\ \vdots & \vdots & \dots & \ddots & \vdots \\ 0 & 0 & \dots & 1 & 0 \end{pmatrix}$$

A while ago, we derived an explicit procedure for the complete formula for the solution of such an iterated process with a special type of matrix. In general, it will not be easy even for very similar systems. A typical case is the study of the dynamics of populations in some biological systems which we discuss below.

The characteristic polynomial  $|A - \lambda E|$  of our matrix is

$$p(\lambda) = (-1)^k (\lambda^k - a_1 \lambda^{k-1} - \dots - a_k),$$

as we can check directly or by expanding the last column and employing induction on  $k$ .

Thus, the eigenvalues are exactly the roots  $\lambda$  of the characteristic polynomial of the linear recurrence. We should have expected this, because having a nonzero solution  $x_n = \lambda^n$  to the linear recurrence means that the matrix  $A$  must bring  $(\lambda^k, \dots, \lambda)^T$  to its  $\lambda$ -multiple. Thus every such  $\lambda$  must be eigenvalue of the matrix  $A$ .

### 3.3.2. Leslie model for population growth.

Imagine that we are dealing with some system of individuals (cattle, insects, cell cultures, etc.) divided into  $m$  groups (according to their age, evolution stage, etc.). The state  $X_n$  is thus given by the vector

$$X_n = (u_1, \dots, u_m)^T$$

depending on the time  $t_n$  in which we are observing the system. A linear model of evolution of such system is then given by the matrix  $A$  of dimension  $m$ , which gives the change of the vector  $X_n$  to

$$X_{n+1} = A \cdot X_n$$

when time changes from  $t_n$  to  $t_{n+1}$ .

(b)

$$T^k \approx \begin{pmatrix} 10 & 2 \\ 7 & 1 \end{pmatrix} \cdot \begin{pmatrix} 0 & 0 \\ 0 & 0 \end{pmatrix} \cdot \begin{pmatrix} 10 & 2 \\ 7 & 1 \end{pmatrix}^{-1} = \begin{pmatrix} 0 & 0 \\ 0 & 0 \end{pmatrix};$$

(c)

$$T^k \approx \begin{pmatrix} 10 & 10 \\ 9 & 3 \end{pmatrix} \cdot \begin{pmatrix} 1.05^k & 0 \\ 0 & 0 \end{pmatrix} \cdot \begin{pmatrix} 10 & 10 \\ 9 & 3 \end{pmatrix}^{-1} = \frac{1.05^k}{60} \begin{pmatrix} -30 & 100 \\ -27 & 90 \end{pmatrix},$$

because for large  $k \in \mathbb{N}$  we can set

(a)

$$\begin{pmatrix} 1 & 0 \\ 0 & 0.8 \end{pmatrix}^k \approx \begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix};$$

(b)

$$\begin{pmatrix} 0.95 & 0 \\ 0 & 0.85 \end{pmatrix}^k \approx \begin{pmatrix} 0 & 0 \\ 0 & 0 \end{pmatrix};$$

(c)

$$\begin{pmatrix} 1.05 & 0 \\ 0 & 0.75 \end{pmatrix}^k \approx \begin{pmatrix} 1.05^k & 0 \\ 0 & 0 \end{pmatrix}.$$

Note that in variant (b), that is for  $a = 0.175$ , it is not necessary to compute the eigenvectors.

Thus we have

(a)

$$\begin{pmatrix} D_k \\ K_k \end{pmatrix} \approx \frac{1}{10} \begin{pmatrix} -10 & 25 \\ -8 & 20 \end{pmatrix} \cdot \begin{pmatrix} D_0 \\ K_0 \end{pmatrix} = \frac{1}{10} \begin{pmatrix} 5(-2D_0 + 5K_0) \\ 4(-2D_0 + 5K_0) \end{pmatrix};$$

(b)

$$\begin{pmatrix} D_k \\ K_k \end{pmatrix} \approx \begin{pmatrix} 0 & 0 \\ 0 & 0 \end{pmatrix} \cdot \begin{pmatrix} D_0 \\ K_0 \end{pmatrix} = \begin{pmatrix} 0 \\ 0 \end{pmatrix};$$

(c)

$$\begin{pmatrix} D_k \\ K_k \end{pmatrix} \approx \frac{1.05^k}{60} \begin{pmatrix} -30 & 100 \\ -27 & 90 \end{pmatrix} \cdot \begin{pmatrix} D_0 \\ K_0 \end{pmatrix} = \frac{1.05^k}{60} \begin{pmatrix} 10(-3D_0 + 10K_0) \\ 9(-3D_0 + 10K_0) \end{pmatrix}.$$

These results can be interpreted as follows:

- (a) If  $2D_0 < 5K_0$ , the sizes of both populations stabilise on non-zero sizes (we say that they are stable); if  $2D_0 \geq 5K_0$ , both populations die out.
- (b) Both populations die out.
- (c) For  $3D_0 < 10K_0$  begins a population boom of both kinds; for  $3D_0 \geq 10K_0$  both populations die out.

As an example, we consider the *Leslie model for population growth*. Here there is the matrix

$$A = \begin{pmatrix} f_1 & f_2 & f_3 & \dots & f_{m-1} & f_m \\ \tau_1 & 0 & 0 & \dots & 0 & 0 \\ 0 & \tau_2 & 0 & \dots & 0 & 0 \\ 0 & 0 & \tau_3 & \ddots & 0 & 0 \\ \vdots & & & \ddots & \ddots & \vdots \\ 0 & 0 & 0 & \dots & \tau_{m-1} & 0 \end{pmatrix},$$

whose parameters are tied with the evolution of a population divided into  $m$  age groups such that  $f_i$  denotes the relative fertility of the corresponding age group (in the observed time shift from  $N$  individuals in the  $i$ -th group arise new  $f_i N$  ones – that is, they are in the first group), while  $\tau_i$  is the relative mortality in the  $i$ -th group in one time interval. Clearly such a model can be used with any number of age groups.

All coefficients are thus non-negative real numbers and the numbers  $\tau_i$  are between zero and one. Note that when all  $\tau$  are equal one, it is actually a linear recurrence with constant coefficients and thus has either exponential growth/decay (for real roots  $\lambda$  of the characteristic polynomial) or oscillation connected with potential growth/decay (for complex roots).

Before we introduce a more general theory, we consider in more detail this specific model.

Direct computation with the Laplace expansion of the last column yields the characteristic polynomial  $p_m(\lambda)$  of the matrix  $A$  for the model with  $m$  groups:

$$p_m(\lambda) = -\lambda p_{m-1}(\lambda) + (-1)^{m-1} f_m \tau_1 \dots \tau_{m-1}.$$

By induction we derive that this characteristic polynomial is of the form

$$p_m(\lambda) = (-1)^m (\lambda^m - a_1 \lambda^{m-1} - \dots - a_{m-1} \lambda - a_m).$$

The coefficients  $a_1, \dots, a_m$ , are all positive if all parameters  $\tau_i$  and  $f_i$  are positive. In particular,

$$a_m = f_m \tau_1 \dots \tau_{m-1}.$$

Consider the distribution of the roots of the polynomial  $p_m(\lambda)$ . We write the characteristic polynomial in the form

$$p_m(\lambda) = \pm \lambda^m (1 - q(\lambda))$$

where  $q(\lambda) = a_1 \lambda^{-1} + \dots + a_m \lambda^{-m}$  is a strictly decreasing non-negative function for  $\lambda > 0$ . For  $\lambda$  positive but very small the value of  $q$  will be arbitrarily large, while for large  $\lambda$ , it will be arbitrarily close to zero. Thus, it seems there exists exactly one positive  $\lambda$  for which  $q(\lambda) = 1$  and thus also  $p_m(\lambda) = 0$ .<sup>2</sup> In other words, for every Leslie matrix (with all the parameters  $f_i$  and  $\tau_i$  positive), there exists exactly one positive real eigenvalue. For actual Leslie models of populations a typical situation is when the only real eigenvalue  $\lambda_1$  is greater or equal to one, while the absolute values of the other eigenvalues are strictly less than one.

<sup>2</sup>Actually, we shall spend a lot of time in chapter 5 to make such considerations precise, involving the convergence and continuity issues.

Even a small change in the size of  $a$  can lead to a completely different result. This is caused by the constancy of the value of  $a$ : it does not depend on the size of the populations. Note that this restriction (that is, assuming  $a$  to be constant) has no interpretation in reality. But still we obtain an estimate on the sizes of  $a$  for stable populations.  $\square$

**3.C.5. Remark.** Another model for the populations of predators and preys is the model by Lotka and Volterra, which describes a relation between the populations by a system of two ordinary differential equations. Using this model both populations oscillate, which is in accord with observations.

Other interesting and well-described models of growth can be found in the collection of exercises after this chapter. (see 3.G.2

In linear models an important role is played by primitive matrices (3.3.3).

**3.C.6.** Which of the matrices

$$A = \begin{pmatrix} 0 & 1/7 \\ 1 & 6/7 \end{pmatrix}, \quad B = \begin{pmatrix} 1/2 & 0 & 1/3 \\ 0 & 1 & 1/2 \\ 1/2 & 0 & 1/6 \end{pmatrix},$$

$$C = \begin{pmatrix} 0 & 1 & 0 \\ 1/4 & 0 & 1/2 \\ 3/4 & 0 & 1/2 \end{pmatrix}, \quad D = \begin{pmatrix} 1/3 & 1/2 & 0 & 0 \\ 1/2 & 1/3 & 0 & 0 \\ 0 & 1/6 & 1/6 & 1/3 \\ 1/6 & 0 & 5/6 & 2/3 \end{pmatrix}$$

$$E = \begin{pmatrix} 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 1 \\ 1 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 \end{pmatrix}$$

are primitive?

**Solution.**

$$A^2 = \begin{pmatrix} 1/7 & 6/49 \\ 6/7 & 43/49 \end{pmatrix}, \quad C^3 = \begin{pmatrix} 3/8 & 1/4 & 1/4 \\ 1/4 & 3/8 & 1/4 \\ 3/8 & 3/8 & 1/2 \end{pmatrix}.$$

So the matrices  $A$  and  $C$  are primitive, since (respectively)  $A^2$  and  $C^3$  are positive matrices. The middle column of the matrix  $B^n$  is always (for  $n \in \mathbb{N}$ ) the vector  $(0, 1, 0)^T$  which contains the entry 0. Hence the matrix  $B$  cannot be primitive. The product

$$\begin{pmatrix} 1/3 & 1/2 & 0 & 0 \\ 1/2 & 1/3 & 0 & 0 \\ 0 & 1/6 & 1/6 & 1/3 \\ 1/6 & 0 & 5/6 & 2/3 \end{pmatrix} \cdot \begin{pmatrix} 0 \\ 0 \\ a \\ b \end{pmatrix} = \begin{pmatrix} 0 \\ 0 \\ a/6 + b/3 \\ 5a/6 + 2b/3 \end{pmatrix}, \quad a, b \in \mathbb{R}$$

$a, b \in \mathbb{R}$ , implies that the matrix  $D^2$  has in the right upper corner a zero two-dimensional (square) sub-matrix. By induction, the same property is shared by the matrices  $D^3 = D \cdot D^2$ ,

If we begin with any state vector  $X$ , given as a sum of eigenvectors

$$X = X_1 + \dots + X_m$$

with eigenvalues  $\lambda_i$ , then iterations yield

$$A^k \cdot X = \lambda_1^k X_1 + \dots + \lambda_m^k X_m.$$

Thus under the assumption that  $|\lambda_i| < 1$  for all  $i \geq 2$ , all components in the eigensubspaces decrease very fast, except for the component  $\lambda_1^k X_1$ .

The distribution of the population among the age groups are thus very fast approaching the ratios of the components of the eigenvector to the dominant eigenvalue  $\lambda_1$ .

As an example, consider the matrix below where individual coefficients are taken from the model for sheep breeding, that is, the values  $\tau$  contain both natural deaths and activities of breeders.

$$A = \begin{pmatrix} 0 & 0.2 & 0.8 & 0.6 & 0 \\ 0.95 & 0 & 0 & 0 & 0 \\ 0 & 0.8 & 0 & 0 & 0 \\ 0 & 0 & 0.7 & 0 & 0 \\ 0 & 0 & 0 & 0.6 & 0 \end{pmatrix}.$$

The eigenvalues are approximately

$$1.03, 0, -0.5, -0.27 + 0.74i, -0.27 - 0.74i$$

with absolute values 1.03, 0, 0.5, 0.78, 0.78 and the eigenvector corresponding to the dominant eigenvalue is approximately

$$X^T = (30 \ 27 \ 21 \ 14 \ 8).$$

We have chosen the eigenvector whose coordinates sum to 100, thus it directly gives us the percentage distribution of the population.

Suppose instead that we wish for a constant population, and that one year old sheep are removed for consumption. Then we need ask how to decrease  $\tau_2$  so that the dominant eigenvalue would be one.

A direct check shows that the farmer could then eat about 10% more of one year old sheep to keep the population constant.

**3.3.3. Matrices with non-negative elements.** Real matrices

which have no negative elements have very special properties. They are very often present in practical models. Thus we introduce the *Perron-Frobenius theory* which deals with such matrices. Actually, we show some results of Perron, we omit the more general situations due to Frobenius.<sup>3</sup>

We begin with some definitions in order to formulate our ideas.

<sup>3</sup>Oskar Perron and Ferdinand Georg Frobenius were two great German mathematicians at the break of the 19th and 20th centuries. Even in this textbook we shall meet their names in Analysis, Number Theory, Algebra. Look up the index.

$D^4 = D \cdot D^3, \dots, D^n = D \cdot D^{n-1}, \dots$ , thus the matrix  $D$  is not primitive. The matrix  $E$  is a permutation matrix (in every row and every column there is exactly one non-zero element, 1). It is not difficult to see that a power of a permutation matrix is again a permutation matrix. Thus the matrix  $E$  is also not primitive. This is easily verified by calculating the powers  $E^2, E^3, E^4$ . The matrix  $E^4$  is a unit matrix.  $\square$

**D. Markov processes**

**3.D.1. Sweet-toothed gambler.** A gambler bets on a coin – whether a flip results in a head or in a tail. At the start of the game he has three sweets. On every flip, he bets on a sweet. If he wins, he gains one additional sweet. If he loses, he loses the sweet. The game ends when he loses all sweets or has at least five sweets. What is the probability that the game does not end after four bets?

**Solution.** Before the  $j$ -th round we can describe the state of the player by the random vector  $X_j = (p_0(j), p_1(j), p_2(j), p_3(j), p_4(j), p_5(j))$ , where  $p_i$  is the probability that the player has  $i$  sweets. If the player has before the  $j$ -th bet  $i$  sweets ( $i = 2, 3, 4$ ), then after the bet he has  $(i - 1)$  sweets with probability  $1/2$ , and he has  $(i + 1)$  sweets with probability  $1/2$ . If he attains five sweets or loses them all, the number of sweets does not change. The vector  $X_{j+1}$  is then obtained from the vector  $X_j$  by multiplying it with the matrix

$$A := \begin{pmatrix} 1 & 0.5 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0.5 & 0 & 0 & 0 \\ 0 & 0.5 & 0 & 0.5 & 0 & 0 \\ 0 & 0 & 0.5 & 0 & 0.5 & 0 \\ 0 & 0 & 0 & 0.5 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0.5 & 1 \end{pmatrix}.$$

At the start,

$$X_1 = \begin{pmatrix} 0 \\ 0 \\ 0 \\ 1 \\ 0 \\ 0 \end{pmatrix}.$$

After four bets the situation is described by the vector

$$X_5 = A^4 X_1 = \begin{pmatrix} 1/8 \\ 3/16 \\ 0 \\ 5/16 \\ 0 \\ 3/8 \end{pmatrix},$$

POSITIVE AND PRIMITIVE MATRICES

**Definition.** A *positive matrix* means a square matrix  $A$  all of whose elements  $a_{ij}$  are real and strictly positive. A *primitive matrix* is a square matrix  $A$  whose power  $A^k$  is positive for some positive  $k \in \mathbb{N}$ .

Recall that *spectral radius of a matrix*  $A$  is the maximum of absolute values of all (complex) eigenvalues of  $A$ . The spectral radius of a linear mapping on a (finite dimensional) vector space coincides with the spectral radius of the corresponding matrix for some basis.

In the sequel, the *norm* of a matrix  $A \in \mathbb{R}^{n^2}$  or of a vector  $x \in \mathbb{R}^n$  will mean the sum of the absolute values of all elements. For a vector  $x$  we write  $|x|$  for its norm.

The following result is very useful and hopefully understandable. But the difficulty of its proof is rather not typical for this textbook. If you prefer, read just the theorem and skip the proof till later on.

PERRON THEOREM

**Theorem.** If  $A$  is a primitive matrix with spectral radius  $\lambda \in \mathbb{R}$ , then  $\lambda$  is a root of the characteristic polynomial of  $A$  with multiplicity one and  $\lambda$  is strictly greater than the absolute value of all other eigenvalues of  $A$ . Furthermore, there exists an eigenvector  $x$  associated with  $\lambda$  such that all elements  $x_i$  of  $x$  are positive.

**PROOF.** We shall present the proof only briefly and we shall rely on intuition from elementary geometry, as well as some results touched much later in this book.

Notice that the matrices  $A$  and  $A^k$  share the eigenvectors, while the corresponding eigenvalues are  $\lambda$  and  $\lambda^k$  respectively. Thus the assertion of the theorem holds if and only if the same is true for  $A^k$ . In particular, we may assume the matrix  $A$  itself is positive, without any loss of generality.

Many of the necessary concepts and properties will be discussed in chapter four and in the subsequent chapters devoted to analytical aspects, so the reader might come back to this proof later.

The first step is to show the existence of an eigenvector which has all elements positive. Consider the standard simplex

$$S = \{x = (x_1, \dots, x_n)^T, |x| = 1, x_i \geq 0, i = 1, \dots, n\}.$$

Since all elements in the matrix  $A$  are positive, the image  $Ax$  for  $x \in S$  has all coordinates positive too. The mapping

$$x \mapsto |A \cdot x|^{-1}(A \cdot x)$$

thus maps  $S$  to itself. This mapping  $S \rightarrow S$  satisfies all the assumptions of the *Brouwer fixed point theorem*<sup>4</sup> and thus there

<sup>4</sup>This theorem is a great example of a blend of (homological) Algebra, (differential) Topology and Analysis. We shall discuss it in Chapter 9, cf. ?? on page ??.

that is, the probability that the game ends in the fourth bet or sooner is one half.

Note that the matrix  $A$  describing the evolution of the probabilist vector  $X$  is itself probabilistic, that is, in each column the sum is one. But it does not have the property required by the Perron-Frobenius theorem. By a simple computation you can check (or you can see it straight without any computation) that there exist two linearly independent eigenvectors corresponding to the eigenvalue 1. These correspond to the case that the player has no sweets, that is  $x = (1, 0, 0, 0, 0, 0)^T$ , or to the case when the player has 5 sweets and the game thus ends with him keeping all the sweets, that is,  $x = (0, 0, 0, 0, 0, 1)^T$ . All other eigenvalues (approximately 0.8, 0.3,  $-0.8$ ,  $-0.3$ ) are in absolute value strictly smaller than one. Thus the components in the corresponding eigensubspaces with iteration of the process with arbitrary initial distribution vanish and the process approaches the limiting value of the probabilistic vector of the form  $(a, 0, 0, 0, 0, 1 - a)$ , where the value  $a$  depends on the initial number of sweets. In our case it is  $a = 0.4$ , if there were 4 sweets at the start, it would be  $a = 0.2$  and so on.  $\square$

**3.D.2. Car rental.** A company that rents cars every week has two branches – one in Prague and one in Brno. A car rented in Brno can be returned in Prague and vice versa. After some time it has been discovered that in Prague, roughly 80 % of the cars rented in Prague and 90 % of the cars rented in Brno are returned there. How to distribute the cars among the branches such that in both there is at the start of the week always the same number of cars as in the week before? How will the situation look like after a long time, if the cars are distributed at the start in a random way?

**Solution.** Denote the components of the vector in question, that is, the initial number of cars in Brno and in Prague by  $x_B$  and  $x_P$  respectively. The distribution of the cars between branches is then described by the vector  $x = \begin{pmatrix} x_B \\ x_P \end{pmatrix}$ . If we consider such a multiple of the vector  $x$  such that the sum of its components is 1, then its components give the percentage distribution of the cars. According to the statement, the state at the end of the week is described by the vector  $\begin{pmatrix} 0.1 & 0.2 \\ 0.9 & 0.8 \end{pmatrix} \begin{pmatrix} x_B \\ x_P \end{pmatrix}$ . The matrix  $A = \begin{pmatrix} 0.1 & 0.2 \\ 0.9 & 0.8 \end{pmatrix}$  thus describes our (linear) system of car rental. If at the end of the week in the branches there should be the same number of cars as at the beginning, we are looking for such a vector  $x$  for

exists vector  $y \in S$  such that it is mapped by this mapping to itself. That means that

$$A \cdot y = \lambda y, \quad \lambda = |A \cdot y|$$

and we have found an eigenvector that lies in  $S$ . By assumption,  $A \cdot y$  has got all coordinates positive, thus  $y$  must have the same property. Moreover,  $\lambda > 0$ .

In order to prove the rest of the theorem, we consider the mapping given by the matrix  $A$  in a more suitable basis, where the coordinates of the eigenvector would be  $(\lambda, \dots, \lambda)$ . Moreover, We multiply the mapping by by the constant  $\lambda^{-1}$ . Thus we work with the matrix  $B$ ,

$$B = \lambda^{-1}(Y^{-1} \cdot A \cdot Y),$$

where  $Y$  is the diagonal matrix with coordinates  $y_i$  of the above eigenvector  $y$  on its diagonal. Evidently  $B$  is also a positive matrix. By the construction, the vector  $z = (1, \dots, 1)^T$  is its eigenvector with eigenvalue 1, because  $Y \cdot z = y$ .

It remains to prove that  $\mu = 1$  is a simple root of the characteristic polynomial of the matrix  $B$  and that all other roots have absolute value strictly smaller than one. Then the proof of the Perron theorem is finished.

In order to do that we use an auxiliary lemma, which is discussed below. Consider for the moment the matrix  $B$  to define the linear mapping that maps the row vectors

$$u = (u_1, \dots, u_n) \mapsto u \cdot B = v,$$

that is, using multiplication from the right (i.e.,  $B$  is viewed as the matrix of a linear map on one-forms). Since  $z = (1, \dots, 1)^T$  is an eigenvector of the matrix  $B$  (with eigenvalue 1), the sum of the coordinates of the row vector  $v$

$$u \cdot B \cdot (1, \dots, 1)^T = \sum_{i,j=1}^n u_i b_{ij} = \sum_{i=1}^n u_i = 1,$$

whenever  $u \in S$ . Therefore the simplex  $S$  maps onto itself and thus has in  $S$  a (row) eigenvector  $w$  with eigenvalue one (a fixed point, by the Brouwer theorem again). Because some power  $B$  is positive by our assumption, the image of the simplex  $S$  under  $B^k$  lies inside of  $S$ .

We continue with the row vectors. Denote by  $P$  the shift of the simplex  $S$  into the origin by the eigenvector  $w$  we have just found. That is,  $P = -w + S$ . Evidently  $P$  is a set containing the origin and is defined by linear inequalities. Clearly,  $\psi(P) = -w + \psi(S) \subset P$  and, thus, the vector subspace  $V \subset \mathbb{R}^n$  generated by  $P$  is invariant with respect to the action of the matrix  $B$  through multiplication of the row vectors from the right. Moreover, if  $\psi(p) \in P$  sits on the boundary of  $P$ , then  $\psi(p + w)$  is on the boundary of  $S$ . Hence restriction of our mapping to  $V$ , and  $P$  itself satisfy the assumptions of the auxiliary lemma discussed below and thus all its eigenvalues are strictly smaller than one.

Now, the entire space decomposes as the sum  $\mathbb{R}^n = V \oplus \text{span}\{w\}$  of invariant subspaces,  $w$  is the eigenvector with eigenvalue 1, while all eigenvalues of the restriction to  $V$  are strictly smaller in absolute value.

which that  $Ax = x$ . That means that we are looking for an eigenvector of the matrix  $A$  associated with the eigenvalue 1.

The characteristic polynomial of the matrix  $A$  is  $(0.1 - \lambda)(0.8 - \lambda) - 0.9 \cdot 0.2 = (\lambda - 1)(\lambda + 0.1)$  and 1 is indeed an eigenvalue of the matrix  $A$ . The corresponding eigenvector  $x = \begin{pmatrix} x_B \\ x_P \end{pmatrix}$  satisfies the equation  $\begin{pmatrix} -0.9 & 0.2 \\ 0.9 & -0.2 \end{pmatrix} \begin{pmatrix} x_B \\ x_P \end{pmatrix} = 0$ . It is thus a multiple of the vector  $\begin{pmatrix} 0.2 \\ 0.9 \end{pmatrix}$ . For determining the percentage distribution we are looking for a multiple such that  $x_B + x_P = 1$ . That is satisfied by the vector  $\frac{1}{1.1} \begin{pmatrix} 0.2 \\ 0.9 \end{pmatrix} = \begin{pmatrix} 0.18 \\ 0.82 \end{pmatrix}$ . The suitable distribution of the cars between Prague and Brno is such that 18% of the cars are in Brno and 82% of the cars are in Prague.

If we choose arbitrarily the initial state  $x = \begin{pmatrix} x_B \\ x_P \end{pmatrix}$ , then the state after  $n$  weeks is described by the vector  $x_n = A^n x$ . It is useful to express the initial vector  $x$  in the basis of the eigenvectors of  $A$ . The eigenvector for the eigenvalue 1 has already been found. Similarly we find eigenvectors for the eigenvalue  $-0.1$ . That is for instance the vector  $\begin{pmatrix} -1 \\ 1 \end{pmatrix}$ .

The initial vector can be expressed as a linear combination  $x = a \begin{pmatrix} 0.2 \\ 0.9 \end{pmatrix} + b \begin{pmatrix} -1 \\ 1 \end{pmatrix}$ . The state after  $n$  weeks is then

$$\begin{aligned} x_n &= A^n \left( a \begin{pmatrix} 0.18 \\ 0.82 \end{pmatrix} + b \begin{pmatrix} -1 \\ 1 \end{pmatrix} \right) \\ &= a \begin{pmatrix} 0.18 \\ 0.82 \end{pmatrix} + b(-0.1)^n \begin{pmatrix} -1 \\ 1 \end{pmatrix} \end{aligned}$$

The second summand is approaching zero for  $n \rightarrow \infty$ . Thus the state stabilises at  $a \begin{pmatrix} 0.18 \\ 0.82 \end{pmatrix}$ . That is, the coordinate of the initial vector at the direction of the first eigenvector. The coefficient can be easily expressed using the initial states of the cars:  $a = \frac{x_B + x_P}{1.1}$ .  $\square$

**3.D.3.** In a certain game you can choose one of two opponents. The probability that you beat the better one is  $1/4$ , while the probability that you beat the worse one is  $1/2$ . But the opponents cannot be distinguished, thus you do not know which one is the better one. You await a large number of games. For each of them you can choose a different opponent. Consider the following two strategies:

1. For the first game choose the opponent randomly. If you win a game, carry on with the same opponent; if you lose a game, change the opponent.

The theorem is nearly proved. We have just to consider the problem that the mapping under question was given by multiplication of the row vectors from the right with the matrix  $B$ , while originally we were interested in the mapping given by the matrix  $B$  and multiplication of the column vectors were from the left. But this is equivalent to the multiplication of the transposed column vectors with the transposed matrix  $B$  in the usual way – from the left. Thus we have proved the claim about eigenvalues for the transpose of  $B$ . But transposing does not change the eigenvalues and so the proof is complete.  $\square$

A bounded polyhedron in  $\mathbb{R}^n$  is a nonempty subset defined by linear inequalities, sitting in some large enough ball. Simplex  $S$  from the proof or any its translation are examples. We shall provide concise explanation of all these concepts in chapter 4.

**Lemma.** Consider any bounded polyhedron  $P \subset \mathbb{R}^n$ , containing a ball around origin  $0 \in \mathbb{R}^n$ . If some iteration of the linear mapping  $\psi : \mathbb{R}^n \rightarrow \mathbb{R}^n$  maps  $P$  into its interior (that is  $\psi(P) \subset P$  and the image does not intersect with the boundary), then the spectral radius of the mapping  $\psi$  is strictly less than one.

**PROOF.** Consider the matrix  $A$  of the mapping  $\psi$  in the standard basis. Because the eigenvalues of  $A^k$  are the  $k$ -th powers of the eigenvalues of the matrix  $A$ , we may assume (without loss of generality) that the mapping  $\psi$  already maps  $P$  into  $P$ . Clearly  $\psi$  cannot have any eigenvalue  $\lambda$  with absolute value greater than one. This is easy to see, if the eigenvalue is real. In the complex case, there will be a 2-dimensional invariant plane in which  $\psi$  is a multiplication by  $|\lambda|$  composed with a rotation, thus  $|\lambda| > 1$  is in conflict with the invariance of  $P$  again.

Next, we argue by contradiction and assume that there exists an eigenvalue  $\lambda$  with  $|\lambda| = 1$ . Then there are two possibilities, either  $\lambda^k = 1$  for suitable  $k$  or there is no such  $k$ .

The image of  $P$  is a closed set (that means that if the points in the image  $\psi(P)$  get arbitrarily close to some point  $y$  in  $\mathbb{R}^n$ , then the point  $y$  is also in the image – this is a general feature of the linear maps on finite dimensional vector spaces). By our assumption, the boundary of  $P$  does not intersect with the image. Thus  $\psi$  cannot have a fixed point on the boundary and there cannot even be any point on the boundary to which some sequence of points in the image would converge.

The first argument excludes that some power of  $\lambda$  is one, because such a fixed point of  $\psi^k$  on the boundary of  $P$  would then exist and thus it would be in the image. In the remaining case there would be a two-dimensional subspace  $W \subset \mathbb{R}^n$  on which the restriction of  $\psi$  acts as a rotation by an irrational angle and thus there exists a point  $y$  in the intersection of  $W$  with the boundary of  $P$ . But then the point  $y$  could be approached arbitrarily close by the points from the set  $\psi^k(y)$  (through all iterations) and thus would have to be in the image too. This leads to a contradiction and thus the lemma is proved.  $\square$

2. For the first two games, choose an opponent randomly. Then for the next two games, if you lost both the previous games, change the opponent, otherwise stay with the same opponent.

Which of the two strategies is better?

**Solution.** Both strategies define a Markov chain. For simplicity denote the worse opponent by  $A$  and the better opponent by  $B$ . In the first case for the states "game with  $A$ " and "game with  $B$ " (in this order), we obtain the probabilistic transition matrix

$$\begin{pmatrix} 1/2 & 3/4 \\ 1/2 & 1/4 \end{pmatrix}.$$

This matrix has all of its elements positive. Thus it suffices to find the probabilistic vector  $x_\infty$ , which is associated with the eigenvalue 1. We compute

$$x_\infty = \left( \frac{3}{5}, \frac{2}{5} \right)^T.$$

Its components correspond to the probabilities that after a long sequence of games the opponent is the player  $A$  or player  $B$ . Thus we can expect that 60 % of the games will be played against the worse of the two opponents. Because

$$\frac{2}{5} = \frac{3}{5} \cdot \frac{1}{2} + \frac{2}{5} \cdot \frac{1}{4},$$

there will be roughly 40 % against the better of the two opponents.

For the second strategy, use the states "two games in a row with  $A$ " and "two games in a row with  $B$ " which lead to the probabilistic transition matrix

$$\begin{pmatrix} 3/4 & 9/16 \\ 1/4 & 7/16 \end{pmatrix}.$$

It is easily determined that now

$$x_\infty = \left( \frac{9}{13}, \frac{4}{13} \right)^T.$$

Against the worse opponent one would then play (9/4)-times more frequently than against the better one. Recall that for the first strategy it is (3/2)-times more frequently. The second strategy is thus better. Note also that for the second strategy, roughly 42,3 % of the games are winning ones. It suffices to enumerate

$$0.423 \doteq \frac{11}{26} = \frac{9}{13} \cdot \frac{1}{2} + \frac{4}{13} \cdot \frac{1}{4}.$$

**3.3.4. Simple corollaries.** Once we know the Perron theorem, the following very useful claim has a surprisingly simple proof. It shows how strong is the primitivity assumption of a matrix.

**Corollary.** If  $A = (a_{ij})$  is a primitive matrix and  $x \in \mathbb{R}^n$  is its eigenvector with all coordinates non-negative and eigenvalue  $\lambda$ , then  $\lambda > 0$  is the spectral radius of  $A$ . Moreover,

$$\min_{j \in \{1, \dots, n\}} \sum_{i=1}^n a_{ij} \leq \lambda \leq \max_{j \in \{1, \dots, n\}} \sum_{i=1}^n a_{ij}.$$

**PROOF.** Because  $A$  is primitive, we can choose  $k$  such that  $A^k$  has only positive elements. Then  $A^k \cdot x = \lambda^k x$  is a vector with all coordinates strictly positive. Obviously  $\lambda > 0$ .

According to the Perron theorem, the spectral radius  $\mu$  of  $A$  is an eigenvalue and the associated eigenvectors  $y$  have positive coordinates only. Thus we may choose such an eigenvector with the property that the difference  $x - y$  has only strictly positive coordinates. Then for all large positive integer powers  $m$  we have

$$0 < A^m \cdot (x - y) = \lambda^m x - \mu^m y,$$

but also  $\lambda \leq \mu$ . If  $\mu = \lambda + \alpha$ ,  $\alpha > 0$ , then

$$0 < \lambda^m x - (\lambda + \alpha)^m y < \lambda^m (x - y - m \frac{\alpha}{\lambda} y)$$

which is clearly negative for  $m$  large enough. Hence  $\lambda = \mu$ .

It remains to estimate the spectral radius using the minimum and maximum of sums of individual columns of the matrix. We denote them by  $b_{\min}$  and  $b_{\max}$ . Choose  $x$  to be the eigenvector with the sum of coordinates equal to one and count:

$$\begin{aligned} \sum_{i,j=1}^n a_{ij} x_j &= \sum_{i=1}^n \lambda x_i = \lambda \\ \lambda &= \sum_{j=1}^n \left( \sum_{i=1}^n a_{ij} \right) x_j \leq \sum_{j=1}^n b_{\max} x_j = b_{\max} \\ \lambda &= \sum_{j=1}^n \left( \sum_{i=1}^n a_{ij} \right) x_j \geq \sum_{j=1}^n b_{\min} x_j = b_{\min}. \quad \square \end{aligned}$$

Note that for instance all Leslie matrices from 3.3.2, as soon as all their parameters  $f_i$  and  $\tau_j$  are strictly positive, are primitive. Thus we can apply the just derived results to them. (Compare this with the ad hoc analysis of the roots of the characteristic polynomial from 3.3.2)

**3.3.5. Markov chains.** A very frequent and interesting case of linear processes with only non-negative elements in a matrix is a mathematical model of a system which can be in one of  $m$  states with various probabilities. At a given point of time the system is in state  $i$  with probability  $x_i$ . The transition from the state  $i$  to the state  $j$  happens with probability  $t_{ij}$ .

We can write the process as follows: at time  $n$  the system is described by the *stochastic vector* (we also say *probability vector*)  $x_n = (u_1(n), \dots, u_m(n))^T$ .  $\square$

**3.D.4. Absent-minded professor.** Consider the following situation. An absent-minded professor carries an umbrella with him, but with probability  $1/2$  he forgets it from wherever he is leaving.

In the morning, he leaves home to go to his office. From his office, he goes for lunch at a restaurant, and then goes back to his office. After he is finished with his work at the office, he leaves for home. Suppose (for simplicity) that he does not go anywhere else. Suppose also that if he leaves it in the restaurant, it will remain there until the next time. Consider this situation as a Markov process and write down its matrix. What is the probability that after many days in the morning the umbrella is located in the restaurant? It is convenient to choose one day as a time unit: from morning to morning.

**Solution.**

$$A = \begin{pmatrix} 11/16 & 3/8 & 1/4 \\ 3/16 & 3/8 & 1/4 \\ 1/8 & 1/4 & 1/2 \end{pmatrix}$$

Compute the element  $a_1^1$ , that is, the probability that the umbrella starts its day at home and stays there, that is, it will be there the next morning. There are three distinct possibilities for the umbrella:

D the professor forgets it when leaving home in the morning  
 $p_1 = \frac{1}{2}$ ,

DPD the professor takes it to the office, then he forgets to take it on to lunch and in the evening he takes it home:  $p_2 = \frac{1}{2} \cdot \frac{1}{2} \cdot \frac{1}{2} = \frac{1}{8}$ ,

DPRPD the professor takes the umbrella with him all the time and does not forget it anywhere:  $p_3 = \frac{1}{2} \cdot \frac{1}{2} \cdot \frac{1}{2} \cdot \frac{1}{2} = \frac{1}{16}$ .

In total  $a_1^1 = p_1 + p_2 + p_3 = \frac{11}{16}$ .

The eigenvector of this matrix corresponding to the dominant eigenvalue 1 is  $(2, 1, 1)$ , and thus the desired probability is  $1/(2 + 1 + 1) = 1/4$ . □

**3.D.5. Algorithm for determining the importance of pages.** Internet browsers can find (almost) all pages containing a given word or phrase on the Internet. But how can a user sort the pages such that a list is sorted according to the relevance of the given pages? One of the possibilities is the following algorithm: the collection of all found pages is considered to be a system, and each of the found pages is one of its states. We describe a random walk on these pages as a Markov process. The probabilities of transitions between pages are given by the hyperlink: each link, say from page

This means that all components of the vector  $x$  are real non-negative numbers and their sum equals one. Components give the distribution of the probability of individual possibilities for the state of the system. The distribution of the probabilities at time  $n + 1$  is given via multiplication by the transition matrix  $T = (t_{ij})$ , that is,

$$x_{n+1} = T \cdot x_n.$$

Since we assume that the vector  $x$  captures all possible states of the system and moves again to some of these states with the total probability one, all columns of  $T$  are also given by stochastic vectors. We call such matrices *stochastic matrices*. Note that every stochastic matrix maps every stochastic vector  $x$  to a stochastic vector  $Tx$  again:

$$\sum_{i,j} t_{ij}x_j = \sum_j \left( \sum_i t_{ij} \right) x_j = \sum_j x_j = 1.$$

Such a sequence  $x_{n+1} = Tx_n$  is called a (discrete) *Markov process* and the resulting sequence of vectors  $x_0, x_1, \dots$  is called a *Markov chain*  $x_n$ .

Now we can exploit the Perron-Frobenius theory in its full power. Because the sum of the rows of the matrix is always equal to the vector  $(1, \dots, 1)$ , we see that the matrix  $T - E$  is singular and thus one is an eigenvalue of the matrix  $T$ . Furthermore, if  $T$  is a primitive matrix (for instance, when all elements are non-zero), we know from the corollary 3.3.4 that one is a simple root of the characteristic polynomial and all others have absolute value strictly smaller than one. This leads to:

ERGODIC THEOREM

**Theorem.** *Markov processes with primitive matrices  $T$  satisfy:*

- there exists a unique eigenvector  $x_\infty$  of the matrix  $T$  with the eigenvalue 1, which is stochastic,
- the iterations  $T^k x_0$  approach the vector  $x_\infty$  for any initial stochastic vector  $x_0$ .

**PROOF.** The first claim follows directly from the positivity of the coordinates of the eigenvector derived in the Perron theorem (notice the dominant eigenvalue comes with multiplicity one).

Next, assume that the algebraic and geometric multiplicities of the eigenvalues of the matrix  $T$  are the same. Then every stochastic vector  $x_0$  can be written (in the complex extension  $\mathbb{C}^n$ ) as a linear combination

$$x_0 = c_1 x_\infty + c_2 y_2 + \dots + c_n y_n,$$

where  $y_2, \dots, y_n$  extend  $x_\infty$  to a basis of the eigenvectors. But then the  $k$ -th iteration gives again a stochastic vector

$$x_k = T^k \cdot x_0 = c_1 x_\infty + \lambda_2^k c_2 y_2 + \dots + \lambda_n^k c_n y_n.$$

Now all eigenvalues  $\lambda_2, \dots, \lambda_n$  are in absolute value strictly smaller than one. So all components of the vector  $x_k$  but the first one approach (in norm) zero. But  $x_k$  is still stochastic,

A to page B, determines the probability ( $1/(\text{total number of links from the page A})$ ), with which the process moves from page A to page B. If from some page there are no leading links, we consider it to be a page from which a link leads to every other page. This gives a probabilistic matrix  $M$  (the element  $m_{ij}$  corresponds to the probability with which we move from the  $i$ -th page to the  $j$ -th page). Thus if one randomly clicks on links in the found pages (and from a linkless page one just chooses randomly the next one) the probability that at a given time (sufficiently large from the beginning) one is located on the  $i$ -th page corresponds to the  $i$ -th component of the unit eigenvector of the matrix  $M$ , corresponding to the eigenvalue 1. Looking at the sizes of these probabilities we define the importance of the individual pages.

This algorithm can be modified by assuming that users stop clicking from a link to a link after certain time and again starts on a random page. Suppose that with probability  $d$  he chooses a new page randomly, and with probability  $(1 - d)$  keeps on clicking. In such a situation the probability of transition between any two pages  $S_i$  and  $S_j$  is non-zero – it is  $d/n + (1 - d)/\text{total number of links at the page } S_i$  if from  $S_i$  there is a link to  $S_j$ , and  $d/n$  otherwise (if there are no links at  $S_i$ , then it is  $1/n$ ). According to the Perron-Frobenius theorem the eigenvalue 1 is with multiplicity one and dominant, and thus the corresponding eigenvector is unique (if we chose transitional probabilities only as described in the previous paragraph, it would not have to be so).

For an illustration, consider pages A, B, C and D. The links lead from A to B and to C, from B to C and from C to A, from D nowhere. Suppose that the probability that the user chooses a random new page is  $1/5$ . Then the matrix  $M$  looks as follows:

$$M = \begin{pmatrix} 1/20 & 1/20 & 17/20 & 1/4 \\ 9/20 & 1/20 & 1/20 & 1/4 \\ 9/20 & 17/20 & 1/20 & 1/4 \\ 1/20 & 1/20 & 1/20 & 1/4 \end{pmatrix}$$

The eigenvector corresponding to the eigenvalue 1 is  $(305/53, 175/53, 315/53, 1)$ , the importance of the pages is thus given according to the order of the sizes of the corresponding components, that is,  $C > A > B > D$ .

Another various applications of the Markov chains are in the additional exercises after this chapter, see 3.G.3

thus the only possibility is that  $c_1 = 1$  and the second claim is proved.

In fact, even if the algebraic and geometric multiplicities of eigenvalues do not coincide we reach the same conclusion using a more detailed study of the root subspaces of the matrix  $T$ . (We meet them when discussing the Jordan matrix decomposition later in this chapter.) Consequently, even in the general case the eigensubspace  $\text{span}\{x_\infty\}$  comes with the unique invariant  $(n - 1)$ -dimensional complement, on which are all eigenvalues in absolute value smaller than one and the corresponding components in  $x_k$  approach zero as before. See the note 3.4.11 where we finish this argument in detail.  $\square$

**3.3.6. Iteration of the stochastic matrices.** We reformulate

the previous theorem into a simple, but surprising result. By convergence to a limit matrix in the following theorem we mean the following: if we say that we want to bound the possible error  $\varepsilon > 0$ , then we can find a lower bound on the number of iterations  $k$  after which all the components of the matrix differ from the limit one by less than  $\varepsilon$ .

**Corollary.** *Let  $T$  be a primitive stochastic matrix from a Markov process and let  $x_\infty$  be the stochastic eigenvector for the dominant eigenvalue 1 (as in the Ergodic Theorem above). Then the iterations  $T^k$  converge to the limit matrix  $T_\infty$ , whose columns all equal to  $x_\infty$ .*

**PROOF.** Columns in the matrix  $T^k$  are images of the vectors of the standard basis under the corresponding iterated linear mapping. But these are images of the stochastic vectors and thus they all converge to  $x_\infty$ .  $\square$

**3.3.7. Final brief remark.** Before leaving the Markov processes, we shortly mention their more general versions with matrices which are not primitive. Here we would need the full Frobenius-Perron theory. Without going into technicalities, consider a process with a block wise diagonal or an upper triangular matrix  $T$ ,

$$T = \begin{pmatrix} P & R \\ 0 & Q \end{pmatrix}$$

and imagine first that  $P, Q$  are primitive and  $R = 0$ . Here we can again apply the above results block wise. In words, if we start in a stay  $x_0$  with all probability concentrated in the first block of coordinates, the process converges to the value  $x_\infty$  which again has all the probability distributed among the first block of coordinates, and the same for the other block.

If  $R > 0$  then we can always jump to the states corresponding to the first block from those in the second block with a non-zero probability and the iterations get more complicated:

$$T^2 = \begin{pmatrix} P^2 & P \cdot R + R \cdot Q \\ 0 & Q^2 \end{pmatrix}$$

$$T^3 = \begin{pmatrix} P^3 & P^2 \cdot R + P \cdot R \cdot Q + R \cdot Q^2 \\ 0 & Q^3 \end{pmatrix}.$$

**E. Unitary spaces**

In the previous chapter we defined the scalar product for real vector spaces (2.3.18). In this chapter we extend its definition to the complex spaces (3.4.1).

**3.E.1. Groups  $O(n)$  and  $U(n)$ .** If we consider all linear mappings from  $\mathbb{R}^3$  to  $\mathbb{R}^3$  which preserve the given scalar product, that is, with respect to the definitions of the lengths of the vectors and deviations of two vector all linear mappings that preserve lengths and angles. Then these mappings form a group (see 1.1.1) with respect to the operation of composition. The composition of two such mappings is, by definition also a mapping that preserves lengths and angles, the unit element of the group is the identity mapping, and the inverse element for a given mapping is its inverse mapping. Such a mapping exists by the condition on the lengths preservation. The matrices of such mappings thus form a group with the operation of matrix multiplication (see ); it is called the *orthogonal group* and is denoted by  $O(n)$ . It is a subgroup of the group of all invertible mappings from  $\mathbb{R}^n$  to  $\mathbb{R}^n$ .

Moreover, if we require that the matrices have determinant one, then we speak of the special orthogonal group  $SO(n)$ . In general the determinant of a matrix in  $O(n)$  can be either 1 or  $-1$ . Similarly we define the *unitary group*  $U(n)$  as the group of all (complex) matrices that correspond to the complex linear mappings from  $\mathbb{C}^n$  to  $\mathbb{C}^n$  which preserve a given scalar product in a unitary space. Analogously,  $SU(n)$  denotes the subgroup of matrices in  $U(n)$  with determinant one. In general, the determinant of a matrix in  $U(n)$  can be any complex unit.

**3.E.2.** Consider the vector space  $V$  of functions  $\mathbb{R} \rightarrow \mathbb{C}$ . Determine whether the mapping  $\varphi$  from the unitary space  $V$  is linear when:

- i)  $\varphi(u) = \lambda u$  where  $\lambda \in \mathbb{C}$
- ii)  $\varphi(u) = u^*$
- iii)  $\varphi(u) = u^2 (= u \cdot u)$
- iv)  $\varphi(u) = \frac{du}{dx}$

For suitable functions  $V$  is a unitary space of infinite dimension. The scalar product is then defined by the relation  $f \cdot g = \int_{-\infty}^{\infty} f(x)\overline{g(x)}dx$ .

**3.E.3.** Show that if  $H$  is a Hermitian matrix, then  $U = \exp(iH) = \sum_{n=0}^{\infty} \frac{1}{n!}(iH)^n$  is a unitary matrix and compute its determinant.

An interesting special case is when  $P = E$  and  $R$  is positive. Then  $Q - E$  must be a regular matrix and a simple computation yields the general iteration (notice  $E$  and  $Q$  commute and thus  $(E - Q)(E + Q + \dots + Q^{k-1}) = E - Q^k$ )

$$T^k = \begin{pmatrix} E & R(E - Q)^{-1}(E - Q^k) \\ 0 & Q^k \end{pmatrix}.$$

Thus, the entire first block of states is formed by eigenvectors with eigenvalue 1 (so these states stay constant with probability 1), while the behavior on the other block is more complicated.

**4. More matrix calculus**

We have seen that understanding the inner structure of matrices is a strong tool for both computation and analysis. It is even more true when considering numerical calculations with matrices. Therefore we return now to the abstract theory.

We introduce special types of linear mappings on vector spaces. We consider general linear mappings whose structure is understood in terms of the Jordan normal form (see 3.4.10). In all these cases, complex scalars are essential. So we extend our discussion of scalar product (see 2.3.18–2.3.21) to complex vector spaces. Actually, in many areas the complex vector spaces are the essential platform necessary for introducing the mathematical models. For instance, this is the case in the so-called quantum computing, which became a very active area of theoretical computer science. Many people hope to construct an effective quantum computer soon.

**3.4.1. Unitary spaces and mappings.** The definitions of scalar product and orthogonality easily extend to the complex case. But we do not mean the complex bilinear symmetric forms  $\alpha$ , since there the quadratic expressions  $\alpha(v, v)$  are not real in general and thus we would not get the right definition of length of vectors. Instead, we define:

UNITARY SPACES

*Unitary space* is a complex vector space  $V$  along with the mapping  $V \times V \rightarrow \mathbb{C}$ ,  $(u, v) \mapsto u \cdot v$  called *scalar product* and satisfying for all vectors  $u, v, w \in V$  and scalars  $a \in \mathbb{C}$  the following axioms:

- (1)  $u \cdot v = \overline{v \cdot u}$  (the bar stands for complex conjugation),
- (2)  $(au) \cdot v = a(u \cdot v)$ ,
- (3)  $(u + v) \cdot w = u \cdot w + v \cdot w$ ,
- (4) if  $u \neq 0$ , then  $u \cdot u > 0$  (notice  $u \cdot u$  is always real).

The real number  $\sqrt{v \cdot v}$  is called the *norm of the vector*  $v$  and a vector is *normalized*, if its norm equals one. Vectors  $u$  and  $v$  are said to be *orthogonal* if their scalar product is zero. A basis composed of mutually orthogonal and normalized vectors is called an *orthonormal basis* of  $V$ .

**Solution.** From the definition of  $\exp$  we can show that  $\exp(A + B) = \exp(A) \cdot \exp(B)$  just as with the exponential mapping in the domain of real numbers. Because  $(u + v)^* = u^* + v^*$  and  $(cv)^* = \bar{c}v^*$ , we obtain

$$U^* = \left( \sum_{n=0}^{\infty} \frac{1}{n!} (iH)^n \right)^* = \sum_{n=0}^{\infty} \frac{1}{n!} (-iH^*)^n$$

and since  $H^* = H$ , then

$$U^* = \sum_{n=0}^{\infty} (-1)^n \frac{1}{n!} (iH)^n = \exp(-iH).$$

Thus

$$U^*U = \exp(iH) \exp(-iH) = \exp(0) = 1.$$

$$\det(U) = e^{\text{trace}(iH)}.$$

□

**3.E.4.** Hermitian matrices  $A, B, C$  satisfy  $[A, C] = [B, C] = 0$  and  $[A, B] \neq 0$ , where  $[,]$  is a commutator of matrices defined by the relation  $[A, B] = AB - BA$ . Show that at least one eigensubspace of the matrix  $C$  must have dimension  $> 1$ .

**Solution.** We prove it by contradiction. Assume that all eigensubspaces of the operator  $C$  have  $\dim = 1$ . Then for any vector  $u$  we can write  $u = \sum_k c_k u_k$  where  $u_k$  are linearly independent eigenvectors of the operator  $C$  associated with the eigenvalue  $\lambda_k$  (and  $c_k = u \cdot u_k$ ). For these eigenvectors

$$0 = [A, C]u_k = ACu_k - CAu_k = \lambda_k Au_k - C(Au_k).$$

From there it follows that  $Au_k$  is an eigenvector of the matrix  $C$  with the eigenvalue  $\lambda_k$ . But then that  $Au_k = \lambda_k^A u_k$  for some number  $\lambda_k^A$ . Similarly,  $Bu_k = \lambda_k^B u_k$  for some number  $\lambda_k^B$ . For the commutator of matrices  $A$  and  $B$  is then obtained

$$[A, B]u_k = ABu_k - BAu_k = \lambda_k^A \lambda_k^B u_k - \lambda_k^B \lambda_k^A u_k = 0$$

so that

$$[A, B]u = [A, B] \sum_k c_k u_k - \sum_k c_k [A, B]u_k = 0.$$

Because  $u$  is arbitrary, it follows that  $[A, B] = 0$ , which is a contradiction. □

**3.E.5. Applications to quantum physics.** In quantum physics we do not use numbers as in classical physics, but a Hermitian operator. This is nothing but a Hermitian mapping, which can (and often does) lead to a linear transformation between unitary spaces of infinite dimension. We can imagine this as a matrix

At first sight this is an extension of the definition of Euclidean vector spaces into the complex domain. We will continue to use the alternative notation  $\langle u, v \rangle$  for the scalar product of vectors  $u$  and  $v$ . As in the real domain, we obtain immediately from the definition the following simple properties of the scalar product for all vectors in  $V$  and scalars in  $\mathbb{C}$ :

$$u \cdot u \in \mathbb{R}$$

$$u \cdot u = 0 \quad \text{if and only if} \quad u = 0$$

$$u \cdot (av) = \bar{a}(u \cdot v)$$

$$u \cdot (v + w) = u \cdot v + u \cdot w$$

$$u \cdot 0 = 0 \cdot u = 0$$

$$\left( \sum_i a_i u_i \right) \cdot \left( \sum_j b_j v_j \right) = \sum_{i,j} a_i \bar{b}_j (u_i \cdot v_j),$$

where the last equality holds for all finite linear combinations. It is a simple exercise to prove everything formally. For instance, the first property follows from (1) since the product  $u \cdot u$  has to be the complex conjugate to itself.

A standard example of the scalar product over the complex vector space  $\mathbb{C}^n$  is

$$(x_1, \dots, x_n)^T \cdot (y_1, \dots, y_n)^T = x_1 \bar{y}_1 + \dots + x_n \bar{y}_n.$$

This expression is also called the standard (positive definite) *Hermitian form* on  $\mathbb{C}^n$ . By conjugation of the coordinates of the second argument, this mapping satisfies all the required properties. The space  $\mathbb{C}^n$  with this scalar product is called the *standard unitary space* of dimension  $n$ . We can denote this scalar product of vectors  $x$  and  $y$  with matrix notation as  $\bar{y}^T \cdot x$  (here the complex conjugation indicated by the bar is performed on all components of  $y$ ).

As usual, those mappings which leave the additional structure invariant are of great importance.

#### UNITARY MAPPINGS

A linear mapping  $\varphi : V \rightarrow W$  between unitary spaces is called a *unitary mapping*, if for all vectors  $u, v \in V$

$$u \cdot v = \varphi(u) \cdot \varphi(v).$$

*Unitary isomorphism* is a bijective unitary mapping.

**3.4.2. Real and complex spaces with scalar product.** In the previous chapter we have already derived some simple properties of spaces with scalar products. The properties and proofs are very similar to the complex case.

In the sequel we shall work with real and complex spaces simultaneously and write  $\mathbb{K}$  for  $\mathbb{R}$  or  $\mathbb{C}$ . In the real case the conjugation is just the identity mapping (it is the restriction of the conjugation in the complex plane to the real line). As in the real case, we define the *orthogonal complement* for a vector subspace  $U \subset V$  in the unitary space  $V$  as

$$U^\perp = \{v \in V; u \cdot v = 0 \text{ for all } u \in U\},$$

which is clearly also a vector subspace in  $V$ .

of infinite dimension. Vectors in this unitary space then represent the states of the given physical system. When measuring a given physical quantity we obtain only values that are eigenvalues of the corresponding operator.

For instance, instead of the coordinate  $x$  we have an operator of the coordinate  $\hat{x}$ , that results in multiplication by  $x$ . If the state of the system is described by the vector  $V$ , then  $\hat{x}(v) = xv$ . This corresponds to the multiplication of the vector by the real number  $x$ . At first glance this Hermitian operator is different from the cases of finite dimension. Evidently every real number is an eigenvalue and ( $\hat{x}$  has a continuous spectrum). Similarly, instead of speed (more precisely, momentum) we have the operator  $\hat{p} = -i\frac{d}{dx}$ . The eigenvectors are the solution of the differential equation  $-i\frac{dv}{dx} = \lambda v$ . Even in this case the spectrum is continuous. This expresses the fact that the corresponding physical quantity is continuous and can attain any real value. On the other hand, we have physical quantities, for instance energy, that can attain only discrete values (energy exists in quanta). The corresponding operators are then really similar to the Hermitian matrices. They have infinitely many eigenvalues.

**3.E.6.** Show that  $\hat{x}$  and  $\hat{p}$  are Hermitian and that

$$[\hat{x}, \hat{p}] = i$$

**Solution.** For any vector  $v$

$$[\hat{x}, \hat{p}]v = \hat{x}\hat{p}v - \hat{p}\hat{x}v = x(-i\frac{dv}{dx}) + i\frac{d(xv)}{dx} = iv$$

from which the result follows. □

**3.E.7.** Show that

$$[\hat{x} - \hat{p}, \hat{x} + \hat{p}] = 2i$$

**Solution.** Evidently  $[\hat{x}, \hat{x}] = 0$  and  $[\hat{p}, \hat{p}] = 0$  The result follows from the linearity of the commutator from the previous exercise. □

**3.E.8. Jordan form.** Find the Jordan form of the following matrices. What is the geometric interpretation of this decomposition of the matrix?

- i)  $A = \begin{pmatrix} -1 & 1 \\ -6 & 4 \end{pmatrix}$
- ii)  $A = \begin{pmatrix} -1 & 1 \\ -4 & 3 \end{pmatrix}$

Although we deal exclusively with finitely-dimensional spaces now, the results in the next two theorems have a natural generalization for Hilbert spaces, which are infinitely-dimensional spaces with scalar products. We shall meet them later, in connection with approximation in vector spaces of real or complex valued functions.

**Theorem.** For every finitely-dimensional space  $V$  of dimension  $n$  with scalar product we have:

- (1) There exists an orthonormal basis in  $V$ .
- (2) Every system of non-zero orthogonal vectors in  $V$  is linearly independent and can be extended to an orthogonal basis.
- (3) For every system of linearly independent vectors  $(u_1, \dots, u_k)$  there exists an orthonormal basis  $(v_1, \dots, v_n)$  such that  $\langle v_1, \dots, v_i \rangle = \langle u_1, \dots, u_i \rangle$ , for all  $1 \leq i \leq k$ , i.e. its vectors consecutively generate the same subspaces as the vector  $u_j$ .
- (4) If  $(u_1, \dots, u_n)$  is an orthonormal basis  $V$ , then the coordinates of every vector  $u \in V$  are expressed via

$$u = (u \cdot u_1)u_1 + \dots + (u \cdot u_n)u_n.$$

- (5) In any orthonormal basis, the scalar product has the coordinate form

$$u \cdot v = \bar{y}^T \cdot x = x_1\bar{y}_1 + \dots + x_n\bar{y}_n$$

where  $x$  and  $y$  are columns of coordinates of the vectors  $u$  and  $v$  in a chosen basis. Notably, every  $n$ -dimensional space with scalar product is isomorphic to the standard Euclidean  $\mathbb{R}^n$  or the unitary  $\mathbb{C}^n$ .

- (6) The orthogonal sum of unitary subspaces  $V_1 + \dots + V_k$  in  $V$  is always a direct sum.
- (7) If  $A \subset V$  is an arbitrary subset, then  $A^\perp \subset V$  is a vector subspace (and thus also unitary), and  $(A^\perp)^\perp \subset V$  is exactly the subspace generated by  $A$ . Furthermore,  $V = \text{span } A \oplus A^\perp$ .
- (8)  $V$  is an orthogonal sum of  $n$  one-dimensional unitary subspaces.

**PROOF.** (1), (2), (3): First we extend the given system of vectors into any basis  $(u_1, \dots, u_n)$  of the space  $V$  and then start the Gramm-Schmidt orthogonalization from 2.3.20. This procedure works in the complex case. It yields an orthogonal basis with properties as required in (3). But from the Gramm-Schmidt orthogonalization algorithm it is clear that if the original  $k$  vectors formed an orthogonal system of vectors, then they continue to do so after the orthogonalization process is applied. Thus we have also proved (2) and (1).

- (4): If  $u = a_1u_1 + \dots + a_nu_n$ , then

$$u \cdot u_i = a_1(u_1 \cdot u_i) + \dots + a_n(u_n \cdot u_i) = a_i\|u_i\|^2 = a_i$$

- (5): If  $u = x_1u_1 + \dots + x_nu_n, v = y_1u_1 + \dots + y_nu_n$ , then

$$\begin{aligned} u \cdot v &= (x_1u_1 + \dots + x_nu_n) \cdot (y_1u_1 + \dots + y_nu_n) \\ &= x_1\bar{y}_1 + \dots + x_n\bar{y}_n. \end{aligned}$$

**Solution.** i) First compute the characteristic polynomial of the matrix  $A$

$$|A - \lambda E| = \begin{vmatrix} -1 - \lambda & 1 \\ -6 & 4 - \lambda \end{vmatrix} = \lambda^2 - 3\lambda + 2$$

The eigenvalues of the matrix  $A$  are the roots of this polynomial, that means that  $\lambda_{1,2} = 1, 2$ . Since the matrix is of order two, and has two distinct eigenvalues, its Jordan form is a diagonal matrix  $J = \begin{pmatrix} 1 & 0 \\ 0 & 2 \end{pmatrix}$ . The eigenvector  $(x, y)$  associated with the eigenvalue 1 satisfies  $0 = (A - E)x = \begin{pmatrix} -2 & 1 \\ -6 & 3 \end{pmatrix} \begin{pmatrix} x \\ y \end{pmatrix}$ , that is,  $-2x + y = 0$ . So the eigenvectors are the multiples of the vector  $(1, 2)$ .

Similarly the eigenvector associated with the eigenvalue 2 is  $(1, 3)$ . The matrix  $P$  is then obtained by writing these eigenvectors into the columns, that is,  $P = \begin{pmatrix} 1 & 1 \\ 2 & 3 \end{pmatrix}$ . For the matrix  $A$ ,  $A = P \cdot J \cdot P^{-1}$ . The inverse of  $P$  is  $P^{-1} = \begin{pmatrix} 3 & -1 \\ -2 & 1 \end{pmatrix}$ , and

$$\begin{pmatrix} -1 & 1 \\ -6 & 4 \end{pmatrix} = \begin{pmatrix} 1 & 1 \\ 2 & 3 \end{pmatrix} \begin{pmatrix} 1 & 0 \\ 0 & 2 \end{pmatrix} \begin{pmatrix} 3 & -1 \\ -2 & 1 \end{pmatrix}$$

This decomposition says that the matrix  $A$  determines a linear mapping that has as basis of the eigenvectors  $(1, 2)$ ,  $(1, 3)$ , the aforementioned diagonal form. Geometrically, this means that in the direction  $(1, 2)$  nothing is changing and in the direction  $(1, 3)$  every vector is being stretched twice.

ii) The characteristic polynomial of the matrix  $A$  is in this case

$$|A - \lambda E| = \begin{vmatrix} -1 - \lambda & 1 \\ -4 & 3 - \lambda \end{vmatrix} = \lambda^2 - 2\lambda + 1 = 0$$

There is a double root  $\lambda = 1$  and the corresponding eigenvector  $(x, y)$  satisfies

$$0 = (A - E)x = \begin{pmatrix} -2 & 1 \\ -4 & 2 \end{pmatrix} \begin{pmatrix} x \\ y \end{pmatrix}$$

The solutions are, as in the previous case, multiples of the vector  $(1, 2)$ . The fact that the system does not have two linearly independent vectors as a solution says that the Jordan form in this case is not optimal, but it will be a matrix  $\begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix}$ . The basis for which  $A$  has this form is the eigenvector  $(1, 2)$  and a vector that maps on this vector by the mapping  $A - E$ . Thus it is a solution of the system of equations

$$\left( \begin{array}{cc|c} -2 & 1 & 1 \\ -4 & 2 & 2 \end{array} \right) \sim \left( \begin{array}{cc|c} -2 & 1 & 1 \\ 0 & 0 & 0 \end{array} \right)$$

(6): We need to show that for any tuple  $V_i, V_j$  from the given subspaces their intersection is the zero vector. If  $u \in V_i$  and  $u \in V_j$ , then  $u \perp u$ , that is,  $u \cdot u = 0$ . This is possible only for the zero vector  $u \in V$ .

(7): Let  $u, v \in A^\perp$ . Then  $(au + bv) \cdot w = 0$  for all  $w \in A$ ,  $a, b \in \mathbb{K}$  (from the distributivity of the scalar product). Thus  $A^\perp$  is a subspace in  $V$ . Let  $(v_1, \dots, v_k)$  be a basis of  $\text{span } A$  chosen among the elements of  $A$ , and let  $(u_1, \dots, u_k)$  be the orthonormal basis resulting from the Gram-Schmidt orthogonalization of the vectors  $(v_1, \dots, v_k)$ . We extend it to an orthonormal basis of the whole  $V$  (both exist by the already proven parts of this proposition). Because it is an orthogonal basis, necessarily  $\text{span}\{u_{k+1}, \dots, u_n\} = \text{span}\{u_1, \dots, u_k\}^\perp = A^\perp$  and  $A \subset \text{span}\{u_{k+1}, \dots, u_n\}^\perp$  (this follows from expressing the coordinates under the orthonormal basis). If  $u \perp \text{span}\{u_{k+1}, \dots, u_n\}$ , then  $u$  is necessarily a linear combination of the vectors  $u_1, \dots, u_k$ , but that happens whenever it is a linear combination of the vectors  $v_1, \dots, v_k$ , which is equivalent to  $u$  being in  $\text{span } A$ .

(8): This is equivalent to the formulation of the existence of the orthonormal basis.  $\square$

### 3.4.3. Important properties of the norm.

Now we have everything prepared for basic properties related to our definition of the norm of vectors. We speak also of the *length of vectors* defined by the scalar product. Note also that all claims always consider finite sets of vectors, Their validity does not depend on the dimension of the space  $V$  where it all takes place.

#### PROPERTIES OF NORM

**Theorem.** Let  $V$  be a vector space with scalar product,  $u$  and  $v$  vectors in  $V$ . Then

(1)  $\|u + v\| \leq \|u\| + \|v\|$ . Equality holds if and only if  $u$  and  $v$  are linearly dependent. This is called the **triangle inequality**.

The solutions are multiples of the vector  $(1, 3)$ . We obtain the same basis as in the previous case and we can write

$$\begin{pmatrix} -1 & 1 \\ -4 & 3 \end{pmatrix} = \begin{pmatrix} 1 & 1 \\ 2 & 3 \end{pmatrix} \begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix} \begin{pmatrix} 3 & -1 \\ -2 & 1 \end{pmatrix}$$

The mapping now acts on the vector as follows: the component in the direction  $(1, 3)$  stays the same. The component in the direction  $(1, 2)$  is multiplied by the sum of the coefficients that determine the components in the directions  $(1, 3)$  and  $(1, 2)$ .  $\square$

**3.E.9.** Find the Jordan form of the matrices  $A_1$  and  $A_2$ , and write down the decomposition. What is the geometric interpretation of this decomposition?  $A_1 = \frac{1}{3} \begin{pmatrix} 5 & -1 \\ -2 & 4 \end{pmatrix}$  and  $A_2 = \frac{1}{3} \begin{pmatrix} 5 & -1 \\ 4 & 1 \end{pmatrix}$  and show how the vectors  $v = (3, 0)$ ,  $A_1 v$  and  $A_2 v$  decompose with respect to the basis of the eigenvectors of the matrix  $A_{1,2}$ .

**Solution.** The matrices have the same Jordan forms as the matrices in the previous exercise. In the basis of the vectors  $(1, 2)$  and  $(1, -1)$ ,

$$\frac{1}{3} \begin{pmatrix} 5 & -1 \\ -2 & 4 \end{pmatrix} = \begin{pmatrix} 1 & 1 \\ 2 & -1 \end{pmatrix} \begin{pmatrix} 1 & 0 \\ 0 & 2 \end{pmatrix} \begin{pmatrix} 1 & 1 \\ 2 & -1 \end{pmatrix}^{-1}$$

and

$$\frac{1}{3} \begin{pmatrix} 5 & -1 \\ 4 & 1 \end{pmatrix} = \begin{pmatrix} 1 & 1 \\ 2 & -1 \end{pmatrix} \begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix} \begin{pmatrix} 1 & 1 \\ 2 & -1 \end{pmatrix}^{-1}$$

For the vector  $v = (3, 0)$ ,  $v = (1, 2) + 2(1, -1)$ . For its images,  $A_1 v = (5, -2) = (1, 2) + 2 \cdot 2 \cdot (1, -1)$  and  $A_2 v = (5, 4) = (2 + 1) \cdot (1, 2) + 2 \cdot (1, -1)$ .  $\square$

### F. Matrix decompositions

**3.F.1.** Prove or disprove:

- Let  $A$  be a square matrix  $n \times n$ . Then the matrix  $A^T A$  is symmetric.
- Let  $A$  be a square matrix with only real positive eigenvalues. Then  $A$  is symmetric.

**3.F.2.** Find an LU-decomposition of the following matrix:

$$\begin{pmatrix} -2 & 1 & 0 \\ -4 & 4 & 2 \\ -6 & 1 & -1 \end{pmatrix}$$

**Solution.**

$$\begin{pmatrix} 1 & 0 & 0 \\ 2 & 1 & 0 \\ 3 & -1 & 1 \end{pmatrix} \begin{pmatrix} -2 & 1 & 0 \\ 0 & 2 & 2 \\ 0 & 0 & 1 \end{pmatrix}$$

First multiply the matrices that correspond to the Gaussian elimination, we thus obtain for the original matrix  $A$ ,  $XA =$

(2)  $|u \cdot v| \leq \|u\| \|v\|$ . Equality holds if and only if  $u$  and  $v$  are linearly dependent. This property is called the **Cauchy inequality**.

(3) If  $(e_1, \dots, e_k)$  is an orthonormal system of vectors, then

$$\|u\|^2 \geq |u \cdot e_1|^2 + \dots + |u \cdot e_k|^2.$$

This property is called the **Bessel inequality**.

(4) If  $(e_1, \dots, e_k)$  is an orthonormal system of vectors, then  $u \in \text{span}\{e_1, \dots, e_k\}$  if and only if

$$\|u\|^2 = |u \cdot e_1|^2 + \dots + |u \cdot e_k|^2.$$

This is called the **Parseval equality**.

(5) If  $(e_1, \dots, e_k)$  is an orthonormal system of vectors and  $u \in V$ , then the vector

$$w = (u \cdot e_1)e_1 + \dots + (u \cdot e_k)e_k$$

is the only vector which minimizes the norm  $\|u - v\|$  among all  $v \in \text{span}\{e_1, \dots, e_k\}$ .

**PROOF.** The verifications are all based on direct computations:

(2): The result is obvious if  $v = 0$ . Otherwise, define the vector  $w = u - \frac{u \cdot v}{v \cdot v} v$ , that is,  $w \perp v$  and compute

$$\begin{aligned} \|w\|^2 &= \|u\|^2 - \frac{(u \cdot v)^2}{\|v\|^2} - \frac{u \cdot v}{\|v\|^2} (v \cdot u) + \frac{(u \cdot v)(\overline{u \cdot v})}{\|v\|^4} \|v\|^2 \\ \|w\|^2 \|v\|^2 &= \|u\|^2 \|v\|^2 - 2(u \cdot v)(\overline{u \cdot v}) + (u \cdot v)(\overline{u \cdot v}) \end{aligned}$$

These are non-negative real values and thus,  $\|u\|^2 \|v\|^2 \geq |u \cdot v|^2$  and the equality holds if and only if  $w = 0$ , that is, whenever  $u$  and  $v$  are linearly dependent.

(1): It suffices to compute

$$\begin{aligned} \|u + v\|^2 &= \|u\|^2 + \|v\|^2 + u \cdot v + v \cdot u \\ &= \|u\|^2 + \|v\|^2 + 2 \operatorname{Re}(u \cdot v) \\ &\leq \|u\|^2 + \|v\|^2 + 2|u \cdot v| \leq \|u\|^2 + \|v\|^2 + 2\|u\| \|v\| \\ &= (\|u\| + \|v\|)^2 \end{aligned}$$

Since we deal with squares of non-negative real numbers, this means that  $\|u + v\| \leq \|u\| + \|v\|$ . Furthermore, equality implies that in all previous inequalities equality also holds. This is equivalent to the condition that  $u$  and  $v$  are linearly dependent (using the previous part).

(3), (4): Let  $(e_1, \dots, e_k)$  be an orthonormal system of vectors. We extend it to an orthonormal basis  $(e_1, \dots, e_n)$  (that is always possible by the previous theorem). Then, again using the previous theorem, we have for every vector  $u \in V$

$$\|u\|^2 = \sum_{i=1}^n (u \cdot e_i)(\overline{u \cdot e_i}) = \sum_{i=1}^n |u \cdot e_i|^2 \geq \sum_{i=1}^k |u \cdot e_i|^2$$

But that is the Bessel inequality. Furthermore, equality holds if and only if  $u \cdot e_i = 0$  for all  $i > k$ , which proves the Parseval equality.

(5): Choose an arbitrary  $v \in \text{span}\{e_1, \dots, e_k\}$  and extend the given orthonormal system to the orthonormal basis  $(e_1, \dots, e_n)$ . Let  $(u_1, \dots, u_n)$  and  $(x_1, \dots, x_k, 0, \dots, 0)$  be

$U$ , where  $X$  is a lower triangular matrix given by the Gaussian reduction, and  $U$  upper triangular. From this equality  $A = X^{-1}U$ , which is the desired decomposition. (Thus we have to compute the inverse of  $X$ ).  $\square$

**3.F.3.** Find the LU-decomposition of the matrix  $\begin{pmatrix} 1 & 1 & 0 \\ 1 & -1 & 2 \\ - & 1 & -1 \end{pmatrix}$ .  $\circ$

**3.F.4. Ray-tracing.** In computer 3D-graphics the image is very often displayed using the Ray-tracing algorithm. The basis of this algorithm is an approximation of the light waves by a ray (line) and an approximation of the displayed objects by polyhedrons. These are bounded by planes and it is necessary to compute where exactly the light rays are reflected from these planes. From physics we know how the rays are reflected – the angle of impact equals the angle of reflection. We have already met this topic in the exercise 1.E.10.

The ray of light in the direction  $v = (1, 2, 3)$  hits the plane given by the equation  $x + y + z = 1$ . In what direction is it reflected?

**Solution.** The unit normal vector to the plane is  $n = \frac{1}{\sqrt{3}}(1, 1, 1)$ . The vector that gives the direction of the reflected ray  $v_R$  lies in the plane given by the vectors  $v, n$ . We can express it as a linear combination of these vectors. Furthermore, the rule for the angle of reflection says that  $\langle v, n \rangle = -\langle v_R, n \rangle$ . From there we obtain a quadratic equation for the coefficient of the linear combination.

This exercise can be solved in an easier, more geometric way. From the diagram we can derive directly that

$$v_R = v - 2\langle v, n \rangle n$$

. In our case,  $v_R = (-3, -2, -1)$ .  $\square$

**3.F.5. Singular decomposition, polar decomposition, pseudoinverse.** Compute the singular decomposition of the matrix

$$A = \begin{pmatrix} 0 & 0 & -\frac{1}{2} \\ -1 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix}$$

. Then compute its polar decomposition and find its pseudoinverse.

**Solution.** First compute  $A^T A$ :

$$A^T A = \begin{pmatrix} 0 & -1 & 0 \\ 0 & 0 & 0 \\ -\frac{1}{2} & 0 & 0 \end{pmatrix} \begin{pmatrix} 0 & 0 & -\frac{1}{2} \\ -1 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix} = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & \frac{1}{4} \end{pmatrix}$$

coordinates of  $u$  and  $v$  under this basis. Then

$$\|u-v\|^2 = |u_1-x_1|^2 + \dots + |u_k-x_k|^2 + |u_{k+1}|^2 + \dots + |u_n|^2$$

and this expression is clearly minimized when choosing the individual vectors to be  $x_1 = u_1, \dots, x_k = u_k$ .  $\square$

**3.4.4. Unitary and orthogonal mappings.** The properties of orthogonal mappings have direct analogues in the complex domain. We can easily formulate them and prove together:

**Proposition.** Consider the linear mapping (endomorphism)  $\varphi : V \rightarrow V$  on the (real or complex) space with scalar product. Then the following conditions are equivalent.

- (1)  $\varphi$  is unitary or orthogonal transformation,
- (2)  $\varphi$  is linear isomorphism and for every  $u, v \in V$

$$\varphi(u) \cdot v = u \cdot \varphi^{-1}(v),$$

- (3) the matrix  $A$  of the mapping  $\varphi$  in any orthonormal basis satisfies  $A^{-1} = \bar{A}^T$  (for Euclidean spaces this means that  $A^{-1} = A^T$ ),
- (4) the matrix  $A$  of a mapping  $\varphi$  in some orthonormal basis satisfies  $A^{-1} = \bar{A}^T$ ,
- (5) the rows of the matrix  $A$  of the mapping  $\varphi$  in an orthonormal basis form an orthonormal basis of the space  $\mathbb{K}^n$  with standard scalar product,
- (6) the columns of the matrix  $A$  of the mapping  $\varphi$  in an orthonormal basis form an orthonormal basis of the space  $\mathbb{K}^n$  with standard scalar product.

**PROOF.** (1)  $\Rightarrow$  (2): The mapping  $\varphi$  is injective, therefore it must be onto. Also  $\varphi(u) \cdot v = \varphi(u) \cdot \varphi(\varphi^{-1}(v)) = u \cdot \varphi^{-1}(v)$ .

(2)  $\Rightarrow$  (3): The standard scalar product is in  $\mathbb{K}^n$ . It is given for columns  $x, y$  of scalars by the expression  $x \cdot y = \bar{y}^T E x = \bar{y} x$ , where  $E$  is the unit matrix. Property (2) thus means that the matrix  $A$  of the mapping  $\varphi$  is invertible and  $\bar{y}^T A x = (\bar{A}^{-1} y)^T x$ . This means that  $(\bar{y}^T A - (\bar{A}^{-1} y)^T) x = 0$  for all  $x \in \mathbb{K}^n$ . By substituting the complex conjugate of the expression in the parentheses for  $x$  we find that equality is possible only when  $\bar{A}^T = A^{-1}$ . (We may also rewrite the expression as  $\bar{y}^T (A - (\bar{A}^{-1})^T) x$  and see the conclusion by substituting the basis vectors for  $x$  and  $y$ .)

- (3)  $\Rightarrow$  (4): This is an obvious implication.
- (4)  $\Rightarrow$  (5) In the relevant basis, the claim is expressed via the matrix  $A$  of the mapping  $\varphi$  as the equation  $A \bar{A}^T = E$ , which is ensured by (4).
- (5)  $\Rightarrow$  (6): We have  $|\bar{A}^T A| = |E| = |A \bar{A}^T| = |A| |\bar{A}| = 1$ , there exists the inverse matrix  $A^{-1}$ . But we also have  $A \bar{A}^T A = A$ , therefore also  $\bar{A}^T A = E$  which is expressed exactly by (6).

(6)  $\Rightarrow$  (1): In the chosen orthonormal basis

$$\varphi(u) \cdot \varphi(v) = (\bar{A} y)^T A x = \bar{y}^T \bar{A}^T A x = \bar{y}^T E x = \bar{y}^T x$$

where  $x$  and  $y$  are columns of coordinates of the vectors  $u$  and  $v$ . That ensures that the scalar product is preserved.  $\square$

to obtain a diagonal matrix. We need to find an orthonormal basis under which the matrix is diagonal and the zero row is the last one. This can be obtained by rotating about the  $x$ -axis through a right angle. The  $y$ -coordinate then goes to  $z$  and  $z$  goes to  $-y$ . This rotation is an orthogonal transformation given by the matrix  $V = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 0 & 1 \\ 0 & -1 & 0 \end{pmatrix}$ . By this, we have found the decomposition  $A^T A = V B V^T$ . here,  $B$  is diagonal with eigenvalues  $(1, \frac{1}{4}, 0)$  on the diagonal. Because  $B = (AV)^T(AV)$ , the columns of the matrix

$$AV = \begin{pmatrix} 0 & 0 & -\frac{1}{2} \\ -1 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix} \begin{pmatrix} 1 & 0 & 0 \\ 0 & 0 & 1 \\ 0 & -1 & 0 \end{pmatrix} = \begin{pmatrix} 0 & \frac{1}{2} & 0 \\ -1 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix}$$

form an orthogonal system of vectors, which we normalise and extend to a basis. That is then of the form  $(0, -1, 0), (1, 0, 0), (0, 0, 1)$ . The transition matrix of changing from this basis to the standard one is then

$$U = \begin{pmatrix} 0 & 1 & 0 \\ -1 & 0 & 0 \\ 0 & 0 & 1 \end{pmatrix}.$$

Finally, we obtain the decomposition  $A = U\sqrt{B}V^T$

$$\begin{pmatrix} 0 & 0 & -\frac{1}{2} \\ -1 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix} = \begin{pmatrix} 0 & 1 & 0 \\ -1 & 0 & 0 \\ 0 & 0 & 1 \end{pmatrix} \begin{pmatrix} 1 & 0 & 0 \\ 0 & \frac{1}{2} & 0 \\ 0 & 0 & 0 \end{pmatrix} \begin{pmatrix} 1 & 0 & 0 \\ 0 & 0 & -1 \\ 0 & 1 & 0 \end{pmatrix}.$$

The geometrical interpretation of decomposition is the following: first, everything is rotated through a right angle by the  $x$ -axis, then follows a projection to the  $xy$  plane such that the unit ball is mapped on the ellipse with major half-axes 1 and  $\frac{1}{2}$ . The result is then rotated through a right angle about the  $z$ -axis.

The polar decomposition  $A = P \cdot W$  can be obtained from the singular one:  $P := U\sqrt{B}U^T$  and  $W := UV^T$ , that is,

$$P = \begin{pmatrix} 0 & 1 & 0 \\ -1 & 0 & 0 \\ 0 & 0 & 1 \end{pmatrix} \begin{pmatrix} 1 & 0 & 0 \\ 0 & \frac{1}{2} & 0 \\ 0 & 0 & 0 \end{pmatrix} \begin{pmatrix} 0 & -1 & 0 \\ 1 & 0 & 0 \\ 0 & 0 & 1 \end{pmatrix} \\ = \begin{pmatrix} \frac{1}{2} & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 0 \end{pmatrix}$$

and

$$W = \begin{pmatrix} 0 & 1 & 0 \\ -1 & 0 & 0 \\ 0 & 0 & 1 \end{pmatrix} \begin{pmatrix} 1 & 0 & 0 \\ 0 & 0 & -1 \\ 0 & 1 & 0 \end{pmatrix} = \begin{pmatrix} 0 & 0 & -1 \\ -1 & 0 & 0 \\ 0 & 1 & 0 \end{pmatrix}.$$

Characterizations from the previous theorem deserve some notes. The matrices  $A \in \text{Mat}_n(\mathbb{K})$  with the property  $A^{-1} = \bar{A}^T$  are called *unitary matrices* for complex scalars (in the case  $\mathbb{R}$  we have already used the name *orthogonal matrices* for them). The definition itself immediately implies that a product of unitary (orthogonal) matrices is again unitary (orthogonal). The same is true for inverses. Unitary matrices thus form a subgroup  $U(n) \subset \text{GL}_n(\mathbb{C})$  in the group of all invertible complex matrices with the product operation. Orthogonal matrices form a subgroup  $O(n) \subset \text{GL}_n(\mathbb{R})$  in the group of real invertible matrices. We speak of a *unitary group* and of an *orthogonal group*.

The simple calculation

$$1 = \det E = \det(A\bar{A}^T) = \det A \overline{\det A} = |\det A|^2$$

shows that the determinant of a unitary matrix has norm equal to one. For real scalars the determinant is  $\pm 1$ . Furthermore, if  $Ax = \lambda x$  for a unitary or orthogonal matrix, then  $(Ax) \cdot (Ax) = x \cdot x = |\lambda|^2(x \cdot x)$ . Therefore the real eigenvalues of orthogonal matrices in the real domain are  $\pm 1$ . The eigenvalues of unitary matrices are always complex units in the complex plane.

The same argument as we have seen with the orthogonal mappings imply that orthogonal complements of invariant subspaces with respect to unitary mappings  $\varphi : V \rightarrow V$  are also invariant. Indeed, if  $\varphi(U) \subset U, u \in U$  and  $v \in U^\perp$  are arbitrary, then

$$\varphi(v) \cdot \varphi(\varphi^{-1}(u)) = v \cdot \varphi^{-1}(u).$$

Because the restriction  $\varphi|_U$  is also unitary, it is a bijection. Notably  $\varphi^{-1}(u) \in U$ . But then  $\varphi(v) \cdot u = 0$ , because  $v \in U^\perp$ . Thus  $\varphi(v) \in U^\perp$ .

This leads to an immediate useful corollary in the complex domain

**Corollary.** *Let  $\varphi : V \rightarrow V$  be a unitary mapping of complex vector spaces. Then  $V$  is an orthogonal sum of one-dimensional eigensubspaces.*

PROOF. There exists at least one eigenvector  $v \in V$ , since complex eigenvalues always exist. Then the restriction of  $\varphi$  to the invariant subspace  $\langle v \rangle^\perp$  is again unitary and also has an eigenvector. After  $n$  such steps we obtain the desired orthogonal basis of eigenvectors. After normalising the vectors we obtain an orthonormal basis.  $\square$

Now it is possible to understand the details of the proof of the spectral decomposition of the orthogonal mapping from 2.4.7 at the end of the second chapter. The real matrix of an orthogonal mapping is interpreted as a matrix of a unitary mapping on a complex extension of Euclidean space. We observe the corollaries of the structure of the roots of the real characteristic polynomial over the complex domain. Automatically we obtain invariant two-dimensional subspaces given by pairs of complex conjugated eigenvalues and hence the corresponding rotation for restricted original real mapping.

From this it follows that

$$\begin{pmatrix} 0 & 0 & -\frac{1}{2} \\ -1 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix} = \begin{pmatrix} \frac{1}{2} & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 0 \end{pmatrix} \begin{pmatrix} 0 & 0 & -1 \\ -1 & 0 & 0 \\ 0 & 1 & 0 \end{pmatrix}$$

The pseudoinverse matrix is then given by the expression

$$A^{(-1)} := VS^U^T, \text{ where } S^U = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 2 & 0 \\ 0 & 0 & 0 \end{pmatrix}. \text{ Thus,}$$

$$\begin{aligned} A^{(-1)} &= \\ &= \begin{pmatrix} 1 & 0 & 0 \\ 0 & 0 & 1 \\ 0 & -1 & 0 \end{pmatrix} \begin{pmatrix} 1 & 0 & 0 \\ 0 & 2 & 0 \\ 0 & 0 & 0 \end{pmatrix} \begin{pmatrix} 0 & -1 & 0 \\ 1 & 0 & 0 \\ 0 & 0 & 1 \end{pmatrix} \\ &= \begin{pmatrix} 0 & -1 & 0 \\ 0 & 0 & 0 \\ 2 & 0 & 0 \end{pmatrix} \end{aligned}$$

□

**3.F.6. QR decomposition.** The QR decomposition of a matrix  $A$  is very useful when we are given a system of linear equations  $Ax = b$  which has no solution, but an approximation as good as possible is needed. That is, we want to minimize  $\|Ax - b\|$ . According to the Pythagorean theorem,  $\|Ax - b\|^2 = \|Ax - b_{\parallel}\|^2 + \|b_{\perp}\|^2$ , where  $b$  is decomposed into  $b_{\parallel}$  which belongs to the range of the linear transformation  $A$ , and into  $b_{\perp}$ , which is perpendicular to this range. The projection on the range of  $A$  can be written in the form  $QQ^T$  for a suitable matrix  $Q$ . Specifically for this matrix we obtain it by the Gram-Schmidt orthonormalisation of the columns of the matrix  $A$ . Then  $Ax - b_{\parallel} = Q(Q^T Ax - Q^T b)$ . The system in the parentheses has a solution, for which  $\|Ax - b\| = \|b_{\perp}\|$ , which is the minimal value. Furthermore, the matrix  $R := Q^T A$  is upper triangular and therefore the approximate solution can be found easily.

Find an approximate solution of the system

$$\begin{aligned} x + 2y &= 1 \\ 2x + 4y &= 4 \end{aligned}$$

**Solution.** Consider the system  $Ax = b$  with  $A = \begin{pmatrix} 1 & 2 \\ 2 & 4 \end{pmatrix}$  and  $b = \begin{pmatrix} 1 \\ 4 \end{pmatrix}$ , which evidently has no solution. We orthonormalise the columns of  $A$ . We take the first of them and divide it by its norm. This yields the first vector of the orthonormal basis  $\frac{1}{\sqrt{5}} \begin{pmatrix} 1 \\ 2 \end{pmatrix}$ . But the second is twice the first and thus it will be after orthonormalisation. Therefore  $Q = \frac{1}{\sqrt{5}} \begin{pmatrix} 1 & 2 \\ 2 & 4 \end{pmatrix}$ . The projector on the range of  $A$  is then  $QQ^T = \frac{1}{5} \begin{pmatrix} 1 & 2 \\ 2 & 4 \end{pmatrix}$ .

**3.4.5. Dual and adjoint mappings.** When discussing vector spaces and linear mappings in the second chapter, we mentioned briefly the dual vector space  $V^*$  of all linear forms over the vector space  $V$ , see 2.3.17. This duality extends to mappings:

DUAL MAPPINGS

For any linear mapping  $\psi : V \rightarrow W$ , the expression

$$(1) \quad \langle v, \psi^*(\alpha) \rangle = \langle \psi(v), \alpha \rangle,$$

where  $\langle \cdot, \cdot \rangle$  denotes the evaluation of the linear forms (the second argument) on the vectors (the first argument), while  $v \in V$  and  $\alpha \in W^*$  are arbitrary, defines the mapping  $\psi^* : W^* \rightarrow V^*$  called the *dual mapping* to  $\psi$ .

Choose bases  $\underline{v}$  in  $V$ ,  $\underline{w}$  in  $W$  and write  $A$  for the matrix of the mapping  $\psi$  in these bases. Then we compute the matrix of the mapping  $\psi^*$  in the corresponding dual bases in the dual spaces. Indeed, the definition says that if we represent the vectors from  $W^*$  in the coordinates as rows of scalars, then the mapping  $\psi^*$  is given by the same matrix as  $\psi$ , if we multiply by it the row vectors from the right:

$$\langle \psi(v), \alpha \rangle = (\alpha_1, \dots, \alpha_n) \cdot A \cdot \begin{pmatrix} v_1 \\ \vdots \\ v_n \end{pmatrix} = \langle v, \psi^*(\alpha) \rangle.$$

This means that the matrix of the dual mapping  $\psi^*$  is the transpose  $A^T$ , because  $\alpha \cdot A = (A^T \cdot \alpha^T)^T$ .

Assume further that we have a vector space with scalar product. Then we can naturally identify  $V$  and  $V^*$  using the scalar product. Indeed, choosing one fixed vector  $w \in V$ , we substitute this vector into the second argument in the scalar product in order to obtain the identification  $V \simeq V^* = \text{Hom}(V, \mathbb{K})$

$$V \ni w \mapsto (v \mapsto \langle v, w \rangle) \in V^*.$$

The non-degeneracy condition on the scalar product ensures that this mapping is a bijection. Notice it is important to use  $w$  as the fixed second argument in the case  $\mathbb{K} = \mathbb{C}$  in order to obtain linear forms. Since factorizing complex multiples in the second argument yields complex conjugated scalars, the identification  $V \simeq V^*$  is linear over real scalars only.

It is clear that the vectors of an orthonormal basis are mapped to forms that constitute the dual basis, i.e. the orthonormal basis are selfdual under our identification. Moreover, every vector is automatically understood as a linear form, by means of the scalar product.

How does the above dual mapping  $W^* \rightarrow V^*$  look in terms of our identification? We use the same notation  $\psi^* : W \rightarrow V$  for the resulting mapping, which is uniquely given as follows:

Next,

$$Q^T b = \frac{1}{\sqrt{5}} \begin{pmatrix} 1 & 2 \\ 2 & 4 \end{pmatrix} \begin{pmatrix} 1 \\ 4 \end{pmatrix} = \frac{9}{\sqrt{5}}$$

and

$$R = \frac{1}{\sqrt{5}} \begin{pmatrix} 1 & 2 \\ 2 & 4 \end{pmatrix} \begin{pmatrix} 1 & 2 \\ 2 & 4 \end{pmatrix} = \frac{1}{\sqrt{5}} \begin{pmatrix} 5 & 9 \\ 9 & 17 \end{pmatrix}.$$

The approximate solution then satisfies  $Rx = Q^T b$ , and here that means  $5x + 9y = 9$ . (The approximate solution is not unique). The QR decomposition of the matrix  $A$  is then

$$\begin{pmatrix} 1 & 2 \\ 2 & 4 \end{pmatrix} = \frac{1}{\sqrt{5}} \begin{pmatrix} 1 \\ 2 \end{pmatrix} \frac{1}{\sqrt{5}} \begin{pmatrix} 5 & 9 \end{pmatrix}$$

□

**3.F.7.** Minimise  $\|Ax - b\|$  for  $A = \begin{pmatrix} 2 & -1 & -1 \\ -1 & 2 & -1 \\ -1 & -1 & 2 \end{pmatrix}$  and

$b = \begin{pmatrix} 1 \\ 0 \\ 0 \end{pmatrix}$ . Hence write down the QR decomposition of the matrix  $A$ .

**Solution.** The normalised first column of the matrix  $A$  is  $e_1 = \frac{1}{\sqrt{6}} \begin{pmatrix} 2 \\ -1 \\ -1 \end{pmatrix}$ . From the second column, subtract its component in the direction  $e_1$ . Then

$$\left\langle \begin{pmatrix} -1 \\ 2 \\ -1 \end{pmatrix}, \frac{1}{\sqrt{6}} \begin{pmatrix} 2 \\ -1 \\ -1 \end{pmatrix} \right\rangle = -\frac{3}{\sqrt{6}}$$

and therefore

$$\begin{pmatrix} -1 \\ 2 \\ -1 \end{pmatrix} - \left\langle \begin{pmatrix} -1 \\ 2 \\ -1 \end{pmatrix}, \frac{1}{\sqrt{6}} \begin{pmatrix} 2 \\ -1 \\ -1 \end{pmatrix} \right\rangle \frac{1}{\sqrt{6}} \begin{pmatrix} 2 \\ -1 \\ -1 \end{pmatrix} = \frac{1}{2} \begin{pmatrix} 0 \\ 3 \\ 3 \end{pmatrix}$$

By this we have created an orthogonal vector, which we normalise to obtain  $e_2 = \frac{1}{\sqrt{2}} \begin{pmatrix} 0 \\ 1 \\ -1 \end{pmatrix}$ . The third column of the matrix  $A$  is already linearly dependent (verify this by computing the determinant, or otherwise). The desired column-orthogonal matrix is then

$$Q = \frac{1}{\sqrt{6}} \begin{pmatrix} 2 & 0 \\ -1 & \sqrt{3} \\ -1 & -\sqrt{3} \end{pmatrix}$$

Next,

$$\begin{aligned} R = Q^T A &= \frac{1}{\sqrt{6}} \begin{pmatrix} 2 & -1 & -1 \\ 0 & \sqrt{3} & -\sqrt{3} \end{pmatrix} \begin{pmatrix} 2 & -1 & -1 \\ -1 & 2 & -1 \\ -1 & -1 & 2 \end{pmatrix} \\ &= \frac{1}{\sqrt{6}} \begin{pmatrix} 6 & -3 & -3 \\ 0 & 3\sqrt{3} & -3\sqrt{3} \end{pmatrix} \end{aligned}$$

and

$$Q^T b = \frac{1}{\sqrt{6}} \begin{pmatrix} 2 & -1 & -1 \\ 0 & \sqrt{3} & -\sqrt{3} \end{pmatrix} \begin{pmatrix} 1 \\ 0 \\ 0 \end{pmatrix} = \frac{1}{\sqrt{6}} \begin{pmatrix} 2 \\ 0 \end{pmatrix}.$$

### ADJOINT MAPPING

For every linear mapping  $\psi : V \rightarrow W$  between spaces with scalar products, there is the *adjoint mapping*  $\psi^*$  uniquely determined by the formula

$$(2) \quad \langle \psi(u), v \rangle = \langle u, \psi^*(v) \rangle.$$

The parentheses means the scalar products on  $W$  or  $V$ , respectively.

Notice that the use of the same parenthesis for evaluation of one-forms and scalar products (which reflects the identification above) makes the defining formulae of dual and adjoint mappings look the same.

Equivalently we can understand the relation (2) to be the definition of the adjoint mapping  $\psi^*$ . By substituting all pairs of vectors from an orthonormal basis for the vectors  $u$  and  $v$  we obtain directly all the values of the matrix of the mapping  $\psi^*$ .

Using the coordinate expression for the scalar product, the formula (2) reveals the coordinate expression of the adjoint mapping:

$$\begin{aligned} \langle \psi(v), w \rangle &= \overline{(w_1, \dots, w_n)} \cdot A \cdot \begin{pmatrix} v_1 \\ \vdots \\ v_n \end{pmatrix} \\ &= \overline{\left( \bar{A}^T \cdot \begin{pmatrix} w_1 \\ \vdots \\ w_n \end{pmatrix} \right)^T} \cdot \begin{pmatrix} v_1 \\ \vdots \\ v_n \end{pmatrix} = \langle v, \psi^*(w) \rangle. \end{aligned}$$

It follows that if  $A$  is the matrix of the mapping  $\psi$  in an orthonormal basis, then the matrix of the adjoint mapping  $\psi^*$  is the transposed and conjugated matrix  $A^*$  – we denote this by  $A^* = \bar{A}^T$ .

The matrix  $A^*$  is called the *adjoint matrix* of the matrix  $A$ . Note that the adjoint matrix is well defined for any rectangular matrix. We should not confuse them with algebraic adjoints, which we used for square matrices when working with determinants.

We can summarise. For any linear mapping  $\psi : V \rightarrow W$  between unitary spaces, with matrix  $A$  in some bases on  $V$  and  $W$ , its dual mapping has the matrix  $A^T$  in the dual basis. If there are scalar products on  $V$  and  $W$ , we identify them (via the scalar products) with their duals. Then the dual mapping coincides with the adjoint mapping  $\psi^* : W \rightarrow V$ , which has the matrix  $A^*$ . The distinction between the matrix of the dual mapping and the matrix of the adjoint mapping is thus in the additional conjugation. This is of course a consequence of the fact that our identification of the unitary space with its dual is not a linear mapping over complex scalars.

**3.4.6. Self-adjoint mappings.** Those linear mappings which coincide with their adjoints:  $\psi^* = \psi$ , are of particular interest. They are called *self-adjoint mappings*. Equivalently we can say that they are the mappings whose matrix  $A$  satisfies  $A = A^*$  in some (and thus in all) orthonormal basis.

The solution of the equation  $Rx = Q^T b$  is  $x = y = z$ . Thus, multiples of the vector  $(1, 1, 1)$  minimize  $\|Ax - b\|$ .

The mapping given by the matrix  $A$  is a projection on the plane with normal vector  $(1, 1, 1)$ .

□

**3.F.8. Linear regression.** The knowledge obtained in this chapter can be successfully used in practice for solving problems with linear regression. It is about finding the best approximation of some functional dependence using a linear function.

Given a functional dependence for some points that is,  $f(a_1^1, \dots, a_n^1) = y_1, \dots, f(a_1^k, a_2^k, \dots, a_n^k) = y_k, k > n$  (we have thus more equations than unknowns) and we wish to find the “best possible” approximation of this dependency using a linear function. That is, we want to express the value of the property as a linear function  $f(x_1, \dots, x_n) = b_1 x_1 + b_2 x_2 + \dots + b_n x_n + c$ . We choose to define “best possible” by the minimisation of

$$\sum_{i=1}^k \left( y_i - \sum_{j=1}^n (b_j x_j + c) \right)^2$$

with regard to the real constants  $b_1, \dots, b_n, c$ . The goal is to find such a linear combination of the columns of the matrix  $A = (a_j^i)$  (with coefficients  $b_1, \dots, b_n$ ), that is closest to the vector  $(y_1, \dots, y_k)$  in  $\mathbb{R}^k$ . Thus it is about finding an orthogonal projection of the vector  $(y_1, \dots, y_k)$  on the subspace generated by the columns of the matrix  $A$ . Using the theorem 3.5.7 this projection is the vector  $(b_1, \dots, b_n)^T = A^{(-1)}(y_1, \dots, b_n)$ .

**3.F.9.** Using the least squares method, solve the system

$$\begin{aligned} 2x + y + 2z &= 1 \\ x + y + 3z &= 2 \\ 2x + y + z &= 0 \\ x + z &= -1 \end{aligned}$$

**Solution.** The system has no solution, since its matrix has rank 3, and the extended matrix has rank 4. The best approximation of the vector  $b = (1, 2, 0, -1)$  can thus be obtained using the theorem 3.5.7 by the vector  $A^{(-1)}b$ .  $AA^{(-1)}b$  is then the best approximation – the perpendicular projection

In the case of Euclidean spaces the self-adjoint mappings are those with symmetric matrices (in orthonormal basis). They are often called *symmetric mappings*.

In the complex domain the matrices that satisfy  $A = A^*$  are called *Hermitian matrices* or also *Hermitian symmetric matrices*. Sometimes they are also called *self-adjoint matrices*. Note that Hermitian matrices form a real vector subspace in the space of all complex matrices, but it is not a vector subspace in the complex domain.

**Remark.** The next observation is of special interest. If we multiply a Hermitian matrix  $A$  by the imaginary unit, we obtain the matrix  $B = iA$ , which has the property

$$B^* = \bar{i} \bar{A}^T = -B.$$

Such matrices are called *anti-Hermitian* or *Hermitian skew-symmetric*. Every real matrix can be written as a sum of its symmetric part and its anti-symmetric part,

$$A = \frac{1}{2}(A + A^T) + \frac{1}{2}(A - A^T).$$

In the complex domain we have analogously

$$A = \frac{1}{2}(A + A^*) + i \frac{1}{2i}(A - A^*).$$

In particular, we may express every complex matrix in a unique way as a sum

$$A = B + iC$$

with Hermitian symmetric matrices  $B = \frac{1}{2}(A + A^*)$  and  $C = \frac{1}{2i}(A - A^*)$ . This is an analogy of the decomposition of a complex number into its real and purely imaginary component and in the literature we often encounter the notation

$$B = \text{re } A = \frac{1}{2}(A + A^*), \quad C = \text{im } A = \frac{1}{2i}(A - A^*).$$

In the language of linear mappings this means that every complex linear automorphism can be uniquely expressed by means of two self-adjoint mappings playing the role of the real and imaginary parts of the original mapping.

**3.4.7. Spectral decomposition.** Consider a self-adjoint mapping  $\psi : V \rightarrow V$  with the matrix  $A$  in some orthonormal basis. Proceed similarly as in 2.4.7 when we diagonalized the matrix of orthogonal mappings.

Again, consider arbitrary invariant subspaces of self-adjoint mappings and their orthogonal complements. If a self-adjoint mapping  $\psi : V \rightarrow V$  leaves a subspace  $W \subset V$  invariant, i.e.  $\psi(W) \subset W$ , then for every  $v \in W^\perp, w \in W$

$$\langle \psi(v), w \rangle = \langle v, \psi(w) \rangle = 0.$$

Thus also,  $\psi(W^\perp) \subset W^\perp$ .

Next, consider the matrix  $A$  of a self-adjoint mapping in an orthonormal basis and an eigenvector  $x \in \mathbb{C}^n$ , i.e.  $A \cdot x = \lambda x$ . We obtain

$$\lambda \langle x, x \rangle = \langle Ax, x \rangle = \langle x, Ax \rangle = \langle x, \lambda x \rangle = \bar{\lambda} \langle x, x \rangle.$$

of the vector  $b$  on the space generated by the columns of the matrix  $A$ .

Because the columns of the matrix  $A$  are linearly independent, its pseudoinverse is given by the relation  $(A^T A)^{-1} A^T$ . Hence

$$\begin{aligned} A^{(-1)} &= \left( \begin{pmatrix} 2 & 1 & 2 \\ 1 & 1 & 3 \\ 2 & 1 & 1 \\ 1 & 0 & 1 \end{pmatrix} \begin{pmatrix} 2 & 1 & 2 & 1 \\ 1 & 1 & 1 & 0 \\ 2 & 3 & 1 & 1 \end{pmatrix} \right)^{-1} \begin{pmatrix} 2 & 1 & 2 & 1 \\ 1 & 1 & 1 & 0 \\ 2 & 3 & 1 & 1 \end{pmatrix} \\ &= \left( \begin{pmatrix} 10 & 5 & 10 \\ 5 & 3 & 6 \\ 10 & 6 & 15 \end{pmatrix} \right)^{-1} \begin{pmatrix} 2 & 1 & 2 & 1 \\ 1 & 1 & 1 & 0 \\ 2 & 3 & 1 & 1 \end{pmatrix} \\ &= \begin{pmatrix} 3/5 & -1 & 0 \\ -1 & 10/3 & -2/3 \\ 0 & -2/3 & 1/3 \end{pmatrix} \begin{pmatrix} 2 & 1 & 2 & 1 \\ 1 & 1 & 1 & 0 \\ 2 & 3 & 1 & 1 \end{pmatrix} \\ &= \begin{pmatrix} 1/5 & -2/5 & 1/5 & 3/5 \\ 0 & 1/3 & 2/3 & -5/3 \\ 0 & 1/3 & -1/3 & 1/3 \end{pmatrix} \end{aligned}$$

The desired  $\mathbf{x}$  is

$$A^{(-1)}b = (-6/5, 7/3, 1/3)^T.$$

The projection (the best possible approximation to the column of the right side) is then the vector  $(3/5, 32/15, 4/15, -13/15)$ .  $\square$

The positive real number  $\langle x, x \rangle$  can be cancelled on both sides and thus  $\bar{\lambda} = \lambda$ , and we see that eigenvalues of Hermitian matrices are always real.

The characteristic polynomial  $\det(A - \lambda E)$  has as many complex roots as is the dimension of the square matrix  $A$  (including multiplicities), and all of them are actually real. Thus we have proved the important general result:

**Proposition.** *The orthogonal complements of invariant subspaces of self-adjoint mappings are also invariant. Furthermore, the eigenvalues of a Hermitian matrix  $A$  are always real.*

The very definition ensures that restriction of a self-adjoint mapping to an invariant subspace is again self-adjoint. Thus the latter proposition implies that there always exists an orthonormal basis of  $V$  composed of eigenvectors. Indeed, start with any eigenvector  $v_1$ , normalize it, consider its linear hull  $V_1$  and restrict the mapping to  $V_1^\perp$ . Consider next another eigenvector  $v_2 \in V_1^\perp$ , take  $V_2 = \text{span}(V_1 \cup \{v_2\})$ , which is again invariant. Continue and construct the sequence of invariant subspaces  $V_1 \subset V_2 \subset \dots \subset V_n = V$ , building the orthonormal basis of eigenvectors, as expected.

Actually, it is easy to see directly that eigenvectors associated with different eigenvalues are perpendicular to each other. Indeed, if  $\psi(u) = \lambda u$ ,  $\psi(v) = \mu v$  then we obtain

$$\lambda \langle u, v \rangle = \langle \psi(u), v \rangle = \langle u, \psi(v) \rangle = \bar{\mu} \langle u, v \rangle = \mu \langle u, v \rangle.$$

Usually this result is formulated using projections onto eigensubspaces. Recall the properties of projections along subspaces, as discussed in 2.3.19. A projection  $P : V \rightarrow V$  is a linear mapping satisfying  $P^2 = P$ . This means that the restriction of  $P$  to its image is the identity and the projector is completely determined by choosing the subspaces  $\text{Im } P$  and  $\text{Ker } P$ .

A projection  $P : V \rightarrow V$  is called *orthogonal* if  $\text{Im } P \perp \text{Ker } P$ . Two orthogonal projections  $P, Q$  are called *mutually perpendicular* if  $\text{Im } P \perp \text{Im } Q$ .

#### SPECTRAL DECOMPOSITION OF SELF-ADJOINT MAPPINGS

**Theorem** (Spectral decomposition). *For every self-adjoint mapping  $\psi : V \rightarrow V$  on a vector space with scalar product there exists an orthonormal basis composed of eigenvectors. If  $\lambda_1, \dots, \lambda_k$  are all distinct eigenvalues of  $\psi$  and if  $P_1, \dots, P_k$  are the corresponding orthogonal and mutually perpendicular projectors onto the eigenspaces corresponding to the eigenvalues, then*

$$\psi = \lambda_1 P_1 + \dots + \lambda_k P_k.$$

*The dimensions of the images of these projections  $P_i$  equal the algebraic multiplicities of the eigenvalues  $\lambda_i$ .*

**3.4.8. Orthogonal diagonalization.** Linear mappings which allow for orthonormal bases as in the latter theorem on spectral decomposition are called *orthogonally diagonalizable*. Of course, they are exactly the mappings for which we can find an orthonormal basis in which the matrix of the mapping is diagonal. We ask what they look like.

In the Euclidean case, this is simple: diagonal matrices are first of all symmetric, thus they are the self-adjoint mappings. As a corollary we note that an orthogonal mapping of an Euclidean space into itself is orthogonally diagonalizable if and only if it is self-adjoint. They are exactly the self-adjoint mappings with eigenvalues  $\pm 1$ .

The situation is much more interesting on unitary spaces. Consider any linear mapping  $\varphi : V \rightarrow V$  on a unitary space. Let  $\varphi = \psi + i\eta$  be the (unique) decomposition of  $\varphi$  into its Hermitian and anti-Hermitian part. If  $\varphi$  has diagonal matrix  $D$  in a suitable orthonormal basis, then  $D = \operatorname{Re} D + i \operatorname{Im} D$ , where the real and the imaginary parts are exactly the matrices of  $\psi$  and  $\eta$ . This follows from the uniqueness of the decomposition. Knowing this in the particular coordinates, we conclude the following computation relations at the level of mappings  $\psi \circ \eta = \eta \circ \psi$  (i.e. the real and imaginary parts of  $\varphi$  commute), and  $\varphi \circ \varphi^* = \varphi^* \circ \varphi$  (since this clearly holds for all diagonal matrices). The mappings  $\varphi : V \rightarrow V$  with the latter property are called the *normal mappings*.

A detailed characterization is given by the following theorem (stated in the notation of this paragraph):

**Theorem.** *The following conditions on a mapping  $\varphi : V \rightarrow V$  on a unitary space  $V$  are equivalent:*

- (1)  $\varphi$  is orthogonally diagonalizable,
- (2)  $\varphi^* \circ \varphi = \varphi \circ \varphi^*$  ( $\varphi$  is a normal mapping),
- (3)  $\psi \circ \eta = \eta \circ \psi$  (the Hermitian and anti-Hermitian parts commute),
- (4) if  $A = (a_{ij})$  is the matrix of  $\varphi$  in some orthonormal basis, and  $\lambda_i$  are the  $m = \dim V$  eigenvalues of  $A$ , then

$$\sum_{i,j=1}^m |a_{ij}|^2 = \sum_{i=1}^m |\lambda_i|^2.$$

**PROOF.** The implication (1)  $\Rightarrow$  (2) was discussed above. (2)  $\Leftrightarrow$  (3): it suffices to calculate

$$\varphi \circ \varphi^* = (\psi + i\eta)(\psi - i\eta) = \psi^2 + \eta^2 + i(\eta\psi - \psi\eta)$$

$$\varphi^* \circ \varphi = (\psi - i\eta)(\psi + i\eta) = \psi^2 + \eta^2 + i(\psi\eta - \eta\psi)$$

Subtraction of the two lines yields

$$\varphi\varphi^* - \varphi^*\varphi = 2i(\eta\psi - \psi\eta).$$

(2)  $\Rightarrow$  (1): If  $\varphi$  is normal, then

$$\begin{aligned} \langle \varphi(u), \varphi(u) \rangle &= \langle \varphi^* \varphi(u), u \rangle = \langle \varphi \varphi^*(u), u \rangle \\ &= \langle \varphi^*(u), \varphi^*(u) \rangle \end{aligned}$$

thus  $|\varphi(u)| = |\varphi^*(u)|$ .

Next, notice  $(\varphi - \lambda \operatorname{id} V)^* = (\varphi^* - \bar{\lambda} \operatorname{id} V)$ . Thus, if  $\varphi$  is normal, then  $(\varphi - \lambda \operatorname{id} V)$  is normal too.

If  $\varphi(u) = \lambda u$ , then  $u$  is in the kernel of  $\varphi - \lambda \text{id}_V$ . Thus the latter equality of norms of values for normal mappings and their adjoints ensures that  $u$  is also in the kernel of  $\varphi^* - \bar{\lambda} \text{id}_V$ . It follows that  $\varphi^*(u) = \bar{\lambda}u$ . We have proved, under the assumption (2), that  $\varphi$  and  $\varphi^*$  have the same eigenvectors and that they are associated to conjugated eigenvalues.

Similarly to our procedure with self-adjoint mappings, we now prove orthogonal diagonalizability. The latter procedure is based on the fact that the orthogonal complements to sums of eigenspaces are invariant subspaces.

Consider an eigenvector  $u \in V$  with eigenvalue  $\lambda$ , and any  $v \in \langle u \rangle^\perp$ . We have

$$\langle \varphi(v), u \rangle = \langle v, \varphi^*(u) \rangle = \langle v, \bar{\lambda}u \rangle = \lambda \langle u, v \rangle = 0.$$

Thus  $\varphi(v) \in \langle u \rangle^\perp$ . The same occurs if  $u$  is replaced by a sum of eigenvectors instead.

(1)  $\Rightarrow$  (4): the expression  $\sum_{i,j} |a_{ij}|^2$  is the trace of the matrix  $AA^*$ , which is the matrix of the mapping  $\varphi \circ \varphi^*$ . Therefore its value does not depend on the choice of the orthonormal basis. Thus if  $\varphi$  is diagonalizable, this expression equals exactly  $\sum_i |\lambda_i|^2$ .

(4)  $\Rightarrow$  (1): This part of the proof is a direct corollary of the Schur theorem on unitary triangulation of an arbitrary linear mapping  $V \rightarrow V$ , which we prove later in 3.4.15. This theorem says that for every linear mapping  $\varphi : V \rightarrow V$  there exists an orthonormal basis under which  $\varphi$  has an upper triangular matrix. Then all the eigenvalues of  $\varphi$  appear on its diagonal. Since we have already shown that the expression  $\sum_{i,j} |a_{ij}|^2$  does not depend on the choice of the orthonormal bases, all elements in the upper triangular matrix, which are not on the diagonal must be zero.  $\square$

**Remark.** We can rephrase the main statement of the latter theorem in terms of matrices. A mapping is normal if and only if its matrix  $A$  satisfies  $AA^* = A^*A$  in some orthonormal basis (and equivalently in any orthonormal basis). Such matrices are called *normal*. Moreover, we can consider the last theorem as a generalization of standard calculations with complex numbers. The linear mappings appear similar to complex numbers in their algebraic form. The role of real numbers is played by self-adjoint mappings, and the unitary mappings play the role of the complex units  $\cos t + i \sin t \in \mathbb{C}$ . The following consequence of the theorem shows the link to the property  $\cos^2 t + \sin^2 t = 1$ .

**Corollary.** *The unitary mappings on a unitary space  $V$  are exactly those normal mappings  $\varphi$  on  $V$  for which the unique decomposition  $\varphi = \psi + i\eta$  into Hermitian and anti-Hermitian parts satisfies  $\psi^2 + \eta^2 = \text{id}_V$ .*

**PROOF.** If  $\varphi$  is unitary, then  $\varphi\varphi^* = \text{id}_V = \varphi^*\varphi$  and thus  $\varphi\varphi^* = (\psi + i\eta)(\psi - i\eta) = \psi^2 + 0 + \eta^2 = \text{id}_V$ . On the other hand, if  $\varphi$  is normal, we can read the latter computation backwards which proves the other implication.  $\square$

**3.4.9. Roots of matrices.** Non-negative real numbers are exactly those which are squares of real numbers (and thus we may find their square roots). At the same time, their positive square roots are uniquely defined. Now we observe a similar behaviour of matrices of the form  $B = A^*A$ . Of course, these are the matrices of the compositions of mappings  $\varphi$  with their adjoints.

By definition,

$$(1) \quad \langle Bx, x \rangle = \langle A^*Ax, x \rangle = \langle Ax, Ax \rangle \geq 0$$

for all vectors  $x$ . Furthermore, we clearly have

$$B^* = (A^*A)^* = A^*A = B.$$

Hermitian matrices  $B$  with the property  $\langle Bx, x \rangle \geq 0$  for all  $x$  are called *positive semidefinite* matrices. If the zero value is attained only for  $x = 0$ , they are called *positive definite*. Analogously, we speak of *positive definite* and *positive semidefinite* (self-adjoint) mappings  $\varphi : V \rightarrow V$ .

For every mapping  $\varphi : V \rightarrow V$  we can define its *square root* as a mapping  $\psi$  such that  $\psi \circ \psi = \varphi$ . The next theorem completely describes the situation when restricting to positive semidefinite mappings.

POSITIVE SEMIDEFINITE SQUARE ROOTS

**Theorem.** For each positive semidefinite square matrix  $B$ , there is the uniquely defined positive semidefinite square root  $\sqrt{B}$ .

If  $P$  is any matrix such that  $P^{-1}BP = D$  is diagonal, then  $\sqrt{B} = P\sqrt{D}P^{-1}$ , where  $D$  has got the (non-negative) eigenvalues of  $B$  on its diagonal and  $\sqrt{D}$  is the matrix with the positive square roots of these values on its diagonal.

**PROOF.** Since  $B$  is a matrix of a self-adjoint mapping  $\varphi$ , there is even an orthonormal  $P$  as in the theorem (cf. Theorem 3.4.7) with all eigenvalues in the diagonal of  $D$  non-negative. Consider  $C = \sqrt{B}$  as defined in the second claim and notice that indeed

$$C^2 = P\sqrt{D}P^{-1}P\sqrt{D}P^{-1} = PDP^{-1} = B.$$

Thus the mapping  $\psi$  given by  $C$  must have the same eigenvectors as  $\varphi$  and thus these two mappings share the decompositions of  $\mathbb{K}^n$  into mutually orthogonal eigenspaces. In particular, both of them will share the bases in which they have diagonal matrices and thus the definition of  $\sqrt{D}$  must be unique in each such basis. This proves that the definition of  $\sqrt{B}$  does not depend on our particular choice of the diagonalization of  $\varphi$ .  $\square$

Notice there could be a lot of different roots, if we relax the positivity condition on  $\sqrt{B}$ , see ??.

**3.4.10. Spectra and nilpotent mappings.** We return to the behavior of linear mappings in full generality. We continue to work with real or complex vector spaces, but without necessarily fixing a scalar product there.

Recall that the *spectrum of a linear mapping*  $f : V \rightarrow V$  is a sequence of roots of the characteristic polynomial of the mapping  $f$ , counting multiplicities. The *algebraic multiplicity* of an eigenvalue is its multiplicity as a root of the characteristic polynomial. The *geometric multiplicity* of an eigenvalue is the dimension of the corresponding subspace of eigenvectors.

A linear mapping  $f : V \rightarrow V$  is called *nilpotent*, if there exists an integer  $k \geq 1$  such that the iterated mapping  $f^k$  is identically zero. The smallest  $k$  with such a property is called the *degree of nilpotency* of the mapping  $f$ . The mapping  $f : V \rightarrow V$  is called *cyclic*, if there exists the basis  $(u_1, \dots, u_n)$  of the space  $V$  such that  $f(u_1) = 0$  and  $f(u_i) = u_{i-1}$  for all  $i = 2, \dots, n$ . In other words, the matrix of  $f$  in this basis is of the form

$$A = \begin{pmatrix} 0 & 1 & 0 & \dots \\ 0 & 0 & 1 & \dots \\ \vdots & \vdots & & \ddots \end{pmatrix}.$$

If  $f(v) = av$ , then  $f^k(v) = a^k \cdot v$  for every natural  $k$ . Note that, the spectrum of nilpotent mapping can contain only the zero scalar (and this is always present).

By the definition, every cyclic mapping is nilpotent. Moreover, its degree of nilpotency equals the dimension of the space  $V$ . The derivative operator on polynomials,  $D(x^k) = kx^{k-1}$ , is an example of a cyclic mapping on the spaces  $\mathbb{K}_n[x]$  of all polynomials of degree at most  $n$  over the scalars  $\mathbb{K}$ .

Perhaps surprisingly, this is also true the other way round – every nilpotent mapping is a direct sum of cyclic mappings. A proof of this claim takes much work. So we formulate first the results we are aiming at, and only then come back to the technical work.

In the resulting theorem describing the *Jordan decomposition*, the crucial role is played by vector (sub)spaces and linear mappings with a single eigenvalue  $\lambda$  given by the matrix

$$(1) \quad J = \begin{pmatrix} \lambda & 1 & 0 & \dots & 0 \\ 0 & \lambda & 1 & \dots & 0 \\ \vdots & \vdots & \ddots & & \vdots \\ 0 & 0 & 0 & \dots & \lambda \end{pmatrix}.$$

These matrices (and the corresponding invariant subspaces) are called *Jordan blocks*.<sup>5</sup>

<sup>5</sup>Camille Jordan was a famous French Mathematician working in Analysis and Algebra at the end of the 19th and the beginning of the 20th centuries.

## JORDAN CANONICAL FORM

**Theorem.** Let  $V$  be a real or complex vector space of dimension  $n$ . Let  $f : V \rightarrow V$  be a linear mapping with  $n$  eigenvalues (in the chosen domain of scalars), counting algebraic multiplicities. Then there exists a unique decomposition of the space  $V$  into the direct sum of subspaces

$$V = V_1 \oplus \cdots \oplus V_k$$

where not only  $f(V_i) \subset V_i$ , but the restriction of  $f$  to each  $V_i$  has a single eigenvalue  $\lambda_i$  and the restriction  $f - \lambda_i \text{id}_{V_i}$  on  $V_i$  is either cyclic or is the zero mapping. In particular, there is a suitable basis in which  $f$  has a block-diagonal matrix  $J$  with Jordan blocks along the diagonal.

We say that the matrix  $J$  from the theorem is in Jordan canonical form. In the language of matrices, we can rephrase the theorem as follows:

**Corollary.** For each square matrix  $A$  over complex scalars, there is an invertible matrix  $P$  such that  $A = P^{-1} J P$  and  $J$  is in canonical Jordan form.

The matrix  $P$  is the transition matrix to the basis from the theorem above. Notice that the total number of ones over the diagonal in  $J$  equals the difference between the total algebraic and geometric multiplicity of the eigenvalues. The ordering of the blocks in the matrix corresponds to the chosen ordering of the subspaces  $V_i$  in the direct sum. Thus, the uniqueness of the matrix  $J$  is true up to the ordering of the Jordan blocks. There is therefore freedom in the choice of the basis for such a Jordan canonical form.

**3.4.11. Remarks.** The existence of the Jordan canonical form is clear for the cases when all eigenvalues are either distinct or when the geometric and algebraic multiplicities of the eigenvalues are the same. In particular, this is the case for all unitary and self-adjoint mappings on unitary vector spaces, while the definition of normal mappings requires exactly this behavior. In particular, the Jordan canonical form of a mapping is diagonal if and only if the mapping is normal.

A consequence of the Jordan canonical form theorem is that for every linear mapping  $f$ , every eigenvalue of  $f$  uniquely determines an invariant subspace that corresponds to all Jordan blocks with this particular eigenvalue. We shall call this subspace the *root subspace* corresponding to the given eigenvalue.

We mention one useful corollary of the Jordan theorem (which is already used in the discussion about the behavior of Markov chains). Assume that the eigenvalues of our mapping  $f$  are all of absolute value less than one. Then repeated application of the linear mapping on every vector  $v \in V$  leads to a decrease of all coordinates of  $f^k(v)$  towards zero, without bounds.

Indeed, assume  $f$  has one eigenvalue  $\lambda$  on all the complex space  $V$  and that  $f - \lambda \text{id}_V$  is cyclic (that is, we consider only one Jordan block separately). Let  $v_1, \dots, v_\ell$  be

the corresponding basis. Then the theorem says that  $f(v_2) = \lambda v_2 + v_1$ ,  $f^2(v_2) = \lambda^2 v_2 + \lambda v_1 + \lambda v_1 = \lambda^2 v_2 + 2\lambda v_1$ , and similarly for other  $v_i$ 's and higher powers. In any case, the iteration of  $f$  results in higher and higher powers of  $\lambda$  for all non-zero components. The smallest of them can differ from the largest one only by less than the dimension of  $V$ . The coefficients are bounded too.

This proves the claim. The same argument can be used to prove that for the mapping with all eigenvalues with absolute value strictly greater than one leads to unbounded growth of all coordinates for the iterations  $f^k(v)$ .

The remainder of this part of the third chapter is devoted to the proof of the Jordan theorem and a few necessary lemmas. It is much more difficult than anything so far. The reader can skip it, until the beginning of the fifth part of this chapter in case of any problems with reading it.

**3.4.12. Root spaces.** We have already seen by explicit examples that the eigensubspaces completely describe geometric properties for some linear mappings only. Thus we now introduce a more subtle tool, the root subspaces.

**Definition.** A non-zero vector  $u \in V$  is called a *root vector* of the linear mapping  $\varphi : V \rightarrow V$ , if there exists an  $a \in \mathbb{K}$  and an integer  $k > 0$  such that  $(\varphi - a \text{id}_V)^k(u) = 0$ . This means that the  $k$ -th iteration of the given mapping sends  $u$  to zero. The set of all root vectors corresponding to a fixed scalar  $\lambda$  along with the zero vector is called the *root subspace* associated with the scalar  $\lambda \in \mathbb{K}$ . We denote it by  $\mathcal{R}_\lambda$ .

If  $u$  is a root vector and the integer  $k$  from the definition is chosen as the smallest possible one for  $u$ , then  $(\varphi - a \text{id}_V)^{k-1}(u)$  is an eigenvector with the eigenvalue  $a$ . Thus we have  $\mathcal{R}_\lambda = \{0\}$  for all scalars  $\lambda$  which are not in the spectrum of the mapping  $\varphi$ .

**Proposition.** Let  $\varphi : V \rightarrow V$  be a linear mapping. Then

- (1)  $\mathcal{R}_\lambda \subset V$  is a vector subspace for every  $\lambda \in \mathbb{K}$ ,
- (2) for every  $\lambda, \mu \in \mathbb{K}$ , the subspace  $\mathcal{R}_\lambda$  is invariant with respect to the linear mapping  $(\varphi - \mu \text{id}_V)$ . In particular  $\mathcal{R}_\lambda$  is invariant with respect to  $\varphi$ ,
- (3) if  $\mu \neq \lambda$ , then  $(\varphi - \mu \text{id}_V)|_{\mathcal{R}_\lambda}$  is invertible,
- (4) the mapping  $(\varphi - \lambda \text{id}_V)|_{\mathcal{R}_\lambda}$  is nilpotent.

**PROOF.** (1) Checking the properties of the vector subspace is easy and is left to the reader.

(2) Assume that  $(\varphi - \lambda \text{id}_V)^k(u) = 0$  and put  $v = (\varphi - \mu \text{id}_V)(u)$ . Then

$$\begin{aligned} (\varphi - \lambda \text{id}_V)^k(v) &= \\ &= (\varphi - \lambda \text{id}_V)^k((\varphi - \lambda \text{id}_V) + (\lambda - \mu) \text{id}_V)(u) \\ &= (\varphi - \lambda \text{id}_V)^{k+1}(u) + (\lambda - \mu) \cdot (\varphi - \lambda \text{id}_V)^k(u) = 0 \end{aligned}$$

(3) If  $u \in \text{Ker}(\varphi - \mu \text{id}_V)|_{\mathcal{R}_\lambda}$ , then

$$(\varphi - \lambda \text{id}_V)(u) = (\varphi - \mu \text{id}_V)(u) + (\mu - \lambda)u = (\mu - \lambda)u.$$

This implies  $0 = (\varphi - \lambda \text{id}_V)^k(u) = (\mu - \lambda)^k u$  and thus also  $u = 0$  for  $\lambda \neq \mu$ .

(4) Choose a basis  $e_1, \dots, e_p$  of the subspace  $\mathcal{R}_\lambda$ . By definition, there exist integers  $k_i$  such that  $(\varphi - \lambda \text{id}_V)^{k_i}(e_i) = 0$ . In particular, the entire mapping  $(\varphi - \lambda \text{id}_V)|_{\mathcal{R}_\lambda}$  must be nilpotent.  $\square$

**3.4.13. Quotient spaces.** Our next aim is to show that the dimension of the root spaces always equals the algebraic multiplicity of the corresponding eigenvalues. First, we introduce some general useful technical tools.

QUOTIENT SPACES

**Definition.** Let  $U \subset V$  be a vector subspace. Define an equivalence relation on the set of all vectors in  $V$  by  $v_1 \sim v_2$  if and only if  $v_1 - v_2 \in U$ . Axioms of equivalence are easy to check. The set  $V/U$  of the classes of this equivalence is equipped by the operations defined by using representatives. That is, for classes  $[u]$  and  $[v]$  determined by the vectors  $u$  and  $v$ , set  $[v] + [w] = [v + w]$ ,  $a[u] = [au]$ . This is a well defined vector space called the *quotient vector space* of the space  $V$  by the subspace  $U$ .

Check the correctness of the definition of the operations and verify all axioms of the vector space in detail!

The classes (vectors) in the quotient space  $V/U$  will often be denoted as formal sums of one representative with all vectors in the subspace  $U$ , for instance  $u + U \in V/U$ ,  $u \in V$ . The class  $0 + U$  is the zero vector in  $V/U$ , i.e. the vector  $u \in V$  represents the zero element in  $V/U$  if and only if  $u \in U$ .

Trivial examples are  $V/\{0\} \cong V$ ,  $V/V \cong \{0\}$ . Another example is the quotient space of the plane  $\mathbb{R}^2$  factored by any one-dimensional subspace (here, every one-dimensional subspace  $U \subset \mathbb{R}^2$  is a line passing through the origin). Then the equivalence classes are all the lines parallel to this line.

**Proposition.** Let  $U \subset V$  be a vector subspace and  $(u_1, \dots, u_n)$  be a basis of  $V$ , such that  $(u_1, \dots, u_k)$  is a basis of  $U$ . Then  $\dim V/U = n - k$  and the vectors

$$u_{k+1} + U, \dots, u_n + U$$

form a basis of  $V/U$ .

**PROOF.**  $V = \text{span}\{u_1, \dots, u_n\}$ , so  $V/U = \text{span}\{u_1 + U, \dots, u_n + U\}$ . But the first  $k$  generators are zero, thus  $V/U = \text{span}\{u_{k+1} + U, \dots, u_n + U\}$ . Assume that the linear combination  $a_{k+1}(u_{k+1} + U) + \dots + a_n(u_n + U) = (a_{k+1}u_{k+1} + \dots + a_nu_n) + U = 0 \in V/U$  vanishes. Equivalently, this linear combination of the vectors  $u_{k+1}, \dots, u_n$  belongs to the subspace  $U$ . Since  $U$  is generated by the remaining vectors in the basis of  $V$ , the latter linear combination is necessarily zero, and so all coefficients  $a_i$  are zero. This proves the linear independence of the generators of  $V/U$ .  $\square$

**3.4.14. Induced mappings on quotient spaces.**

Assume that  $U \subset V$  is an invariant subspace with respect to linear mapping  $\varphi : V \rightarrow V$  and choose basis  $u_1, \dots, u_n$  of the space  $V$  such that the first  $k$  vectors of this basis is a basis of  $U$ . With this basis,  $\varphi$  has block matrix  $A = \begin{pmatrix} B & C \\ 0 & D \end{pmatrix}$ . Then we can prove the following lemma:

**Lemma.** (1) the mapping  $\varphi$  induces a linear mapping  $\varphi_{V/U} : V/U \rightarrow V/U$ ,  $\varphi_{V/U}(v+U) = \varphi(v)+U$  with the matrix  $D$  under the induced basis  $u_{k+1}+U, \dots, u_n+U$  on  $V/U$ ,

(2) the characteristic polynomial of  $\varphi_{V/U}$  divides the characteristic polynomial of  $\varphi$ .

**PROOF.** For  $v, w \in V, u \in U, a \in \mathbb{K}$  we have  $\varphi(v+u) \in \varphi(v)+U$  (because  $U$  is invariant),  $(\varphi(v)+U) + (\varphi(w)+U) = \varphi(v+w)+U$  and  $a(\varphi(v)+U) = a\varphi(v)+U = \varphi(av)+U$  (because  $\varphi$  is linear), thus the mapping  $\varphi_{V/U}$  is well-defined and linear. Moreover the very definition of the matrix of a mapping in a basis implies that the matrix of  $\varphi_{V/U}$  in the induced basis on  $V/U$  is exactly the matrix  $D$  (when counting the images of the basis elements the coefficients of the matrix  $C$  add only to the class  $U$ ).

The characteristic polynomial of the induced mapping  $\varphi_{V/U}$  is thus  $|D - \lambda E|$ , while characteristic polynomial of the original mapping  $\varphi$  is  $|A - \lambda E| = |B - \lambda E||D - \lambda E|$ .  $\square$

**Corollary.** Let  $V$  be a vector space over  $\mathbb{K}$  of dimension  $n$  and let  $\varphi : V \rightarrow V$  be a linear mapping whose spectrum contains  $n$  elements (that is, all roots of the characteristic polynomial lie in  $\mathbb{K}$  and we count their multiplicities). Then there exists a sequence of invariant subspaces  $\{0\} = V_0 \subset V_1 \subset \dots \subset V_n = V$  with dimensions  $\dim V_i = i$ . Consider a basis  $u_1, \dots, u_n$  of the space  $V$  such that  $V_i = \text{span}\{u_1, \dots, u_i\}$ . In this basis, the matrix of the mapping  $\varphi$  is an upper triangular matrix:

$$\begin{pmatrix} \lambda_1 & \dots & * \\ \vdots & \ddots & \vdots \\ 0 & \dots & \lambda_n \end{pmatrix},$$

with the spectrum  $\lambda_1, \dots, \lambda_n$  on the diagonal.

**PROOF.** The subspaces  $V_i$  are constructed inductively. Let  $\{\lambda_1, \dots, \lambda_n\}$  be the spectrum of the mapping  $\varphi$ . Thus the characteristic polynomial of the mapping  $\varphi$  is of the form  $\pm(\lambda - \lambda_1) \cdots (\lambda - \lambda_n)$ . We choose  $V_0 = \{0\}$ ,  $V_1 = \text{span}\{u_1\}$ , where  $u_1$  is an eigenvector with eigenvalue  $\lambda_1$ . According to the previous theorem, the characteristic polynomial of the mapping  $\varphi_{V/V_1}$  is of the form  $\pm(\lambda - \lambda_2) \cdots (\lambda - \lambda_n)$ . Assume that we have already constructed linearly independent vectors  $u_1, \dots, u_k$  and invariant subspaces  $V_i = \text{span}\{u_1, \dots, u_i\}$ ,  $i = 1, \dots, k < n$  such that the characteristic polynomial of  $\varphi_{V/V_k}$  is of the form  $\pm(\lambda - \lambda_{k+1}) \cdots (\lambda - \lambda_n)$  and  $\varphi(u_i) \in (\lambda_i \cdot u_i + V_{i-1})$  for all  $i = 1, \dots, k$ .

We want to add one more vector  $u_{k+1}$  with analogous properties. There exists an eigenvector  $u_{k+1} + V_k \in V/V_k$  of the mapping  $\varphi_{V/V_k}$  with the eigenvalue  $\lambda_{k+1}$ . Consider the space  $V_{k+1} = \text{span}\{u_1, \dots, u_{k+1}\}$ . If the vector  $u_{k+1}$  is a linear combination of the vectors  $u_1, \dots, u_k$  then  $u_{k+1} + V_k$  would be the zero class in  $V/V_k$ . But this is not possible. Thus  $\dim V_{k+1} = k + 1$ . It remains to study the induced mapping  $\varphi_{V/V_{k+1}}$ . The characteristic polynomial of this mapping is of degree  $n - k - 1$  and divides the characteristic polynomial of the mapping  $\varphi$ . But completing the vectors  $u_1, \dots, u_{k+1}$  to the basis of  $V$  yields a block matrix of the mapping  $\varphi$  with an upper triangular submatrix  $B$  in the left upper corner and zero in the left lower corner. The diagonal elements are exactly the scalars  $\lambda_1, \dots, \lambda_{k+1}$ . Therefore the roots of the characteristic polynomial of the induced mapping have the required properties.  $\square$

**Remark.** If  $V$  decomposes into the direct sum of eigenspaces for  $\varphi$ , the latter results do not say anything new. But their significance consists in the fact, that only the existence of  $\dim V$  roots of the characteristic polynomial (counting multiplicities) is assumed. This is ensured whenever the field  $\mathbb{K}$  is algebraically closed, for instance the complex numbers  $\mathbb{C}$ . As a direct consequence we see that the determinant and the trace of the mapping  $\varphi$  are always the product and the sum of the elements in the spectrum, respectively.

This can be also used for all real matrices. Just consider them to be complex, calculate the determinant or the trace as the product or sum of eigenvalues and because both determinant and the trace are algebraic expressions in terms of the elements of the matrix, the results will be correct.

**3.4.15. Orthogonal triangulation.** If we are given a scalar product on a vector space  $V$  and  $U \subset V$  is a subspace, then clearly  $V/U \simeq U^\perp$  where  $v \in U^\perp$  is identified with  $v + U$ . Moreover, each class of the quotient space  $V/U$  contains exactly one vector from  $U^\perp$  (the difference of two such vector is in  $U \cap U^\perp$ ). We can exploit this observation in every inductive step of the proof of the theorem above. Choose the representative  $u_{k+1} \in V_k^\perp$  of the eigenvector of  $\varphi_{V/V_k}$ . This modification leads to the orthogonal basis with the properties required in the claim about triangulation in the corollary above. Therefore there exists such an orthonormal basis, and we arrive at a very important theorem:

SCHUR'S ORTHOGONAL TRIANGULATION THEOREM

**Theorem.** Let  $\varphi : V \rightarrow V$  be a linear mapping on a vector space with scalar product. Let there be  $m = \dim V$  eigenvalues, counting multiplicities. Then there exists an orthonormal basis of the space  $V$  such that the matrix of  $\varphi$  in this basis is upper triangular with eigenvalues  $\lambda_1, \dots, \lambda_m$  on the diagonal.

**3.4.16. Theorem.** Let  $\varphi : V \rightarrow V$  be a linear mapping and  $\lambda_1, \dots, \lambda_k$  be all distinct eigenvalues. Then the sum of the

root spaces  $\mathcal{R}_{\lambda_1}, \dots, \mathcal{R}_{\lambda_k}$  is direct. Furthermore, for every eigenvalue  $\lambda$  the dimension of the subspace  $\mathcal{R}_\lambda$  equals the algebraic multiplicity of  $\lambda$ .

**PROOF.** We prove first the independence of nonzero vectors from different root spaces. We proceed by induction over the number  $k$  of root spaces. The claim is obvious if  $k = 1$ . Assume that the theorem holds for cases with less than  $k > 1$  root spaces and assume that vectors  $u_1 \in \mathcal{R}_{\lambda_1}, \dots, u_k \in \mathcal{R}_{\lambda_k}$  satisfy  $u_1 + \dots + u_k = 0$ . Then,  $(\varphi - \lambda_k \text{id}_V)^j(u_k) = 0$  for suitable  $j$ , and moreover all  $y_i = (\varphi - \lambda_k \text{id}_V)^j(u_i)$  are non-zero vectors in  $\mathcal{R}_{\lambda_i}$ ,  $i = 1, \dots, k-1$ , whenever  $u_i$  are non-zero by Proposition 3.4.12. But at the same time

$$y_1 + \dots + y_{k-1} = (\varphi - \lambda_k \cdot \text{id}_V)^j \left( \sum_{i=1}^k u_i \right) = 0$$

and, according to the inductive assumption, all  $y_i$  are zero. But then also all  $u_i$ ,  $1 \leq i < k$  must vanish and thus  $u_k = 0$ , too. This proves the first claim.

It remains consider the dimensions of the root spaces  $\mathcal{R}_\lambda$ . Consider an eigenvalue  $\lambda$  of  $\varphi$ , use the same notation  $\varphi$  for the restriction  $\varphi|_{\mathcal{R}_\lambda}$  and write  $\psi : V/\mathcal{R}_\lambda \rightarrow V/\mathcal{R}_\lambda$  for the mapping induced by  $\varphi$  on the quotient space.

Assume that the dimension  $\mathcal{R}_\lambda$  is strictly smaller than the algebraic multiplicity of the root  $\lambda$  of the characteristic polynomial. In view of lemma 3.4.14,  $\lambda$  is also an eigenvalue of the mapping  $\psi$ . Let  $(v + \mathcal{R}_\lambda) \in V/\mathcal{R}_\lambda$  be the corresponding eigenvector, that is,  $\psi(v + \mathcal{R}_\lambda) = \lambda(v + \mathcal{R}_\lambda)$ . Then  $v \notin \mathcal{R}_\lambda$  and  $\varphi(v) = \lambda v + w$  for suitable  $w \in \mathcal{R}_\lambda$ . Thus  $w = (\varphi - \lambda \text{id}_V)(v)$  and  $(\varphi - \lambda \text{id}_V)^j(w) = 0$  for suitable  $j$ . We conclude that  $(\varphi - \lambda \text{id}_V)^{j+1}(v) = 0$ , which contradicts the choice  $v \notin \mathcal{R}_\lambda$ .

It follows that the dimension of  $\mathcal{R}_\lambda$  equals the algebraic multiplicity of the root  $\lambda$  of the characteristic polynomial of the mapping  $\varphi : V \rightarrow V$ .  $\square$

Combining the latter theorem with the triangulation result from Corollary 3.4.14, we can formulate:

**Corollary.** Consider a linear mapping  $\varphi : V \rightarrow V$  on a vector space  $V$  over scalars  $\mathbb{K}$ , whose entire spectrum is in  $\mathbb{K}$ . Then  $V = \mathcal{R}_{\lambda_1} \oplus \dots \oplus \mathcal{R}_{\lambda_n}$  is the direct sum of the root subspaces. If we choose suitable bases for these subspaces, then under this basis  $\varphi$  has block-diagonal form with upper triangular matrices in the blocks and eigenvalues  $\lambda_i$  on the diagonal.

**3.4.17. Nilpotent and cyclic mappings.** Now almost everything is prepared for the discussion about canonical forms of matrices. It only remains to clear the relation between cyclic and nilpotent mappings and combine already proved results.

**Theorem.** Let  $\varphi : V \rightarrow V$  be a nilpotent linear mapping. Then there exists a decomposition of  $V$  into a direct sum of subspaces  $V = V_1 \oplus \dots \oplus V_k$  such that the restriction of  $\varphi$  to each summand  $V_i$  is cyclic.

PROOF. We provide a straightforward construction of a basis of the space  $V$  such that the action of the mapping  $\varphi$  on the basis vectors directly shows the decomposition into the cyclic mappings.

Let  $k$  be the degree of nilpotency of the mapping  $\varphi$  and write  $P_i = \text{Im}(\varphi^i)$ ,  $i = 0, \dots, k$ . Thus,

$$\{0\} = P_k \subset P_{k-1} \subset \dots \subset P_1 \subset P_0 = V.$$

Choose a basis  $e_1^{k-1}, \dots, e_{p_{k-1}}^{k-1}$  of the space  $P_{k-1}$ , where  $p_{k-1} > 0$  is the dimension of  $P_{k-1}$ . By definition,  $P_{k-1} \subset \text{Ker } \varphi$ , i.e.  $\varphi(e_j^{k-1}) = 0$  for all  $j$ .

Assume that  $P_{k-1} \neq V$ . Since  $P_{k-1} = \varphi(P_{k-2})$ , there necessarily exist the vectors  $e_j^{k-2}$ ,  $j = 1, \dots, p_{k-1}$  in  $P_{k-2}$ , such that  $\varphi(e_j^{k-2}) = e_j^{k-1}$ . Assume

$$a_1 e_1^{k-1} + \dots + a_{p_{k-1}} e_{p_{k-1}}^{k-1} + b_1 e_1^{k-2} + \dots + b_{p_{k-1}} e_{p_{k-1}}^{k-2} = 0.$$

Applying  $\varphi$  on this linear combination yields  $b_1 e_1^{k-1} + \dots + b_{p_{k-1}} e_{p_{k-1}}^{k-1} = 0$ . This is a linear combination of independent vectors, therefore all  $b_j = 0$ . But then also  $a_j = 0$ . Thus the linear independence of all  $2p_{k-1}$  chosen vectors is established. Next, extend them to a basis

$$(1) \quad \begin{array}{l} e_1^{k-1}, \dots, e_{p_{k-1}}^{k-1} \\ e_1^{k-2}, \dots, e_{p_{k-1}}^{k-2}, e_{p_{k-1}+1}^{k-2}, \dots, e_{p_{k-2}}^{k-2} \end{array}$$

of the space  $P_{k-2}$ . The images of the added basis vectors are in  $P_{k-1}$ . Necessarily they must be linear combinations of the basis elements  $e_1^{k-1}, \dots, e_{p_{k-1}}^{k-1}$ . We can thus adjust the chosen vectors  $e_{p_{k-1}+1}^{k-2}, \dots, e_{p_{k-2}}^{k-2}$  by adding the appropriate linear combinations of the vectors  $e_1^{k-2}, \dots, e_{p_{k-1}}^{k-2}$  with the result that they are in the kernel of  $\varphi$ . Thus we may assume our choice in the scheme (1) has this property.

Assume that we have already constructed a basis of the subspace  $P_{k-\ell}$  such that we can directly arrange it into the scheme similar to (1)

$$\begin{array}{l} e_1^{k-1}, \dots, e_{p_{k-1}}^{k-1} \\ e_1^{k-2}, \dots, e_{p_{k-1}}^{k-2}, e_{p_{k-1}+1}^{k-2}, \dots, e_{p_{k-2}}^{k-2} \\ e_1^{k-3}, \dots, e_{p_{k-1}}^{k-3}, e_{p_{k-1}+1}^{k-3}, \dots, e_{p_{k-2}}^{k-3}, e_{p_{k-2}+1}^{k-3}, \dots, e_{p_{k-3}}^{k-3} \\ \vdots \\ e_1^{k-\ell}, \dots, e_{p_{k-1}}^{k-\ell}, e_{p_{k-1}+1}^{k-\ell}, \dots, e_{p_{k-2}}^{k-\ell}, e_{p_{k-2}+1}^{k-\ell}, \dots, e_{p_{k-\ell}}^{k-\ell} \end{array}$$

where the value of the mapping  $\varphi$  on any basis vector is located above it. The value is zero if there is nothing above that basis vector.

If  $P_{k-\ell} \neq V$ , then again there must exist vectors  $e_1^{k-\ell-1}, \dots, e_{p_{k-\ell}}^{k-\ell-1}$  which map to  $e_1^{k-\ell}, \dots, e_{p_{k-\ell}}^{k-\ell}$ . We can extend them to a basis  $P_{k-\ell-1}$ , say, by the vectors

$$e_{p_{k-\ell}+1}^{k-\ell-1}, \dots, e_{p_{k-\ell-1}}^{k-\ell-1}.$$

Again, exactly as when adjusting (1) above, we choose the additional basis vectors from the kernel of  $\varphi$ . and analogically as before we verify that we indeed obtain a basis for  $P_{k-\ell-1}$ .

After  $k$  steps we obtain a basis for the whole  $V$ , which has the properties given for the basis of the subspace  $P_{k-\ell}$ . Individual columns of the resulting scheme then generate the subspaces  $V_i$ . Additionally we have found the bases of these subspaces which show that corresponding restrictions of  $\varphi$  are cyclic mappings.  $\square$

**3.4.18. Proof of the Jordan theorem.** Let  $\lambda_1, \dots, \lambda_k$  be all the distinct eigenvalues of the mapping  $\varphi$ . From the assumptions of the Jordan theorem it follows that  $V = \mathcal{R}_{\lambda_1} \oplus \dots \oplus \mathcal{R}_{\lambda_k}$ .

The mappings  $\varphi_i = (\varphi|_{\mathcal{R}_{\lambda_i}} - \lambda_i \text{id}_{\mathcal{R}_{\lambda_i}})$  are nilpotent and thus each of the root spaces is a direct sum

$$\mathcal{R}_{\lambda_i} = P_{1,\lambda_i} \oplus \dots \oplus P_{j_i,\lambda_i}$$

of spaces on which the restriction of the mapping  $\varphi - \lambda_i \text{id}_V$  is cyclic. Matrices of these restricted mappings on  $P_{r,s}$  are Jordan blocks corresponding to the zero eigenvalue, the restricted mapping  $\varphi|_{P_{r,s}}$  has thus for its matrix the Jordan block with the eigenvalue  $\lambda_i$ .

For the proof of Jordan theorem it remains to verify the claim about uniqueness (up to reordering the blocks). Because the diagonal values  $\lambda_i$  are given as roots of the characteristic polynomial, their uniqueness is immediate. The decomposition to root spaces is unique as well. Thus, without loss of generality we may assume that there is just one eigenvalue  $\lambda$  and we are going to express the dimensions of individual Jordan blocks using the ranks  $r_k$  of the mapping  $(\varphi - \lambda \text{id}_V)^k$ . This will show that the blocks are uniquely determined (up to their order). On the other hand, changing the order of the blocks corresponds to renumbering the vectors of basis, thus we can obtain them in any order.

If  $\psi$  is a cyclic operator on an  $m$ -dimensional space, then the defect of the iterated mapping  $\psi^k$  is  $k$  for  $0 \leq k \leq m$ , while the defect is  $m$  for all  $k \geq m$ . This implies that if our matrix  $J$  of the mapping  $\varphi$  on the  $n$ -dimensional space  $V$  (remind we assume  $V = \mathcal{R}_{\lambda}$ ) contains  $d_k$  Jordan blocks of the order  $k$ , then the defect  $D_\ell = n - r_\ell$  of the matrix  $(J - \lambda E)^\ell$  is

$$D_\ell = d_1 + 2d_2 + \dots + \ell d_\ell + \ell d_{\ell+1} + \dots$$

Now, taking the combination  $2D_k - D_{k-1} - D_{k+1}$  we cancel all those terms in the latter expression which coincide for  $\ell = k-1, k, k+1$  and we are left with

$$2D_k - D_{k-1} - D_{k+1} = d_k.$$

Substituting for  $D_\ell$ 's, we finally arrive at

$$d_k = 2n - 2r_k - n + r_{k-1} - n + r_{k+1} = r_{k-1} - 2r_k + r_{k+1}.$$

This is the requested expression for the sizes of the Jordan blocks and the theorem is proved.

**3.4.19. Remarks.** The proof of the theorem about the existence of the Jordan canonical form was constructive, but it does not give an efficient algorithmic approach for the construction. Now we show how our results can be used for explicit computation of the basis in which the given mapping  $\varphi : V \rightarrow V$  has its matrix in the canonical Jordan form.<sup>6</sup>

- (1) Find the roots of the characteristic polynomial.
- (2) If there are less than  $n = \dim V$  roots (counting multiplicities), then there is no canonical form.
- (3) If there are  $n$  linearly independent eigenvectors, there is a basis of  $V$  composed of eigenvectors under which  $\varphi$  has diagonal matrix.
- (4) Let  $\lambda$  be the eigenvalue with geometric multiplicity strictly smaller than the algebraic multiplicity and  $v_1, \dots, v_k$  be the corresponding eigenvectors. They should be the vectors on the upper boundary of the scheme from the proof of the theorem 3.4.17. We need to complete the basis by application of iterations  $\varphi - \lambda \text{id}_V$ . By doing this we also find in which row the vectors should be located. Hence we find the linearly independent solutions  $w_i$  of the equations  $(\varphi - \lambda \text{id})(w_i) = v_i$  from the rows below it. Repeat the procedure iteratively (that is, for  $w_i$  and so on). In this way, we find the “chains” of basis vectors that give invariant subspaces, where  $\varphi - \lambda \text{id}$  is cyclic (the columns from the scheme in the proof).

The procedure is practical for matrices when the multiplicities of the eigenvalues are small, or at least when the degrees of nilpotency are small. For instance, for the matrix

$$A = \begin{pmatrix} 2 & 0 & 1 \\ 0 & 2 & 1 \\ 0 & 0 & 2 \end{pmatrix}$$

we obtain the two-dimensional subspace of eigenvectors

$$\text{span}\{(1, 0, 0)^T, (0, 1, 0)^T\},$$

but we still do not know, which of them are the “ends of the chains”. We need to solve the equations  $(A - 2E)x = (a, b, 0)^T$  for (yet unknown) constants  $a, b$ . This system is solvable if and only if  $a = b$ , and one of the possible solutions is  $x = (0, 0, 1)^T$ ,  $a = b = 1$ . The entire basis is then composed of  $(1, 1, 0)^T$ ,  $(0, 0, 1)^T$ ,  $(1, 0, 0)^T$ . Note that we have free choices on the way and thus there are many such bases.

<sup>6</sup>There is a beautiful purely algebraic approach to compute the Jordan canonical form efficiently, but it does not give any direct information about the right basis. This algebraic approach is based on polynomial matrices and Weierstrass divisors. We shall not go into details in this textbook.

### 5. Decompositions of the matrices and pseudoinversions

Previously we concentrated on the geometric description of the structure of a linear mapping. Now we translate our results into the language of matrix decomposition. This is an important topic for numerical methods and matrix calculus in general.

Even when computing effectively with real numbers we use decompositions into products. The simplest one is the unique expression of every real number in the form

$$a = \text{sgn}(a) \cdot |a|,$$

that is, as a product of the sign and the absolute value. Proceeding in the same way with complex numbers, we obtain their polar form. That is, we write  $z = (\cos \varphi + i \sin \varphi)|z|$ . Here the complex unit plays the role of the sign and the other factor is a non-negative real multiple.

In the following paragraphs we list briefly some useful decompositions for distinct types of matrices. Remind, we met suitable decompositions earlier, for instance for positive semidefinite matrices in paragraph 3.4.9 when finding the square roots. We shall start with similar simple examples.

**3.5.1. LU-decomposition.** In paragraphs 2.1.7 and 2.1.8 we transformed matrices over scalars from any field into row echelon form. For this we used elementary row transformations, based on successive multiplication of our matrix by invertible lower triangular matrices  $P_i$ . In this way we added multiples of the rows above the currently transformed one.

Sometimes we also interchanged the rows, which corresponded to multiplication by a *permutation matrix*. That is a square matrix in which all elements are zero except exactly one value 1 in each row and column. To imagine why, consider a matrix with just one non-zero element in the first column but not in the first row. When we used the backwards elimination to transform the matrix into the blockwise form

$$\begin{pmatrix} E_h & 0 \\ 0 & 0 \end{pmatrix}$$

(remind  $E_h$  stays for the unit matrix of rank  $h$ ) then we potentially needed to interchange columns as well. This was achieved by multiplying by a permutation matrix from the right hand side.

For simplicity, assume we have a square matrix  $A$  of size  $m$  and that Gaussian elimination does not force a row interchange. Thus all matrices  $P_i$  can be lower triangular with ones on diagonal. Finally we note that inverses of such  $P_i$  are again lower triangular with ones on the diagonal (either remember the algorithm 2.1.10 or the formula in 2.2.11). We obtain

$$U = P \cdot A = P_k \cdot \dots \cdot P_1 \cdot A$$

where  $U$  is an upper triangular matrix. Thus

$$A = L \cdot U$$

where  $L$  is lower triangular matrix with ones on diagonal and  $U$  is upper triangular. This decomposition is called *LU-decomposition* of the matrix  $A$ . We can also absorb the diagonal values of  $U$  into a diagonal matrix  $D$  and obtain the *LDU-decomposition* where both  $U$  and  $L$  have just ones along the diagonal,  $A = LDU$ .

For a general matrix  $A$ , we need to add the potential permutations of rows during Gaussian elimination. Then we obtain the general result. (Think why we can always put the necessary permutation matrices to the most left and most right positions!)

LU-DECOMPOSITION

Let  $A$  be any square matrix of size  $m$  over a field of scalars. Then we can find lower triangular matrix  $L$  with ones on its diagonal, upper triangular matrix  $U$  and permutation matrices  $P$  and  $Q$ , all of size  $m$ , such that

$$A = P \cdot L \cdot U \cdot Q.$$

**3.5.2. Remarks.** As one direct corollary of the Gaussian elimination we can observe that, up to a choice of suitable bases on the domain and codomain, every linear mapping  $f : V \rightarrow W$  is given by a matrix in block-diagonal form with unit matrix of the size equal to the dimension of the image of  $f$ , and with zero blocks all around. This can be reformulated as follows: every matrix  $A$  of the type  $m/n$  over a field of scalars  $\mathbb{K}$  can be decomposed into the product

$$A = P \cdot \begin{pmatrix} E & 0 \\ 0 & 0 \end{pmatrix} \cdot Q,$$

where  $P$  and  $Q$  are suitable invertible matrices.

Previously (in 3.4.10) we discussed properties of linear mappings  $f : V \rightarrow V$  over complex vector spaces. We showed that every square matrix  $A$  of dimension  $m$  can be decomposed into the product

$$A = P \cdot J \cdot P^{-1},$$

where  $J$  is a block-diagonal with Jordan blocks associated with the eigenvalues of  $A$  on the diagonal. Indeed, this is just a reformulation of the Jordan theorem, because multiplying by the matrix  $P$  and by its inverse from the other side corresponds in this case just to the change of the basis on the vector space  $V$  (with transition matrix  $P$ ). The quoted theorem says that every mapping has Jordan canonical form in a suitable basis.

Analogously, when discussing the self-adjoint mappings we proved that for real symmetric matrices or for complex Hermitian matrices there exists a decomposition into the product

$$A = P \cdot D \cdot P^*,$$

where  $D$  is the diagonal matrix with all (always real) eigenvalues on the diagonal, counting multiplicities. Indeed, we

proved that there is an orthonormal basis consisting of eigenvectors. Thus the transition matrix  $P$  reflecting the appropriate change of the basis must be orthogonal. In particular,  $P^{-1} = P^*$ .

For real orthogonal mappings we derived analogous expression as for the symmetric ones, i.e.  $A = P \cdot B \cdot P^*$ . But in this case the matrix  $B$  is block-diagonal with blocks of size two or one, expressing rotations, mirror symmetry and identities with respect to the corresponding subspaces.

**3.5.3. Singular decomposition theorem.** We return to general linear mappings  $f : V \rightarrow W$  between vector spaces (generally distinct). We assume that scalar products are defined on both spaces and we restrict ourselves to orthonormal bases only.

If we want a similar decomposition result as above, we must proceed in a more refined way than in the case of arbitrary bases. But the result is surprisingly similar and strong:

SINGULAR DECOMPOSITION

**Theorem.** Let  $A$  be a matrix of the type  $m/n$  over real or complex scalars. Then there exist square unitary matrices  $U$  and  $V$  of dimensions  $m$  and  $n$ , and a real diagonal matrix  $D$  with non-negative elements of dimension  $r$ ,  $r \leq \min\{m, n\}$ , such that

$$A = U S V^*, \quad S = \begin{pmatrix} D & 0 \\ 0 & 0 \end{pmatrix}$$

and  $r$  is the rank of the matrix  $AA^*$ .

The matrix  $S$  is determined uniquely up to the order of the diagonal elements  $s_i$  in  $D$ . Moreover,  $s_i$  are the square roots of the positive eigenvalues  $d_i$  of the matrix  $AA^*$ .

If  $A$  is a real matrix, then the matrices  $U$  and  $V$  are orthogonal.

**PROOF.** Assume first that  $m \leq n$ . Denote by  $\varphi : \mathbb{K}^n \rightarrow \mathbb{K}^m$  the mapping between real or complex spaces with standard scalar products, given by the matrix  $A$  in the standard bases.

We can reformulate the statement of the theorem as follows: there exists orthonormal bases on  $\mathbb{K}^n$  and  $\mathbb{K}^m$  in which the mapping  $\varphi$  is given by the matrix  $S$  from the statement of the theorem.

As noted before, the matrix  $A^*A$  is positive semidefinite. Therefore it has only real non-negative eigenvalues and there exists an orthonormal basis  $\underline{w}$  of  $\mathbb{K}^n$  in which the corresponding mapping  $\varphi^* \circ \varphi$  is given by a diagonal matrix with eigenvalues on the diagonal. In other words, there exists a unitary matrix  $V$  such that  $A^*A = V B V^*$  for a real diagonal matrix  $B$  with non-negative eigenvalues  $(d_1, d_2, \dots, d_r, 0, \dots, 0)$  on the diagonal,  $d_i \neq 0$  for all  $i = 1, \dots, r$ . Thus

$$B = V^* A^* A V = (A V)^*(A V).$$

This is equivalent to the claim that the first  $r$  columns of the matrix  $AV$  are orthogonal, while the remaining columns vanish because they have zero norm.

Next, we denote the first  $r$  columns of  $AV$  as  $v_1, \dots, v_r \in \mathbb{K}^m$ . Thus,  $\langle v_i, v_i \rangle = d_i$ ,  $i = 1, \dots, r$ , and the normalized vectors  $u_i = \frac{1}{\sqrt{d_i}}v_i$  form an orthonormal system of non-zero vectors. Extend them to an orthonormal basis  $\underline{u} = u_1, \dots, u_m$  for the entire  $\mathbb{K}^m$ . Expressing the original mapping  $\varphi$  in the bases  $\underline{u}$  of  $\mathbb{K}^n$  and  $\underline{u}$  of  $\mathbb{K}^m$ , yields the matrix  $\sqrt{B}$ . The transformations from the standard bases to the newly chosen ones correspond to the multiplication from the left by a unitary (orthogonal) matrix  $U$  and from the right by  $V^{-1} = V^*$ . This is the claim of the theorem.

If  $m > n$ , we can apply the previous part of the proof to the matrix  $A^*$  which implies the desired result.

All the previous steps in the proof are also valid in the real domain with real scalars.  $\square$

This proof of the theorem about singular decomposition is constructive and we can indeed use it for computing the unitary (orthogonal) matrices  $U$  and  $V$  and the non-zero diagonal elements of the matrix  $S$ .

The diagonal values of the matrix  $D$  from the previous theorem are called *singular values of the matrix  $A$* .

**3.5.4. Further comments.** When dealing with real scalars, the singular values of a linear mapping  $\varphi : \mathbb{R}^n \rightarrow \mathbb{R}^m$  have a simple geometric meaning:

Let  $K \subset \mathbb{R}^n$  be the unit ball in the standard scalar product. The image  $\varphi(K)$  is always an  $m$ -dimensional ellipsoid (possibly degenerate). The singular values of the matrix  $A$  are then the norms of the main half-axes. The theorem says further that the original ball allows an orthogonal set of diameters, whose images are exactly the half-axes of this ellipsoid.

For square matrices it can be seen that  $A$  is invertible if and only if all singular values are non-zero. The ratio of the greatest to the smallest singular value is an important parameter for the robustness of many numerical computations with matrices, for instance the computation of the inverse matrix. Note that there are fast methods of computation (approximations) for eigenvalues. Thus the singular decomposition is a very effective tool to work with.

**3.5.5. Polar decomposition theorem.** The singular decomposition theorem is the starting point for many other useful tools. We present several direct corollaries (which by themselves are non-trivial and important).

The statement of the singular decomposition theorem saying that for any matrix  $A$ , real or complex,  $A = USW^*$  with  $S$  diagonal with non-negative real numbers on the diagonal and  $U$  and  $W$  unitary, can be rephrased as

$$A = USU^*UW^*$$

and let us denote  $P = USU^*$ ,  $V = UW^*$ . The first of the matrices,  $P$ , is Hermitian (in the real case, symmetric) and positive semidefinite (because  $P$  and  $S$  are matrices of the the same mapping in different orthonormal bases). At the same time,  $V$  is the product of two unitary matrices and thus again is unitary (in the real case orthogonal).

Next, assume that  $A = PV = QZ$  are two such decompositions of the matrix  $A$  into the product of a positive semidefinite Hermitian matrix and a unitary matrix. Clearly,  $A^* = WSU^*$ . Thus  $AA^* = USSU^* = P^2$ , and the matrix  $P$  is actually the square root of the easily computable Hermitian matrix  $AA^*$ . In particular, this proves that  $P$  is uniquely determined, cf. 3.4.9.

Further, assume that  $A$  is invertible. Then also  $P$  is invertible and  $Z = V = P^{-1}A$ .

We have derived a very useful analogy of the decomposition of a real number into a sign and the absolute value:

POLAR DECOMPOSITION

**Theorem.** Every square complex matrix  $A$  of dimension  $n$  can be expressed in the form  $A = PV$ , where  $P$  is a Hermitian positive semi-definite square matrix of the same dimension while  $V$  is unitary.

The matrix  $P = \sqrt{AA^*}$  is uniquely given, and if  $A$  is invertible, the decomposition is unique and  $V = (\sqrt{AA^*})^{-1}A$ .

If  $A$  is a matrix of real scalars, then  $P$  is symmetric and  $V$  is orthogonal.

If we apply the same theorem to  $A^*$  instead of  $A$ , we obtain the same result, but with the order of the Hermitian and unitary matrices is reversed. This means  $A = VP$  with  $V$  unitary and  $P = \sqrt{A^*A}$  positive semidefinite. The matrices in the corresponding right and left polar decompositions will in general be different.

Actually, if  $A$  is invertible, it is easy to check, that the matrices in the left are polar decomposition coincide if and only if  $A$  is normal. Look at theorem 3.4.8 and verify it yourself.

In the complex case the analogy with the decomposition of numbers is even more entertaining. The positive semidefinite  $P$  again plays the role of the absolute value of the complex number. The unitary matrix  $V$  uniquely allows the expression as a sum  $V = \text{re } V + i \text{ im } V$  with Hermitian real and imaginary parts and the property  $(\text{re } V)^2 + (\text{im } V)^2 = E$ . We obtain a full analogy for the polar form for the complex numbers (see the final remark and corollary in 3.4.8). But note that in the higher dimensional case, it is important in which order this “polar form” of matrix is written. It is possible in both ways, but the results differ in general.

**3.5.6. QR decomposition.** For many practical applications it is faster to use another decomposition of matrices, which is an analogy of the Schur orthogonal triangulation theorem:

QR DECOMPOSITION

**Theorem.** For every complex matrix  $A$  of the type  $m/n$  there exists a unitary matrix  $Q$  and an upper triangular matrix  $R$  such that  $A = QR$ .

If all the scalars are real, then both  $Q$  and  $R$  are real (i.e.  $Q$  orthogonal).

**PROOF.** In the geometric formulation we need to prove that for every mapping  $\varphi : \mathbb{K}^n \rightarrow \mathbb{K}^m$  with the matrix  $A$  in the standard bases we can choose a new orthonormal basis on  $\mathbb{K}^n$  for which  $\varphi$  has upper triangular matrix.

Consider the images  $\varphi(e_1), \dots, \varphi(e_n) \in \mathbb{K}^m$  of the vectors of the standard orthonormal basis of  $\mathbb{K}^n$ . Choose from them a maximal linearly independent system  $v_1, \dots, v_k$  in such a way that the removed dependent vectors are always a linear combination of the previous vectors. Extend it into a basis  $v_1, \dots, v_m$ . Let  $u_1, \dots, u_m$  be an orthonormal basis  $\mathbb{K}^m$  obtained by the Gramm-Schmidt orthogonalization of this system of vectors.

For every  $e_i$ ,  $\varphi(e_i)$  is either one of  $v_j$ ,  $j \leq i$ , or it is a linear combination of  $v_1, \dots, v_{i-1}$ . Therefore in the expression of  $\varphi(e_i)$  in the basis  $\underline{u}$  only the vectors  $u_1, \dots, u_i$  appear. Thus, in the standard basis on  $\mathbb{K}^n$  and  $\underline{u}$  on  $\mathbb{K}^m$ , the mapping  $\varphi$  has an upper triangular matrix  $R$ . The change of the basis  $\underline{u}$  on  $\mathbb{K}^m$  corresponds to the multiplication by a unitary matrix  $Q^*$  from the left. That is,  $R = Q^*A$ , equivalently  $A = QR$ .

The last claim is clear from the construction.  $\square$

**3.5.7. Pseudoinversions.** Finally, we discuss an especially useful and important extension of the inversion concept, which is of great importance for numerical procedures and also in Statistics.

Technically, the following quite straightforward application of singular decompositions of matrices allows us to define the pseudoinverse. However, we should beware that the singular decomposition is not unique and thus we must verify that such a definition is consistent. We shall see that in the next theorem.

PSEUDOINVERSE MATRICES

Let  $A$  be a real or complex matrix of the type  $m/n$ . Let

$$A = U S V^*, \quad S = \begin{pmatrix} D & 0 \\ 0 & 0 \end{pmatrix}$$

be its singular decomposition (in particular,  $D$  is invertible). The matrix

$$A^\dagger := V S^\dagger U^*, \quad S^\dagger = \begin{pmatrix} D^{-1} & 0 \\ 0 & 0 \end{pmatrix}$$

is called the *pseudoinverse matrix* of the matrix  $A$ .

In geometric terms, we may view the linear mapping  $\varphi$  given by the matrix  $A$  in the two special orthonormal basis, where  $\varphi$  has got the matrix  $S$  with non-negative diagonal entries. We take the inverse of the “invertible part” of  $\varphi$  and

complete it trivially to the pseudoinverse<sup>7</sup> mapping  $\varphi^\dagger$ . The result is then viewed in the original basis and yields  $A^\dagger$ .

As the following theorem shows, the pseudoinverse is an important generalization of the notion of inverse matrix, together with direct applications. At the same time, property (3), together with property (2), verifies the appropriateness of the definition.

PROPERTIES OF PSEUDOINVERSE MATRICES

**Theorem.** *Let  $A$  be a real or complex matrix of the type  $m/n$  and let  $A^\dagger$  be its pseudoinverse. Then:*

(1) *if  $A$  is invertible (necessarily square), then*

$$A^\dagger = A^{-1},$$

(2)  *$A^\dagger A$  and  $AA^\dagger$  are Hermitian (in real case symmetric) and*

$$AA^\dagger A = A, \quad A^\dagger AA^\dagger = A^\dagger.$$

(3) *the pseudoinverse matrices  $A^\dagger$  are uniquely defined by the four properties from (2). Thus if some matrix  $B$  of the type  $n \times m$  has the properties that  $BA$  and  $AB$  are both Hermitian,  $ABA = A$  and  $BAB = B$ , then  $B = A^\dagger$ .*

(4) *if  $A$  is a matrix of the system of linear equations  $Ax = b$  with  $b \in \mathbb{K}^m$ , then the vector  $y = A^\dagger b \in \mathbb{K}^n$  minimizes the norm  $\|Ax - b\|$  for all vectors  $x \in \mathbb{K}^n$ .*

(5) *the system of linear equations  $Ax = b$  with  $b \in \mathbb{K}^m$  is solvable if and only if  $AA^\dagger b = b$ . In this case all solutions are given by the expression*

$$x = A^\dagger b + (E - A^\dagger A)u,$$

*where  $u \in \mathbb{K}^n$  is arbitrary.*

**PROOF.** (1): If  $A$  is invertible, then the matrix  $S = U^*AV$  is also invertible and directly from the definition  $S^\dagger = S^{-1}$ . Consequently,  $A^\dagger A = AA^\dagger = E$ .

(2): Direct computation yields  $SS^\dagger S = S$  and  $S^\dagger SS^\dagger = S^\dagger$ , therefore

$$AA^\dagger A = USV^*VS^\dagger U^*USV^* = USS^\dagger SV^* = USV^* = A$$

and analogically for the second equation. Furthermore,

$$\begin{aligned} (AA^\dagger)^* &= (USS^\dagger U^*)^* = U(S^\dagger)^* S^* U^* \\ &= U(SS^\dagger)^* U^* = USS^\dagger U^* = AA^\dagger. \end{aligned}$$

It can be proved similarly that  $(A^\dagger A)^* = A^\dagger A$ .

<sup>7</sup>This concept was introduced by Eliakim Hastings Moore, an American mathematician, around 1920. It was reinvented by Roger Penrose and others later. In the literature, it is often called the *Moore-Penrose pseudoinverse*. Roger Penrose is an extremely influential mathematical physicist and philosopher of science working in Oxford, known also for his many best-selling popular books such as *The Emperor's New Mind: Concerning Computers, Minds, and The Laws of Physics* (1989); *Shadows of the Mind: A Search for the Missing Science of Consciousness* (1994); *The Road to Reality: A Complete Guide to the Laws of the Universe* (2004); *Cycles of Time: An Extraordinary New View of the Universe* (2010).

(3) The claim can be proved by direct computation. Of course we can consider the matrices  $A$ ,  $A^\dagger$ ,  $B$  as the matrices of the mappings  $\varphi$ ,  $\varphi^\dagger$ , and  $\psi$  in the standard bases on  $\mathbb{K}^n$  and  $\mathbb{K}^m$ , or any other pair of orthonormal bases. The requested equality is equivalent to the equality  $\varphi^\dagger = \psi$  independently of the choice of the bases. We choose a couple of orthogonal bases from the singular decomposition of  $A$ . Then the mapping  $\varphi$  has the matrix  $S$  from the definition of the pseudoinverse  $A^\dagger$ , so we write directly

$$A = \begin{pmatrix} D & 0 \\ 0 & 0 \end{pmatrix}, \quad A^\dagger = \begin{pmatrix} D^{-1} & 0 \\ 0 & 0 \end{pmatrix},$$

with the diagonal matrix  $D$  consisting of all non-zero singular values. We write again  $B$  for the matrix of  $\psi$  in these bases. Clearly  $B$  and  $A$  satisfy the assumptions of the claim (3). Thus

$$A^\dagger A = \begin{pmatrix} E & 0 \\ 0 & 0 \end{pmatrix}, \quad ABA = A$$

and we obtain

$$A^\dagger = A^\dagger ABA A^\dagger = \begin{pmatrix} E & 0 \\ 0 & 0 \end{pmatrix} B \begin{pmatrix} E & 0 \\ 0 & 0 \end{pmatrix} = \begin{pmatrix} D^{-1} & 0 \\ 0 & 0 \end{pmatrix}.$$

Consequently

$$B = \begin{pmatrix} D^{-1} & P \\ Q & R \end{pmatrix}$$

for suitable matrices  $P$ ,  $Q$  and  $R$ . Next,

$$BA = \begin{pmatrix} D^{-1} & P \\ Q & R \end{pmatrix} \begin{pmatrix} D & 0 \\ 0 & 0 \end{pmatrix} = \begin{pmatrix} E & 0 \\ QD & 0 \end{pmatrix}$$

is Hermitian. Thus  $QD = 0$  which implies  $Q = 0$  (the matrix  $D$  is diagonal and invertible). Analogously, the assumption that  $AB$  is Hermitian implies that  $P$  is zero. Finally, we compute

$$B = BAB = \begin{pmatrix} D^{-1} & 0 \\ 0 & R \end{pmatrix} \begin{pmatrix} D & 0 \\ 0 & 0 \end{pmatrix} \begin{pmatrix} D^{-1} & 0 \\ 0 & R \end{pmatrix}.$$

On the right side in the right-lower corner there is zero, and thus also  $R = 0$  and the claim is proved.

(4): Consider the mapping  $\varphi : \mathbb{K}^n \rightarrow \mathbb{K}^m$ ,  $x \mapsto Ax$ , and direct sums  $\mathbb{K}^n = (\text{Ker } \varphi)^\perp \oplus \text{Ker } \varphi$ ,  $\mathbb{K}^m = \text{Im } \varphi \oplus (\text{Im } \varphi)^\perp$  of the orthogonal complements. The restricted mapping  $\tilde{\varphi} := \varphi|_{(\text{Ker } \varphi)^\perp} : (\text{Ker } \varphi)^\perp \rightarrow \text{Im } \varphi$  is a linear isomorphism. If we choose suitable orthonormal bases on  $(\text{Ker } \varphi)^\perp$  and  $\text{Im } \varphi$  and extend them to orthonormal bases on whole spaces, the mapping  $\varphi$  will have matrix  $S$  and  $\tilde{\varphi}$  the matrix  $D$  from the theorem about the singular decomposition. In the next section, we shall discuss in detail that for any given  $b \in \mathbb{K}^m$ , there is the unique vector which minimizes the distance  $\|b - z\|$  among all  $z \in \text{Im } \varphi$  (in analytic geometry we shall say that the point  $z$  realises the distance of  $b$  from the affine subspace  $\text{Im } \varphi$ ), see 4.1.16). The properties of the norm proved in theorem 3.4.3 directly imply that this is exactly the component  $z = b_1$  of the decomposition  $b = b_1 + b_2$ ,  $b_1 \in \text{Im } \varphi$ ,  $b_2 \in (\text{Im } \varphi)^\perp$ .

Now, in our choice of bases, the mapping  $\varphi^\dagger$  is given by the matrix  $S^\dagger$  from the singular decomposition theorem. In

particular,  $\varphi^\dagger(\text{Im } \varphi) = (\text{Ker } \varphi)^\perp$ ,  $D^{-1}$  is the matrix of the restriction  $\varphi^\dagger|_{\text{Im } \varphi}$ , and  $\varphi^\dagger|_{(\text{Im } \varphi)^\perp}$  is zero. Indeed,

$$\varphi \circ \varphi^\dagger(b) = \varphi(\varphi^\dagger(z)) = z$$

and the proof is finished.

(5) Evidently, the equality  $Ax = b$ , with  $x \in \mathbb{K}^n$  fixed, implies

$$b = Ax = AA^\dagger Ax = AA^\dagger b.$$

Thus the condition is necessary. On the other hand, if this condition holds, then the choice  $x = A^\dagger b + (E - A^\dagger A)u$  as in (5) implies

$$Ax = A(A^\dagger b + (E - A^\dagger A)u) = b + (A - AA^\dagger A)u = b.$$

The rank of the matrix  $E - A^\dagger A$  gives the correct size of the image of the corresponding mapping according to the Kronecker-Capelli theorem (cf. 2.3.5) about the solution of the system of linear equations, and thus we obtain all solutions in this way.  $\square$

**Remark.** Notice that the last computation in the proof verifies that  $(E - A^\dagger A)$  is the matrix of the projection of  $\mathbb{R}^n$  onto the subspaces of all solutions of the homogenous system  $Ax = 0$ .

It can be also shown that the matrix  $A^\dagger$  minimizes the square of the norm of the expression

$$AA^\dagger - E$$

that is, the sum of squares of all elements of the given matrix.

The claim (4) of the theorem can be also interpreted as follows.  $AA^\dagger$  is the matrix of the orthogonal projection from the vector space  $\mathbb{R}^m$ , onto the subspace generated by the columns of the matrix  $A$  ( $m$  is the number of the rows of the matrix  $A$ ). This interpretation has a strong meaning for matrices having more rows than columns. Moreover, for matrices  $A$  whose columns are independent vectors, the expression  $(A^T A)^{-1} A^T$  makes sense and it is not hard to verify that this matrix satisfies all the properties from (1) and (2) from the previous theorem. Thus it is the pseudoinverse  $A^\dagger$  of the matrix  $A$ .

**3.5.8. Linear regression.** The approximation property (4)

from the previous theorem is very useful in the cases where we are to find as good an approximation as possible for the (non-existent) solution of a given system  $Ax = b$ , where  $A$  is a real matrix of the type  $m/n$  and  $m > n$ .

For instance, an experiment gives many measured real values  $b_j$ ,  $j = 1, \dots, m$ . We want to find a linear combination of only a few fixed functions  $f_i$ ,  $i = 1, \dots, n$  which approximates the values  $b_j$  as good as possible. The actual values of the fixed functions at the relevant points  $y_j \in \mathbb{R}$  define the matrix  $a_{ij} = f_i(y_j)$ . The columns of the matrix are given by values of the individual functions  $f_i$  at the considered points. The goal is to determine the coefficients  $x_i \in \mathbb{R}$

so that the sum of the squares of the deviations from the actual values

$$\sum_{j=1}^m (b_j - (\sum_{i=1}^n x_i f_i(y_j)))^2 = \sum_{j=1}^m (b_j - (\sum_{i=1}^n a_{ij} x_i))^2$$

is minimized. By the previous theorem, the optimal coefficients are  $A^\dagger b$ .

As an example, consider just three functions  $f_0(y) = 1$ ,  $f_1(y) = y$ ,  $f_2(y) = y^2$ . Assume that the “measured values” of their unknown combination  $g(y) = x_0 + x_1 y + x_2 y^2$  in integral values for  $y$  between 1 and 5 are  $b^T = (1, 12, 6, 27, 33)$ . (This vector  $b$  arose by computing the values  $1 + y + y^2$  at the given points adjusted by random integral values in the range  $\pm 10$ .) This leads in our case to the matrix  $A = (b_{ji})$

$$A^T = \begin{pmatrix} 1 & 1 & 1 & 1 & 1 \\ 1 & 2 & 3 & 4 & 5 \\ 1 & 4 & 9 & 16 & 25 \end{pmatrix}.$$

The requested optimal coefficients for the combination are

$$\begin{aligned} x &= A^\dagger \cdot b \\ &= \begin{pmatrix} \frac{9}{5} & 0 & -\frac{4}{5} & -\frac{3}{5} & \frac{3}{5} \\ -\frac{37}{35} & \frac{23}{70} & \frac{6}{7} & \frac{37}{70} & -\frac{23}{35} \\ \frac{1}{7} & -\frac{1}{14} & -\frac{1}{7} & -\frac{1}{14} & \frac{1}{7} \end{pmatrix} \cdot \begin{pmatrix} 1 \\ 12 \\ 6 \\ 27 \\ 33 \end{pmatrix} \\ &\simeq \begin{pmatrix} 0.600 \\ 0.614 \\ 1.214 \end{pmatrix}. \end{aligned}$$

The resulting approximation can be seen in the picture, where the given values  $b$  are shown by the diamonds, while the dashed curve stays for the resulting approximation  $g(y) = x_1 + x_2 y + x_3 y^2$ .

The computation was produced in Maple and taking 15 values  $y_i = 1 + i + i^2$ , with a random vector of deviations from the same range added produced the following picture:

**G. Additional exercises for the whole chapter**

**3.G.1.** Solve the following LP problem

$$\begin{aligned} & \text{minimize } \{7x - 5y + 3z\} \\ & 0 \leq x \leq 6, \quad -2 \leq y \leq 7, \quad -4 \leq z \leq 9. \end{aligned}$$

**Solution.** Introduce new variables  $y'$  and  $z'$  by setting  $y = y' - 2$ ,  $z = z' - 4$ . In the variables  $\{x, y', z'\}$  the original LP problem takes the form

$$\begin{aligned} & \text{maximize } \{-7x + 5y' - 3z'\} \\ & x \leq 6, \quad y' \leq 9, \quad z' \leq 13, \quad x, y', z' \geq 0. \end{aligned}$$

Dropping the primes at  $y$  and  $z$ , we obtain an initial LP tableaux:

	$x$	$y$	$z$	$t$	$s$	$r$	
Objective	7	-5	3	0	0	0	0
$t$	1	0	0	1	0	0	6
$s$	0	1	0	0	1	0	9
$r$	0	0	1	0	0	1	13

The second and final tableaux, is

	$x$	$y$	$z$	$t$	$s$	$r$	
Objective	7	0	3	0	5	0	45
$t$	1	0	0	1	0	0	6
$y$	0	1	0	0	1	0	9
$r$	0	0	1	0	0	1	13

which provides the solution

$$x = 0, \quad y' = 9, \quad z' = 0.$$

In the original notation this means

$$x = 0, \quad y = 7, \quad z = -4.$$

This solution can be easily guessed from the beginning. □

**3.G.2.** Solve the following LP problem: A small firm specializes in making five types of spare automotive parts. Each part is first cast from iron in the casting shop and is then sent to the finishing shop where holes are drilled, surfaces are turned, and edges are ground. The required worker-hours (per 100 units), for each type of parts in each of the two shops, are shown below:

Part type	1	2	3	4	5
Casting	2	1	3	3	1
Finishing	2	2	1	1	1

The profits from the five parts are \$30, \$20, \$40, \$25 and \$10 (per 100 units), respectively. The capacities of the casting and finishing shops over the next month are 700 and 1000 worker-hours respectively. Determine the quantities of each type of spare part to be made during the month, so as to maximize the firm's profit. Assume that there is sufficient demand for the firm to sell whatever it is capable of producing.

**Solution.** Let  $x_j$  be the number of produced units (in multiples of ten thousand) of the part of the type  $j = 1, \dots, 5$ . Then the LP problem can be formulated as

$$\begin{aligned} &\text{maximize } \{30x_1 + 20x_2 + 40x_3 + 25x_4 + 10x_5\} \\ &2x_1 + x_2 + 3x_3 + 3x_4 + x_5 + t = 7 \\ &2x_1 + 2x_2 + x_3 + x_4 + x_5 + s = 10 \\ &x_j \geq 0, \quad j = 1, \dots, 5. \end{aligned}$$

The first, second, and third LP tableaux are respectively

	$x_1$	$x_2$	$x_3$	$x_4$	$x_5$	$t$	$s$	
Objective	-3	-2	-4	$-\frac{5}{2}$	-1	0	0	0
$t$	②	1	3	3	1	1	0	7
$s$	2	2	1	1	1	0	1	10

	$x_1$	$x_2$	$x_3$	$x_4$	$x_5$	$t$	$s$	
Objective	0	$-\frac{1}{2}$	$\frac{1}{3}$	2	$\frac{1}{2}$	$\frac{3}{2}$	0	$\frac{21}{2}$
$x_1$	1	$\frac{1}{2}$	$\frac{3}{2}$	$\frac{3}{2}$	$\frac{1}{2}$	$\frac{1}{2}$	0	$\frac{7}{2}$
$s$	0	①	-2	-2	0	-1	1	3

	$x_1$	$x_2$	$x_3$	$x_4$	$x_5$	$t$	$s$	
Objective	0	0	$-\frac{1}{2}$	1	$\frac{1}{2}$	1	$\frac{1}{2}$	$\frac{24}{2}$
$x_1$	1	0	$\frac{5}{2}$	$\frac{5}{2}$	$\frac{1}{2}$	1	-1	2
$x_2$	0	①	-2	-2	0	-1	1	3

	$x_1$	$x_2$	$x_3$	$x_4$	$x_5$	$t$	$s$	
Objective	$\frac{1}{5}$	0	0	$\frac{3}{2}$	$\frac{3}{5}$	$\frac{6}{5}$	$\frac{3}{10}$	$\frac{62}{5}$
$x_3$	$\frac{2}{5}$	0	1	1	$\frac{1}{5}$	$\frac{2}{5}$	$-\frac{1}{5}$	$\frac{4}{5}$
$x_2$	$\frac{4}{5}$	1	0	0	$\frac{3}{5}$	$-\frac{1}{5}$	$\frac{1}{5}$	$\frac{23}{5}$

The final tableau provides the solution.

$$x_2 = \frac{23}{5}, \quad x_3 = \frac{4}{5}, \quad x_j = 0, \quad j = 1, 4, 5.$$

Thus, optimal profit is achieved by producing 46,000 parts of type 2 and 8,000 parts of type 3. □

**3.G.3. Model of spreading of annual plants.** Consider some plants that blossom at the beginning of summer, then produce seeds and die at the peak of summer. Some of the seeds burst into flowers at the end of the autumn. Some survive the winter in the ground and burst into flowers at the start of the spring. The flowers that burst out in autumn and survive the winter are usually larger in the spring, and usually produce more seeds. After this, the whole cycle repeats itself.

The year is thus divided into four parts and in each of these parts we distinguish between some “forms” of the flower:

Part	Stage
beginning of spring	small and big seedlings
beginning of summer	small, medium and big blossoming flowers
peak of summer	seeds
autumn	seedlings and seeds

Denote by  $x_1(t)$  and by  $x_2(t)$  the number of small and large seedlings respectively at the start of the spring in year  $t$ . Denote by  $y_1(t)$ ,  $y_2(t)$  and  $y_3(t)$  the number of small, medium and large flowers respectively in the summer of that year. From the

small seedlings either small or large flowers grow. From the large seedlings either medium or big flowers grow. Each of the seedlings can of course die (weather, be eaten by a cow, etc.) and nothing grows out of it. Denote by  $b_{ij}$  the probability that the seedling of the  $j$ -th size,  $j = 1, 2$  grows into a flower of the  $i$ -th size,  $i = 1, 2, 3$ . Then we have

$$0 < b_{11} < 1, \quad b_{12} = 0, \quad 0 < b_{21} < 1, \quad 0 < b_{22} < 0, \\ b_{31} = 0, \quad 0 < b_{32} < 1, \quad b_{11} + b_{21} < 1, \quad b_{22} + b_{32} < 1$$

(think in detail about what each of these inequalities expresses). If we consider classical probability, we can compute  $b_{11}$  as a ratio of the positive results (small seedling grows into a small flower) and of all possible results (the number of small seedlings). That is,  $b_{11} = y_1(t)/x_1(t)$ , or

$$y_1(t) = b_{11}x_1(t).$$

Analogously,

$$y_3(t) = b_{32}x_2(t).$$

Denote for a while by  $y_{2,1}(t)$  and  $y_{2,2}(t)$  the number of medium flowers that grow out of small and large seedlings respectively. Then  $y_2(t) = y_{2,1}(t) + y_{2,2}(t)$  and  $b_{21} = y_{2,1}(t)/x_1(t)$ ,  $b_{22} = y_{2,2}(t)/x_2(t)$  and thus

$$y_2(t) = b_{21}x_1(t) + b_{22}x_2(t).$$

Write

$$B = \begin{pmatrix} b_{11} & 0 \\ b_{21} & b_{22} \\ 0 & b_{32} \end{pmatrix}, \quad x(t) = \begin{pmatrix} x_1(t) \\ x_2(t) \end{pmatrix}, \quad y(t) = \begin{pmatrix} y_1(t) \\ y_2(t) \\ y_3(t) \end{pmatrix}$$

and rewrite the previous equation in matrix notation

$$y(t) = Bx(t).$$

Denote by  $c_{11}$ ,  $c_{12}$  and  $c_{13}$  the number of seeds produced by small, medium and large flowers respectively. Denote by  $z(t)$  the total number of produced seeds in the summer of year  $t$ . Then

$$z(t) = c_{11}y_1(t) + c_{12}y_2(t) + c_{13}y_3(t).$$

In matrix calculus

$$z(t) = Cy(t)$$

with the notation

$$C = (c_{11} \quad c_{12} \quad c_{13}).$$

If we want the matrix  $C$  to describe the modelled reality, we assume that the inequalities

$$0 < c_{11} < c_{12} < c_{13}$$

hold.

Finally, denote by  $w_1(t)$  and  $w_2(t)$  the number of seeds that burst in the autumn and the number of seeds that stay in the ground during the winter respectively. Denote by  $d_{11}$  and  $d_{21}$  the probabilities that the seeds burst out in the autumn and that the seeds do not burst respectively. Denote by  $f_{11}$  and  $f_{22}$  the probabilities that the seedling and the seed do not die during the winter respectively. The probabilities  $d_{11}$ ,  $d_{21}$  must satisfy the inequalities

$$0 < d_{11}, \quad 0 < d_{21}, \quad d_{11} + d_{21} = 1.$$

Since a seedling dies in the winter more easily than a seed hidden in the ground, we assume that

$$0 < f_{11} < f_{22} < 1.$$

When denoting

$$D = \begin{pmatrix} d_{11} \\ d_{21} \end{pmatrix}, \quad F = \begin{pmatrix} f_{11} & 0 \\ 0 & f_{22} \end{pmatrix}, \quad w(t) = \begin{pmatrix} w_1(t) \\ w_2(t) \end{pmatrix}$$

we obtain, with similar ideas as before, the equalities

$$w(t) = Dz(t), \quad x(t+1) = Fw(t).$$

Because the matrix multiplication is associative, we can compose the recurrent formulas:

$$\begin{aligned} x(t+1) &= Fw(t) = F(Dz(t)) = (FD)z(t) \\ &= (FD)(Cy(t)) = (FDC)y(t) \\ &= (FDC)(Bx(t)) = (FDCB)x(t), \\ y(t+1) &= Bx(t+1) = B(Fw(t)) = (BF)w(t) \\ &= (BF)(Dz(t)) = (BFD)z(t) = (BFD)(Cy(t)) \\ &= (BFDC)y(t), \\ z(t+1) &= Cy(t+1) = C(Bx(t+1)) = (CB)x(t+1) \\ &= (CB)(Fw(t)) = (CBF)w(t) = (CBF)(Dz(t)) \\ &= (CBFD)z(t), \\ w(t+1) &= Dz(t+1) = D(Cy(t+1)) = (DC)y(t+1) \\ &= (DC)(Bx(t+1)) = (DCB)x(t+1) \\ &= (DCB)(Fw(t)) = (DCBF)w(t). \end{aligned}$$

Using the notation

$$A_x = FDCB, \quad A_y = BFDC, \quad A_z = CBFD, \quad A_w = DCBF,$$

we simplify them into the formula

$$\begin{aligned} x(t+1) &= A_x x(t), \quad y(t+1) = A_y y(t), \quad z(t+1) = A_z z(t), \\ w(t+1) &= A_w w(t). \end{aligned}$$

From these formulas we can compute the distribution of the population of the flowers in any part of any year, if we know the starting distribution of the population (that is, in the year zero).

For instance, let the distribution of the population be known in the summer, that is,  $z(0)$  of seeds. The distribution of the population at the beginning of the spring in the  $t$ -th year is

$$\begin{aligned} x(t) &= A_x x(t-1) = A_x^2 x(t-2) = \dots = A_x^{t-1} x(1) \\ &= A_x^{t-1} Fw(0) = A_x^{t-1} FDz(0). \end{aligned}$$

Note that the matrix  $A_z = CBF D$  is of the type  $1 \times 1$ ; it is not a matrix but just a scalar. We can denote by  $\lambda = A_z$ , and compute

$$\begin{aligned}
 (1) \quad \lambda &= CBF D \\
 &= (c_{11} \quad c_{12} \quad c_{13}) \begin{pmatrix} b_{11} & 0 \\ b_{21} & b_{22} \\ 0 & b_{32} \end{pmatrix} \begin{pmatrix} f_{11} & 0 \\ 0 & f_{22} \end{pmatrix} \begin{pmatrix} d_{11} \\ d_{21} \end{pmatrix} \\
 &= (c_{11}b_{11} + c_{12}b_{21} \quad c_{12}b_{22} + c_{13}b_{32}) \begin{pmatrix} f_{11}d_{11} \\ f_{22}d_{21} \end{pmatrix} \\
 &= b_{11}c_{11}d_{11}f_{11} + b_{21}c_{12}d_{11}f_{11} + b_{22}c_{12}d_{21}f_{22} \\
 &\quad + b_{32}c_{13}d_{21}f_{22}
 \end{aligned}$$

and order the previous computation into a suitable form

$$\begin{aligned}
 x(t) &= (FDCB)^{t-1}FDz(0) = FD(CBF D)^{t-2}CBF D z(0) \\
 &= FD(CBF D)^{t-1}z(0) = FDA_z^{t-1}z(0) \\
 &= \lambda^{t-1}FDz(0).
 \end{aligned}$$

In this way only two matrix multiplications remain.

We list concrete values of the matrices  $B, C, D, F$ ; they are the parameters of a hypothetical flower, which were inspired by the actual grass *Vulpia ciliata*:

$$\begin{aligned}
 B &= \begin{pmatrix} 0.3 & 0 \\ 0.1 & 0.6 \\ 0 & 0.2 \end{pmatrix}, \quad C = (1 \quad 10 \quad 100), \quad D = \begin{pmatrix} 0.5 \\ 0.5 \end{pmatrix}, \\
 F &= \begin{pmatrix} 0.05 & 0 \\ 0 & 0.1 \end{pmatrix}.
 \end{aligned}$$

Now we can compute the individual matrices, which map the vector describing the distribution of the population in some vegetative part of the year on the vector of the distribution of the population in the same part of the next year:

$$\begin{aligned}
 A_x &= \begin{pmatrix} 0.0325 & 0.6500 \\ 0.0650 & 1.3000 \end{pmatrix} \quad A_y = \begin{pmatrix} 0.0075 & 0.0750 & 0.7500 \\ 0.0325 & 0.3250 & 3.2500 \\ 0.0100 & 0.1000 & 1.0000 \end{pmatrix}, \\
 A_z &= 1.3325, \quad A_w = \begin{pmatrix} 0.0325 & 1.3000 \\ 0.0325 & 1.3000 \end{pmatrix}.
 \end{aligned}$$

The value of  $\lambda = A_z = 1.3325$  expresses the relative increment of the population between two years. Check for yourself that each of the matrices  $A_x, A_y, A_w$  has only one non-zero eigenvalue  $\lambda = 1.3325$ . The other eigenvalues are equal to 0.

We show one more application of the given model. We are interested in the “flexibility” of the reaction of the relative increment  $\lambda$  on the change of the individual “demographic parameters” – for instance, how the change of the probabilities of survival of the seeds changes the yearly increment. We reformulate the question. By the *flexibility of the reaction of the characteristic  $\lambda$  on the parameter  $s$* , denoted by  $e(\lambda, s)$ , we mean the relative change of the value  $\lambda$  related to the relative change of the parameter  $s$ . Even more precisely: by  $\lambda(s)$  we denote the yearly increment in dependence on the parameter  $s$ . Then  $\Delta\lambda(s) = \lambda(s + \Delta s) - \lambda(s)$  expresses the absolute change of the relative increment  $\lambda$  with the absolute change of the parameter  $s$  by  $\Delta s$ . The relative change of the increment of the parameter  $s$  is  $\Delta s/s$ . The flexibility is then the ratio of these two relative changes, that is,

$$e(\lambda, s) = \frac{\Delta\lambda(s)/\lambda(s)}{\Delta s/s} = \frac{s}{\lambda(s)} \frac{\lambda(s + \Delta s) - \lambda(s)}{\Delta s}.$$

Specifically, the yearly relative increment of the population depending on the survival of the seeds over the winter is, according to (1)

$$\lambda(f_{22}) = d_{21}(b_{22}c_{12} + b_{32}c_{13})f_{22} + d_{11}(b_{11}c_{11}f_{11} + b_{21}c_{12}f_{11})$$

and for specific values of the other parameters

$$\lambda(f_{22}) = 13f_{22} + 0.0325.$$

Because  $f_{22} = 0.1$ , we can compute

$$\lambda(0.1) = 1.3325, \quad \lambda(0.1 + \Delta s) = 1.3325 + 13\Delta s,$$

$$\Delta\lambda(0.1) = 13\Delta s,$$

therefore

$$e(\lambda, 0.1) = \frac{0.1}{1.3325} \frac{13\Delta s}{\Delta s} \doteq 0.976.$$

Analogically we can compute the flexibility of the reaction of the relative increment  $\lambda$  of the population on the other “demographic parameters”. The results are summarised in the table

parameter	flexibility	parameter	flexibility
$b_{11}$	0.006	$c_{11}$	0.006
$b_{21}$	0.019	$c_{12}$	0.244
$b_{22}$	0.225	$c_{13}$	0.751
$b_{23}$	0.750	$f_{11}$	0.024
$d_{11}$	0.024	$f_{22}$	0.976
$d_{21}$	0.976		

From it we can see that the increment  $\lambda$  is mostly influenced by the number of the seeds that overwinter (parameter  $d_{21}$ ) and their survivability (parameter  $f_{22}$ ). This revelation is not surprising. Farmers have been aware of this fact since neolithic times. The result shows that the mathematical model adequately describes the reality.

**3.G.4.** Consider the following Leslie model in which a farmer breeds sheep. The birth-rate of sheep depends only on their age and on average is 2 lambs per sheep between one and two years of age, 5 lambs per sheep between two and three years of age and 2 lambs per sheep between three and four years of age. Younger sheep do not deliver any lambs. Every year, half of the sheep die, uniformly distributed among all age groups. Every sheep older than four years is sent to the butchery. The farmer would like to sell (living) lambs younger than one year for their skin. What proportion of the lambs can be sold every year to ensure that the size of the herd remains the same? In what ratio will the sheep then be distributed among individual age categories?

**Solution.** The matrix of the model (without action of the farmer) is

$$L = \begin{pmatrix} 0 & 2 & 5 & 2 \\ \frac{1}{2} & 0 & 0 & 0 \\ 0 & \frac{1}{2} & 0 & 0 \\ 0 & 0 & \frac{1}{2} & 0 \end{pmatrix}$$

The farmer can influence how many sheep younger than one year stay in his herd to the next year, that is, he can influence the element  $l_{12}$  of the matrix  $L$ . Thus we are dealing with the model

$$L = \begin{pmatrix} 0 & 2 & 5 & 2 \\ a & 0 & 0 & 0 \\ 0 & \frac{1}{2} & 0 & 0 \\ 0 & 0 & \frac{1}{2} & 0 \end{pmatrix}.$$

We are looking for an  $a$  such that the matrix has the eigenvalue 1 (we know that it has only one real positive eigenvalue). The characteristic polynomial of this matrix is

$$\lambda^4 - 2a\lambda^2 - \frac{5}{2}\lambda - \frac{1}{2}.$$

If we require it to have 1 as a root, then  $a = \frac{1}{5}$ . The farmer can thus sell  $\frac{1}{2} - \frac{1}{5} = \frac{3}{10}$  of lambs that are born that year. The corresponding eigenvector for the eigenvalue 1 of the given matrix is  $(20, 4, 2, 1)$  and in these ratios the population stabilises.

□

**3.G.5.** Consider the Leslie population growth model for the population of rats, divided into three groups according to age: younger than one year, between one year and two years and between two years and three years. Assume that there exists no rat older than three years. The average birth-rate of one rat in individual age categories is the following: in the first group it is zero, in the second and in the third it is 2 rats. The mortality in the second group is zero, that is, the rats that survive their first year die after three years of life. Determine the mortality in the first group, if you know that the population stagnates (the total number of rats does not change). ○

**3.G.6. Model of evolution of a whale population.** For the evolution of a population, females are important. The important factor is not age but fertility. From this point of view we can divide the females into newborns (juvenile), that is, females who are yet fertile; young fertile females; adult females with the highest fertility, and postclimacterial females who are no longer fertile, but are still important with respect to taking care of newborns and food gathering.

We model the evolution of such a population by time. For a time unit, we choose the time it takes to reach adulthood. A newborn female who survives this interval becomes fertile. The evolution of a young female to full fertility and to postclimacterial state depends on the environment. That is, the transition to the next category is a random event. Analogously, the death of an individual is also a random event. A young fertile female has less children per unit interval than an adult female. We formalise these statements.

Denote by  $x_1(t)$ ,  $x_2(t)$ ,  $x_3(t)$ ,  $x_4(t)$  the number of juvenile, young, adult and postclimacterial females in time  $t$  respectively. The amount can be expressed as a number of individuals, but also as a number of individuals relative per unit area (population density), or as a total biomass. Denote further by  $p_1$  the probability that a juvenile female survives the unit time interval and becomes fertile, and by  $p_2$  and  $p_3$  the respective probabilities that a young female becomes adult and that an adult female becomes old. Another random event is the death (positively formulated: survival) of females who do not move to the next category – we denote the probabilities respectively as  $q_2$ ,  $q_3$  and  $q_4$  for young, adult and old females. Each of the numbers  $p_1, p_2, p_3, q_2, q_3, q_4$  is a probability from the interval  $[0,1]$ .

A young female can survive, reach adulthood or die; these events are mutually exclusive, together they form a sure certain event and cannot be excluded. Thus,  $p_2 + q_2 < 1$ . For similar reasons  $p_3 + q_3 < 1$ . Finally, we denote by  $f_2$  and  $f_3$  the average number of daughters of a young and adult female, respectively. These parameters satisfy  $0 < f_2 < f_3$ .

The expected number of newborn females in the next time interval is the sum of the daughters of young and of the adult females, that is

$$x_1(t+1) = f_2x_2(t) + f_3x_3(t).$$

Denote temporarily by  $x_{2,1}(t+1)$  the number of young females in time  $t+1$ , who were juvenile in the previous time interval.

Denote temporarily by  $x_{2,2}(t+1)$  the number of young females, who were already fertile in time  $t$ , survived that time interval, but did not move into the adulthood.

The probability  $p_1$  that a juvenile female survives the interval can be expressed by classical probability, that is, by the ratio  $x_{2,1}(t+1)/x_1(t)$ . Similarly the probability  $q_2$  can be expressed as the ratio  $x_{2,2}(t+1)/x_2(t)$ . Since young females in time  $t+1$  are exactly those who survived the juvenile stage and were already fertile, did survive and did not evolve,

$$x_2(t+1) = x_{2,1}(t+1) + x_{2,2}(t+1) = p_1x_1(t) + q_2x_2(t).$$

Similarly, the expected number of fully fertile females is

$$x_3(t+1) = p_2x_2(t) + q_3x_3(t)$$

and the expected number of postclimacterial females is

$$x_4(t+1) = p_3x_3(t) + q_4x_4(t).$$

FIGURE 1. Evolution of a population of orca whale. On the horizontal axis the time is in years, on the vertical axis is the size of the population. Individual areas depict the number of juvenile, young, adult and old females respectively, from below.

Now we can denote

$$A = \begin{pmatrix} 0 & f_2 & f_3 & 0 \\ p_1 & q_2 & 0 & 0 \\ 0 & p_2 & q_3 & 0 \\ 0 & 0 & p_3 & q_4 \end{pmatrix}, \quad x(t) = \begin{pmatrix} x_1(t) \\ x_2(t) \\ x_3(t) \\ x_4(t) \end{pmatrix}$$

and rewrite the previous recurrent formulas in matrix form

$$x(t+1) = Ax(t).$$

Using this matrix difference equation we can compute the expected number of females in individual categories, if we know the distribution of the population at some initial time.

Specifically, for the population of orca whales the following parameters were observed:

$$\begin{aligned} p_1 &= 0.9775, & q_2 &= 0.9111, & f_2 &= 0.0043, \\ p_2 &= 0.0736, & q_3 &= 0.9534, & f_3 &= 0.1132, \\ p_3 &= 0.0452, & q_4 &= 0.9804; \end{aligned}$$

The time interval is in this case one year.

If we start at the time  $t = 0$  with a unit measure of young females in some unoccupied area, that is, with the vector  $x(0) = (0, 1, 0, 0)^T$ , we can compute

$$x(1) = \begin{pmatrix} 0 & 0.0043 & 0.1132 & 0 \\ 0.9775 & 0.9111 & 0 & 0 \\ 0 & 0.0736 & 0.9534 & 0 \\ 0 & 0 & 0.0452 & 0.9804 \end{pmatrix} \begin{pmatrix} 0 \\ 1 \\ 0 \\ 0 \end{pmatrix} = \begin{pmatrix} 0.0043 \\ 0.9111 \\ 0.0736 \\ 0 \end{pmatrix},$$

$$x(2) = \begin{pmatrix} 0 & 0.0043 & 0.1132 & 0 \\ 0.9775 & 0.9111 & 0 & 0 \\ 0 & 0.0736 & 0.9534 & 0 \\ 0 & 0 & 0.0452 & 0.9804 \end{pmatrix} \begin{pmatrix} 0.0043 \\ 0.9111 \\ 0.0736 \\ 0 \end{pmatrix} = \begin{pmatrix} 0.01224925 \\ 0.83430646 \\ 0.13722720 \\ 0.00332672 \end{pmatrix}$$

The results of the computation can be also expressed graphically; see the diagram 1. Try a computation and graphical depiction of the results for a different initial distribution of the population. The result should be an observation that the total population grows exponentially, but the ratios of the sizes of individual groups stabilise on constant values.

The matrix  $A$  thus has the eigenvalues

$$\lambda_1 = 1.025441326, \lambda_2 = 0.980400000, \lambda_3 = 0.834222976, \lambda_4 = 0.004835698.$$

The eigenvector associated with the largest eigenvalue  $\lambda_1$  is

$$w = (0.03697187, 0.31607121, 0.32290968, 0.32404724);$$

this vector is normed such that the sum of its components equals 1.

Compare the evolution of the size of the population with the exponential function  $F(t) = \lambda_1^t x_0$ , where  $x_0$  is the total size of the initial population. Compute also the relative distribution of individual categories in the population after a certain time of evolution. Compare it with the components of the eigenvector  $w$ . They will appear very close, this is caused by the fact that  $A$  has only a single eigenvalue with the greatest absolute value. Also, the vector space generated by the eigenvectors associated with the eigenvalues  $\lambda_2, \lambda_3, \lambda_4$  has only the zero vector with the non-negative orthant intersection. The structure of the matrix  $A$  itself does not ensure such an easily predictable evolution, since it is a reducible matrix (see ??).

**3.G.7. Model of growth of population of teasels *Dipsacus sylvestris*.** This plant can be seen in four stages. Either as a blossoming plant or as a rosette of leaves. With the rosette there are three sizes – small, medium and large. The life cycle of this monoecious perennial plant can be described as follows.

A blossoming plant produces a number of seeds in late summer and dies. From the seeds, some of them sprout in that year into a rosette of leaves, usually of medium size. Other seeds spend the winter in the ground. Some of the seeds in the ground sprout in the spring into a rosette, but because they were weakened during the winter, the size is usually small. After three or more winters the “sleeping” (formally, dormant) seeds die as they lose the ability to sprout. Depending on the environment of the plant, a small or medium rosette can grow during the year, and any rosette can stay in its category or die (wither, be eaten by insects, etc.) A medium or large rosette can burst into a flower in the next year. A blossoming flower then produces seeds and the cycle repeats.

In order to be able to predict the spreading of the population of the teasels, we need to quantify the described events. Botanists discovered that a blossoming plant produces on average 431 seeds. The probabilities that a seed sprouts, that a rosette grows or bursts into a flower are summarised in the following table:

event	probability
seed produced by a flower dies	0.172
seed sprouts into a small rosette in the current year	0.008
seed sprouts into a medium rosette in the current year	0.070
seed sprouts into a large rosette in the current year	0.002
seed sprouts into a small rosette after spending the winter	0.013
seed sprouts into a medium rosette after spending the winter	0.007
seed sprouts into a large rosette after spending the winter	0.001
seed sprouts into a small rosette after spending two winters	0.001
seed dies after spending one winter	0.013
small rosette survives but does not grow	0.125
medium rosette survives but does not grow	0.238
large rosette survives but does not grow	0.167
small rosette grows into a medium one	0.125
small rosette grows into a large one	0.036
medium rosette grows into a large one	0.245
medium rosette bursts into a flower	0.023
large rosette bursts into a flower	0.750

Note that all the relevant events in the life cycle have their probabilities given and that the events are mutually incompatible.

Imagine that we always observe the population at the beginning of the vegetative year, say in March, and that all considered events take place in the rest of the year, say from April to February. In the population there are blossoming flowers, rosettes of three sizes, produced seeds and seeds that have been dormant for a year or two. This leads to a division of the population into seven classes – just-produced seeds, seeds dormant for one year, seeds dormant for two years, rosettes small, medium and large and blossoming flowers. But the just-produced seeds are changed either into rosettes or they spend winter in the same year, thus they do not form an individual category. We denote:

$x_1(t)$  — the number of seeds dormant for one year in the spring of the year  $t$

$x_2(t)$  — the number of seeds dormant for two years in the spring of the year  $t$

$x_3(t)$  — the number of small rosettes in the spring of the year  $t$

$x_4(t)$  — the number of medium rosettes in the spring of the year  $t$

$x_5(t)$  — the number of large rosettes in the spring of the year  $t$

$x_6(t)$  — the number of blossoming flowers in the spring of the year  $t$

The number of produced seeds in the year  $t$  is  $431x_6(t)$ . The probability that a seed stays dormant for the first year equals the probability that the seed does not sprout into a rosette and does not die, that is,  $1 - (0.008 + 0.070 + 0.002 + 0.172) = 0.748$ .

The expected number of seeds dormant for winter in the next year is thus

$$x_1(t+1) = 0.748 \cdot 431x_6(t) = 322.388x_6(t).$$

The probability that the seed that has been dormant for one year stays dormant for the second year equals the probability that the dormant seed does not sprout into a rosette and that it does not die, that is,  $1 - 0.013 - 0.007 - 0.001 - 0.013 = 0.966$ .

The expected number of seeds dormant for two winters is thus

$$x_2(t+1) = 0.966x_1(t).$$

A small rosette can sprout from the seeds immediately, from a seed dormant for one year or from a seed dormant for two years. The expected number of small rosettes sprouted from non-dormant seeds in the year  $t$  equals  $0.008 \cdot 431x_6(t) = 3.448x_6(t)$ . The expected number of small rosettes sprouted from the seeds dormant for one and two years is  $0.013x_1(t)$  and  $0.010x_2(t)$  respectively. With these newly sprouted small rosettes there are in the population also the older small rosettes (those that have not grown yet) – of those there are  $0.125x_3(t)$ . The total expected number of small rosettes is thus

$$x_3(t+1) = 0.013x_1(t) + 0.010x_2(t) + 0.125x_3(t) + 3.448x_6(t).$$

Analogously we determine the expected number of medium and large rosettes

$$\begin{aligned} x_4(t+1) &= 0.007x_1(t) + 0.125x_3(t) + 0.238x_4(t) + 0.070 \cdot 431x_6(t) = \\ &= 0.007x_1(t) + 0.125x_3(t) + 0.238x_4(t) + 30.170x_6, \end{aligned}$$

$$\begin{aligned} x_5(t+1) &= 0.245x_4(t) + 0.167x_5(t) + 0.002 \cdot 431x_6(t) = \\ &= 0.245x_4(t) + 0.167x_5(t) + 0.862x_6(t). \end{aligned}$$

The blossoming flower can arise either from medium or from large rosette. The expected number of blossoming flowers is thus

$$x_6(t+1) = 0.023x_4(t) + 0.750x_5(t).$$

We have thus reached six recurrent formulas for individual components of the investigated plant. We now denote

$$A = \begin{pmatrix} 0 & 0 & 0 & 0 & 0 & 322.388 \\ 0.966 & 0 & 0 & 0 & 0 & 0 \\ 0.013 & 0.010 & 0.125 & 0 & 0 & 3.448 \\ 0.007 & 0 & 0.125 & 0.238 & 0 & 30.170 \\ 0.008 & 0 & 0.038 & 0.245 & 0.167 & 0.862 \\ 0 & 0 & 0 & 0.023 & 0.750 & 0 \end{pmatrix}, \quad x(t) = \begin{pmatrix} x_1(t) \\ x_2(t) \\ x_3(t) \\ x_4(t) \\ x_5(t) \\ x_6(t) \end{pmatrix}$$

and write the previous equalities in matrix form suitable for the computation

$$x(t+1) = Ax(t).$$

If we know the distribution of the individual components of the population in some initial year  $t = 0$ , then we can compute the expected numbers of flowers and seeds in the following years. We can also compute the total number of individuals  $n(t)$  at the time  $t$ ,  $n(t) = \sum_{i=1}^6 x_i(t)$ . We can compute the relative distribution of the individual components  $x_i(t)/n(t)$ ,  $i = 1, 2, 3, 4, 5, 6$  and the yearly relative change in the population  $n(t+1)/n(t)$ . The results of such calculations for fifteen years, and the case above of one blossoming flower, are given in the table 1. Unlike the whale population, the image would not be very clear, as

$t$	$x_1$	$x_2$	$x_3$	$x_4$	$x_5$	$x_6$	$n(t)$
0	0.00	0.00	0.00	0.00	0.00	1.00	1.00
1	322,39	0.00	3,45	30,17	0.86	0.00	356,87
2	0.00	311,43	4,62	9,87	10,25	1,34	337,50
3	432,13	0.00	8,31	43,37	5,46	7,91	497,18
4	2550,50	417,44	33,93	253,07	22,13	5,09	3282,16
5	1641,69	2463,78	59,13	235,96	91,78	22,42	4514,76
6	7227,10	1585,88	130,67	751,37	107,84	74,26	9877,12
7	23941,29	6981,37	382,20	2486,25	328,89	98,16	34218,17
8	31646,56	23127,29	767,29	3768,67	954,73	303,85	60568,39
9	97958,56	30570,58	1786,27	10381,63	1627,01	802,72	143126,78

TABLE 1. Modelled evolution of the population of teasels *Dipsacus sylvestris*. Sizes of the individual components of population, the total size of population, relative distribution of the individual components of population and the relative increments of sizes.

the numbers of flowers are negligible compared to the numbers of seeds (the individual areas for flowers would merge in the picture).

The matrix  $A$  has eigenvalues

$$\begin{aligned} \lambda_1 &= 2.3339 & \lambda_4 &= 0.1187 + 0.1953i \\ \lambda_2 &= -0.9569 + 1.4942i & \lambda_5 &= 0.1187 - 0.1953i \\ \lambda_3 &= -0.9569 - 1.4942i & \lambda_6 &= -0.1274 \end{aligned}$$

The eigenvector associated with the eigenvalue  $\lambda_1$  is

$$w = (0.6377, 0.2640, 0.0122, 0.0693, 0.0122, 0.0046);$$

this vector is normed such that the sum of its components is one. With increasing time  $t$ , the relative increment in the size of the population approaches the eigenvalue  $\lambda_1$ , the relative distribution of the components in the population approach the components of the normed eigenvector associated with the eigenvector  $\lambda_1$ . Every non-negative matrix that has non-zero elements in the same positions as  $A$  is primitive. The evolution of the population necessarily approaches a stable structure.

**3.G.8. Nonlinear model of population.** Investigate in detail the evolution of the population for a non-linear model from the text book (1.12), with  $K = 1$  and

- i) rate of growth  $r = 1$  and the initial state  $p(1) = 0.2$
- ii) rate of growth  $r = 1$  and the initial state  $p(1) = 2$
- iii) rate of growth  $r = 1$  and the initial state  $p(1) = 3$
- iv) rate of growth  $r = 2.2$  and the initial state  $p(1) = 0.2$
- v) rate of growth  $r = 3$  and the initial state  $p(1) = 0.2$

Compute some members of the sequence and predict the future growth of the population.

**Solution.**

- i) The first ten members of the sequence  $p(n)$  is in the following table. From there we can see that the size of the population converges to the value 1.

n	p(n)
1	0.2
2	0.36
3	0.5904
4	0.83222784
5	0.971852502
6	0.999207718
7	0.999999372

Graph for the evolution of the population for  $r = 1$  and  $p(1) = 0.2$ :

- ii) For the initial value  $p(1) = 2$  we obtain  $p(2) = 0$  and after that the population does not change.
- iii) For  $p(1) = 3$  we obtain

n	p(n)
1	3
2	-15
3	-255
4	-65535

and from there we see that the populations decreases under all bounds.

- iv) For the measure of growth  $r = 2, 2$  and the initial state  $p(1) = 0.2$  we obtain

n	p(n)
1	0.2
2	0.552
3	1.0960512
4	0,864441727
5	1.122242628
6	0.820433675
7	1.144542647
8	0.780585155
9	1.157383491
10	0.756646772
11	1.161738128
12	0.748363958
13	1.162657716
14	0.74660417

Instead of convergence we obtain in this case an oscillation – after some time the population jumps between the values 1,16 and 0.74. The graph of the evolution of the population for  $r = 2, 2$  and  $p(1) = 0.2$  then looks as follows:

- v) For the rate of growth  $r = 3$  and the initial state  $p(1) = 0.2$  we obtain

n	p(n)
1	0.2
2	0.68
3	1.3328
4	0.00213248
5	0.008516278
6	0.033847529
7	0.131953152
8	0.475577705
9	1.223788359
10	0.402179593
11	1.123473097
12	0.707316989
13	1.328375987
14	0.019755658
15	0.077851775
16	0.293224403
17	0.91495596
18	1.148390614
19	0.63715945
20	1.330721306
21	0.010427642
22	0.041384361
23	0.160399447

In this case the situation is more complicated – the population starts oscillating between more values. In order to be able to see between what values, we would need to compute more members. For the members from the table we have the following graph:

□

**3.G.9.** In a laboratory an experiment is carried on with the same probability of success and failure. If the experiment succeeds, the probability of success of the second experiment is 0.7. If the first experiment fails, the probability of success of the second experiment is only 0.6.

This process is continued indefinitely. For any  $n \in \mathbb{N}$  determine the probability that the  $n$ -th experiment is successful.

**Solution.** Introduce the probabilistic vector

$$x_n = (x_n^1, x_n^2)^T, \quad n \in \mathbb{N},$$

where  $x_n^1$  is the probability of the success of the  $n$ -th experiment and  $x_n^2 = 1 - x_n^1$  is the probability of its failure. According to the statement

$$x_1 = \begin{pmatrix} 1/2 \\ 1/2 \end{pmatrix}$$

and hence also

$$x_2 = \begin{pmatrix} 0.7 & 0.6 \\ 0.3 & 0.4 \end{pmatrix} \cdot \begin{pmatrix} 1/2 \\ 1/2 \end{pmatrix} = \begin{pmatrix} 13/20 \\ 7/20 \end{pmatrix}.$$

Using the notation

$$T = \begin{pmatrix} 7/10 & 3/5 \\ 3/10 & 2/5 \end{pmatrix}$$

it holds that

$$(1) \quad x_{n+1} = T \cdot x_n, \quad n \in \mathbb{N},$$

because the probabilistic vector  $x_{n+1}$  depends only on  $x_n$  and this dependency is identical for both  $x_2$  and  $x_1$ . From the relation (1) we have directly

$$(2) \quad x_{n+1} = T \cdot T \cdot x_{n-1} = \cdots = T^n \cdot x_1, \quad n \geq 2, n \in \mathbb{N}.$$

Therefore we express  $T^n$ ,  $n \in \mathbb{N}$ . It is a Markov process, and thus 1 is an eigenvalue of the matrix  $T$ . The second eigenvalue 0.1, and follows for instance from the fact that the trace (the sum of the elements on the diagonal) equals the sum of the eigenvalues (every eigenvalue is counted with its algebraic multiplicity). To these eigenvalues then correspond the eigenvectors

$$\begin{pmatrix} 2 \\ 1 \end{pmatrix}, \quad \begin{pmatrix} 1 \\ -1 \end{pmatrix}.$$

We thus obtain

$$T = \begin{pmatrix} 2 & 1 \\ 1 & -1 \end{pmatrix} \cdot \begin{pmatrix} 1 & 0 \\ 0 & 1/10 \end{pmatrix} \cdot \begin{pmatrix} 2 & 1 \\ 1 & -1 \end{pmatrix}^{-1},$$

that is, for  $n \in \mathbb{N}$  we have

$$\begin{aligned} T^n &= \begin{pmatrix} 2 & 1 \\ 1 & -1 \end{pmatrix} \cdot \begin{pmatrix} 1 & 0 \\ 0 & 1/10 \end{pmatrix}^n \cdot \begin{pmatrix} 2 & 1 \\ 1 & -1 \end{pmatrix}^{-1} = \\ &= \begin{pmatrix} 2 & 1 \\ 1 & -1 \end{pmatrix} \cdot \begin{pmatrix} 1^n & 0 \\ 0 & 10^{-n} \end{pmatrix} \cdot \begin{pmatrix} 2 & 1 \\ 1 & -1 \end{pmatrix}^{-1}. \end{aligned}$$

Substitution

$$\begin{pmatrix} 2 & 1 \\ 1 & -1 \end{pmatrix}^{-1} = \frac{1}{3} \begin{pmatrix} 1 & 1 \\ 1 & -2 \end{pmatrix}$$

and multiplication yields

$$T^n = \frac{1}{3} \begin{pmatrix} 2 + 10^{-n} & 2 - 2 \cdot 10^{-n} \\ 1 - 10^{-n} & 1 + 2 \cdot 10^{-n} \end{pmatrix}, \quad n \in \mathbb{N}.$$

From there, from (1) and from (2) it follows that

$$x_{n+1} = \left( \frac{2}{3} - \frac{1}{6 \cdot 10^n}, \frac{1}{3} + \frac{1}{6 \cdot 10^n} \right)^T, \quad n \in \mathbb{N}.$$

Specially, we see that for big  $n$  the probability of success of the  $n$ -th experiment is close to  $2/3$ . □

**3.G.10.** A student in a student dormitory is very “socially tired”. As a result, he is not able to fully perceive the universe around him and coordinate his movements. In this state he decides to invite his friend who lives at the end of the hall to the party-in-progress. But at the other end of the hall there lives somebody he definitely does not wish to invite.

He is so “tired”, that he attains the decision to make a step in a desired direction only in 53 of 100 attempts (in the remaining 47, he makes a step in exactly the opposite direction).

Assuming that he starts in the middle of the hall and that the distance to both of the doors at the ends corresponds to twenty of his awkward steps, determine the probability that he first reaches the desired door.

○

**3.G.11.** Let  $n \in \mathbb{N}$  of persons be playing the “silent post”. For simplicity, assume that the first person whispers to the second person exactly one (arbitrarily chosen) of the words “yes”, “no”. The second person then whispers to the third person

the choice of the words “yes”, “no” that the second person thinks the first person whispered. This continues to the  $n$ -th person. If the probability that the word changes (on purpose or accidentally) to the alternative word during one transmission is  $p \in (0,1)$ , determine for large  $n \in \mathbb{N}$  the probability that the  $n$ -th person correctly receives the same word as transmitted by the first person.

**Solution.** We can view this problem as a Markov chain with two states called Yes and No. We say that the process is in the "yes" state in time  $m \in \mathbb{N}$ , if the  $m$ -th person thinks that the received word is "yes". For the order of the states "yes", "no", the probabilistic matrix is

$$T = \begin{pmatrix} 1-p & p \\ p & 1-p \end{pmatrix}.$$

The product of the matrix  $T^{m-1}$  and the probabilistic vector of the initial choice of the first person then gives the probability of what the  $m$ -th person thinks. We do not have to compute the powers of this matrix, because all the elements of the matrix  $T$  are positive numbers. Furthermore, this matrix is doubly stochastic. Thus for large  $n \in \mathbb{N}$  the probabilistic vector is close to the vector  $(1/2, 1/2)^T$ . The probability that the  $n$ -th person says "yes", is thus approximately the same as the probability that the  $n$ -th person says "no", independently of the initial word. For a large number of participants roughly half of them hears "yes". We repeat that this does not depend on the initial word.

For completeness, we determine what would be the result if we assumed that the probability of change from "yes", to "no" is for any person equal to  $p \in (0,1)$  and the probability of change from "no" to "yes", equals (generally distinct)  $q \in (0,1)$ . In this case for the same order of the states we obtain a probabilistic matrix

$$T = \begin{pmatrix} 1-p & q \\ p & 1-q \end{pmatrix}.$$

This leads (for large  $n \in \mathbb{N}$ ) to the probabilistic vector close to the vector

$$\left( \frac{q}{p+q}, \frac{p}{p+q} \right)^T,$$

which for instance follows from the expression of the matrix

$$T^n = \frac{1}{p+q} \left[ \begin{pmatrix} q & q \\ p & p \end{pmatrix} + (1-p-q)^n \begin{pmatrix} p & -q \\ -p & q \end{pmatrix} \right].$$

Again, with sufficiently many people it does not depend on the initial choice of the word. Simply speaking, in this model, it does not depend on the initial state, because the people decide what the transmitted information is about; more precisely, the people themselves decide about the frequency of appearance of "yes" and "no", if there are enough of them and there is no checking present.

The obtained result was experimentally confirmed. In a psychological experiment, an individual was repeatedly exposed to an event that could have been interpreted in two ways. It was being done in time intervals that ensured that the subject still remembered the previous event. See for instance "T. Havránek et al.: *Matematika pro biologické a lékařské vědy*, Praha, Academia 1981", where there is an experiment in which an ambiguous object (say, a drawing of a cube which can be perceived from both the bottom and the top) is in fixed time intervals lighted on. Such process is a Markov chain with the transition matrix

$$\begin{pmatrix} 1-p & q \\ p & 1-q \end{pmatrix},$$

where  $p, q \in (0,1)$ . □

**3.G.12.** Petr regularly meets his friend. But he is "well-known" for his bad timekeeping. But he is trying to change. Thus in half of the cases he arrives on time, and in one tenth of the cases he comes even sooner, given that he was late for the previous meeting. But if he was on time or sooner for the last meeting, he returns back to his "carelessness" and with probability 0.8 he arrives late, and with only 0.2 he is on time. What is the probability that on the 20<sup>th</sup> meeting he arrives late, given that he was on time on the eleventh?

**Solution.** This is a Markov process with states "Petr comes late", "Petr comes on time", "Petr comes sooner" with the probabilistic transition matrix (with the given order of states)

$$T = \begin{pmatrix} 0.4 & 0.8 & 0.8 \\ 0.5 & 0.2 & 0.2 \\ 0.1 & 0 & 0 \end{pmatrix}.$$

The eleventh meeting is determined by the probabilistic vector  $(0, 1, 0)^T$  (when Petr comes on time). To the twentieth meeting corresponds the vector

$$T^9 \cdot \begin{pmatrix} 0 \\ 1 \\ 0 \end{pmatrix} = \begin{pmatrix} 0, 571\,578\,368 \\ 0, 371\,316\,224 \\ 0, 057\,105\,408 \end{pmatrix}.$$

The desired probability is thus 0, 571 578 368 (exactly). We add that

$$T^9 = \begin{pmatrix} 0.571\,316\,224 & 0.571\,578\,368 & 0.571\,578\,368 \\ 0.371\,512\,832 & 0.371\,316\,224 & 0.371\,316\,224 \\ 0.057\,170\,944 & 0.057\,105\,408 & 0.057\,105\,408 \end{pmatrix}.$$

From this, it is seen that it really does not depend on whether Petr came on the eleventh meeting late (first column), on time (second) or sooner (third).  $\square$

**3.G.13.** Two students  $A$  and  $B$  spend every Monday morning by playing a certain computer game. The person who wins then pays for both of them in the evening in the restaurant. The game can also be a draw – then each pays for half the meal. The result of the previous game partially determines the next game. If a week ago student  $A$  has won, then with the probability  $3/4$  wins again and with probability  $1/4$  it is a draw. A draw is repeated with probability  $2/3$ . With probability  $1/3$  the next game is won by  $B$ . If student  $B$  won a game, then with probability  $1/2$  he wins again and with probability  $1/4$ , student  $A$  wins the next game. Determine the probability that today each of them pays half of the costs, if the first game played long time ago was won by  $A$ .

**Solution.** This a Markov process with the states "student  $A$  wins", "the game ends with a draw", "student  $B$  wins" (in this order), with the probabilistic transition matrix

$$T = \begin{pmatrix} 3/4 & 0 & 1/4 \\ 1/4 & 2/3 & 1/4 \\ 0 & 1/3 & 1/2 \end{pmatrix}.$$

We want to find the probability of the transition from the first state to the second after a large number  $n \in \mathbb{N}$  of steps (weeks). The matrix  $T$  is primitive, because

$$T^2 = \begin{pmatrix} 9/16 & 1/12 & 5/16 \\ 17/48 & 19/36 & 17/48 \\ 1/12 & 7/18 & 1/3 \end{pmatrix}.$$

Thus it suffices to find the probabilistic eigenvector  $x_\infty$  of the matrix  $T$  associated with the eigenvalue 1. It is straightforward to compute

$$x_\infty = \left( \frac{2}{7}, \frac{3}{7}, \frac{2}{7} \right)^T.$$

The vector  $x_\infty$  differs only very slightly from the probabilistic vector for large  $n$ . It does not depend on the initial state. For large  $n \in \mathbb{N}$ , we obtain

$$T^n \approx \begin{pmatrix} 2/7 & 2/7 & 2/7 \\ 3/7 & 3/7 & 3/7 \\ 2/7 & 2/7 & 2/7 \end{pmatrix}.$$

The desired probability is the element of this matrix on the second position in the first column (the second component of the vector  $x_\infty$ ). Hence the result is  $3/7$ .  $\square$

**3.G.14. Popularity of the media.** In a certain country there are two television channels. From a public survey it follows that in one year  $1/6$  of the viewers of the first channel move to the second,  $1/5$  viewers of the second move to the first channel.

Determine the time evolution of the number of viewers watching given channels using Markov processes. Write down a matrix of the process, and find its eigenvalues and eigenvectors. ○

**3.G.15. Students at the lecture.** Students can be divided into, say, three groups – those that are present at a lecture and pay attention, those that are present but pay no attention and those who are in a pub instead. Now observe, lecture after lecture, how the numbers in the individual groups change. The first step is to observe what are the probabilities that a student changes his state. Suppose that it is as follows:

A student who pays attention: with probability 50% stays in the same state, with 40% stops paying attention and with 10% moves to the pub. A student who pays no attention: starts paying attention with 10%, with 50% stays in the same state and with 40% moves to the pub. A student who is in the pub has zero probability of returning to the lectures.

How does the model evolve in time? How does the situation change if we assume at least ten percent probability that a student returns from the pub to the lecture (but is not going to pay any attention)?

**Solution.** The matrix of the Markov process is  $\begin{pmatrix} 0.5 & 0.1 & 0 \\ 0.4 & 0.5 & 0 \\ 0.1 & 0.4 & 1 \end{pmatrix}$ . Its characteristic polynomial is  $(0.5 - \lambda)^2(1 - \lambda) - 0.4(1 - \lambda) = 0$ . Evidently one is an eigenvalue of this matrix (the other roots are 0.3 and 0.7). In the course of time, the students divide into groups as described by the corresponding eigenvector – which is a solution of the equality  $\begin{pmatrix} -0.5 & 0.1 & 0 \\ 0.4 & -0.5 & 0 \\ 0.1 & 0.4 & 0 \end{pmatrix} \begin{pmatrix} x \\ y \\ z \end{pmatrix} = 0$ . These are multiples of the vector  $(0, 0, 1)$ . In other words, all the students end up in the pub.

Such a result is clear even without any computation – as the probability of returning from the pub is zero, all students end up in the pub. Adding 10 percent possibility for leaving the pub, this changes. The corresponding matrix is now  $\begin{pmatrix} 0.5 & 0.1 & 0 \\ 0.4 & 0.5 & 0.1 \\ 0.1 & 0.4 & 0.9 \end{pmatrix}$ . Again the state stabilises on the eigenvector associated with the eigenvalue 1. In this case the solution of the equation

$$\begin{pmatrix} -0.5 & 0.1 & 0 \\ 0.4 & -0.5 & 0.1 \\ 0.1 & 0.4 & -0.1 \end{pmatrix} \begin{pmatrix} x \\ y \\ z \end{pmatrix} = 0$$

is wanted. A solution is for instance the vector  $(1, 5, 21)$ . The distribution of the students in the individual group is then given by the multiple of this vector such that the coordinates sum to one, that is, the vector  $(\frac{1}{27}, \frac{5}{27}, \frac{21}{27})$ . Again, most of the students end up in the pub, but some will be at school. □

**3.G.16. Roulette.** A roulette player has the following strategy: he comes to play with €10. He always bets everything he has. He always bets on black (there are 37 numbers in the roulette, 18 black, 18 red and zero). The player ends whenever he has either nothing, or when he wins €80. Consider this problem as a Markov process and write down its matrix.

**Solution.** In the course of the game and at its end, the player can have only one of the following amounts of money (in €): 0, 10, 20, 40, 80. If we view the situation as a Markov process, then these amounts corresponds to its states, and we construct the matrix:

$$A = \begin{pmatrix} 1 & a & a & a & 0 \\ 0 & 0 & 0 & 0 & 0 \\ 0 & b & 0 & 0 & 0 \\ 0 & 0 & b & 0 & 0 \\ 0 & 0 & 0 & b & 1 \end{pmatrix},$$

where  $a = \frac{19}{37}$  and  $b = \frac{18}{37}$ . Note that the matrix is probabilistic and singular. The eigenvalue 1 is a double one. The game does not converge to a single vector  $x_\infty$ , but ends in one of the eigenvectors associated with eigenvalue 1, that is, either  $(1, 0, 0, 0, 0)$  (the player loses it all), or  $(0, 0, 0, 0, 1)$  (the player wins €80). Furthermore we observe that the game ends

after three bets, that is, the sequence  $\{A^n\}_{n=1}^\infty$ , is constant for  $n \geq 3$ :

$$A^\infty := A^3 = A^n = \begin{pmatrix} 1 & a + ab + ab^2 & a + ab & a & 0 \\ 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 \\ 0 & b^3 & b^2 & b & 1. \end{pmatrix}$$

We easily determine that the game ends with the probability  $a + ab + ab^2 \doteq 0.885$  as a loss and with the probability roughly 0.115 as a win of €80. (We multiply by the matrix  $A^\infty$  the initial vector  $(0, 1, 0, 0, 0)$  and obtain the vector  $(a + ab + ab^2, 0, 0, 0, b^3)$ .)  $\square$

**3.G.17.** Consider the situation from the previous case and assume that the probability of both win and loss is  $1/2$ . Denote by  $A$  the matrix of the process. Without using any computational software determine  $A^{100}$ .  $\circ$

**3.G.18.** Based on the temperature at 14:00, the days are divided into warm, average, and cold. From the all-year statistics, after a warm day the next day is warm in 50 % of the cases and is average in 30 % of the cases, after an average day the next day is average in 40 % of the cases, and cold in 30 % of the cases, and after a cold day, the next day is cold in 50 % of the cases, and average in 30 % of the cases.

Without any further information, derive how many warm, cold, and average days can be expected in a year.

**Solution.** For each day exactly one of the states warm day, average day, cold day is attained. If the vector  $x_n$  has as its components the probabilities that a certain ( $n$ -th) day is warm, average and cold (respectively), then the components of the vector

$$x_{n+1} = \begin{pmatrix} 0.5 & 0.3 & 0.2 \\ 0.3 & 0.4 & 0.3 \\ 0.2 & 0.3 & 0.5 \end{pmatrix} \cdot x_n$$

show the probabilities that the next day is warm, average and cold respectively. To verify, it suffices to substitute

$$x_n = \begin{pmatrix} 1 \\ 0 \\ 0 \end{pmatrix}, \quad x_n = \begin{pmatrix} 0 \\ 1 \\ 0 \end{pmatrix}, \quad x_n = \begin{pmatrix} 0 \\ 0 \\ 1 \end{pmatrix},$$

while for instance for the third choice we must obtain the probabilities that after a cold day there follows a warm, average and cold day respectively. We see that the problem is a Markov chain problem with probabilistic transitional matrix

$$T = \begin{pmatrix} 0.5 & 0.3 & 0.2 \\ 0.3 & 0.4 & 0.3 \\ 0.2 & 0.3 & 0.5 \end{pmatrix}.$$

Because all the elements of this matrix are positive, there exists a probabilistic vector

$$x_\infty = (x_\infty^1, x_\infty^2, x_\infty^3)^T,$$

to which the vector  $x_n$  approaches as  $n$  grows, independently of the vector  $x_n$  for small  $n$ . Furthermore, by the corollary of the Perron-Frobenius theorem,  $x_\infty$  is the eigenvector of the matrix  $T$  with the eigenvalue 1. Thus

$$\begin{aligned} x_\infty^1 &= 0.5 x_\infty^1 + 0.3 x_\infty^2 + 0.2 x_\infty^3, \\ x_\infty^2 &= 0.3 x_\infty^1 + 0.4 x_\infty^2 + 0.3 x_\infty^3, \\ x_\infty^3 &= 0.2 x_\infty^1 + 0.3 x_\infty^2 + 0.5 x_\infty^3, \\ 1 &= x_\infty^1 + x_\infty^2 + x_\infty^3, \end{aligned}$$

where the last condition means that the vector  $x_\infty$  is probabilistic. It is easy to see that this system has a unique solution

$$x_\infty^1 = x_\infty^2 = x_\infty^3 = \frac{1}{3}.$$

Thus we can expect roughly the same number of warm, average and cold days.

We emphasise that the sum of the numbers from any column of the matrix  $T$  must equal 1, otherwise it would not be a Markov process. Because  $T^T = T$ , the matrix  $T$  is symmetric, and the sum of all numbers from any row also equals 1. We say that a matrix with non-negative elements and with the property that the sum of the numbers in any column or in any row

equals one is called doubly stochastic. An important property of every doubly stochastic primitive matrix (for any dimension – the number of states) is that the corresponding vector  $x_\infty$  has all of its components identical. That is, after sufficiently many iterations all the states in the corresponding Markov chain are attained with the same frequency.  $\square$

**3.G.19.** John goes running every evening. He has three tracks – short, middle and long. Whenever he chooses a short track, the next day he feels bad about it and chooses with equal probabilities between long and medium. Whenever he chooses a long track, the next day he chooses arbitrarily among all three. Whenever he chooses the medium track, the next he feels good about it, and again chooses with equal probabilities between medium and long. Assume that he has been running like this for very many days. How often does he choose the short track and how often the long track? What is the probability that he chooses a long track when he picked it a week before?

**Solution.** Clearly it is a Markov process with three possible states – choices for a short, medium or long track. This order of the states gives a probabilistic transition matrix

$$T = \begin{pmatrix} 0 & 0 & 1/3 \\ 1/2 & 1/2 & 1/3 \\ 1/2 & 1/2 & 1/3 \end{pmatrix}.$$

It suffices to observe that (for instance) the second column corresponds to the choice of the medium track during the previous day. This means that with the probability  $1/2$ , a medium track will be chosen (the second row), and with probability  $1/2$  a long track will be chosen (the third row). Since

$$T^2 = \begin{pmatrix} 1/6 & 1/6 & 1/9 \\ 5/12 & 5/12 & 4/9 \\ 5/12 & 5/12 & 4/9 \end{pmatrix},$$

we can use the corollary of the Perron-Frobenius theorem for Markov chains. It is not difficult to compute the eigenvector corresponding to the eigenvalue 1. It is a probabilistic vector, namely:

$$\left( \frac{1}{7}, \frac{3}{7}, \frac{3}{7} \right)^T.$$

The numbers  $1/7, 3/7, 3/7$  are then respectively the probabilities that in a randomly chosen day he choose a short, medium or long track.

Suppose on a certain day, John (that is, in time  $n \in \mathbb{N}$ ) chooses a long track. This corresponds to the probabilistic vector

$$x_n = (0, 0, 1)^T.$$

For the following day,

$$x_{n+1} = \begin{pmatrix} 0 & 0 & 1/3 \\ 1/2 & 1/2 & 1/3 \\ 1/2 & 1/2 & 1/3 \end{pmatrix} \cdot \begin{pmatrix} 0 \\ 0 \\ 1 \end{pmatrix} = \begin{pmatrix} 1/3 \\ 1/3 \\ 1/3 \end{pmatrix},$$

and after seven days

$$x_{n+7} = T^7 \cdot \begin{pmatrix} 0 \\ 0 \\ 1 \end{pmatrix} = T^6 \cdot \begin{pmatrix} 1/3 \\ 1/3 \\ 1/3 \end{pmatrix}.$$

The enumeration gives us as components of  $x_{n+7}$  the values

0.142 861 225 ...; 0.428 569 387 ...; 0.428 569 387 ...

Thus the probability that he chooses a long track under the condition that he chose it seven days ago is roughly  $0.428\,569 \approx 3/7 \doteq 0.428\,571$ .  $\square$

**3.G.20.** A production line is not reliable: individual products differ in quality in a significant way. A certain worker tries to improve the quality of the products and intervenes to the process. The products are distributed into classes I, II, III according to their quality, and a report found out that

after a product of class I, the next product has the same quality in 80 % of the cases and is of quality II in 10 % of the cases;

after a product of the class II, the next product is of class II in 60 % of the cases and is of quality I in 20 % of the cases, and

after a product of quality III, the next product is of quality III in 50 % of the cases while in 25 % of the cases it is of quality II.

Compute the probability that the 18-th product is of the quality I, given that the 16-th product is of quality III.

**Solution.** First we solve the problem without using a Markov chain. Since 16-th product is of the class III, the event in question is satisfied by the cases

- 17-th product is of the class I and 18-th product is of class I;
- 17-th product is of the class II and 18-th product is of class I;
- 17-th product is of the class III and 18-th product is of class I,

with probabilities respectively

- $0.25 \cdot 0.8 = 0.2$ ;
- $0.25 \cdot 0.2 = 0.05$ ;
- $0.5 \cdot 0.25 = 0.125$ .

Thus the solution is

$$0.375 = 0.2 + 0.05 + 0.125.$$

Now view the problem as a Markov process. From the statement there corresponds the probabilistic matrix

$$\begin{pmatrix} 0.8 & 0.2 & 0.25 \\ 0.1 & 0.6 & 0.25 \\ 0.1 & 0.2 & 0.5 \end{pmatrix}.$$

The situation that the product is in class III is given by the probabilistic vector  $(0.0.1)^T$ . For the next product we obtain the probabilistic vector

$$\begin{pmatrix} 0.25 \\ 0.25 \\ 0.5 \end{pmatrix} = \begin{pmatrix} 0.8 & 0.2 & 0.25 \\ 0.1 & 0.6 & 0.25 \\ 0.1 & 0.2 & 0.5 \end{pmatrix} \cdot \begin{pmatrix} 0 \\ 0 \\ 1 \end{pmatrix}.$$

For the next product in order there follows the vector

$$\begin{pmatrix} 0.375 \\ 0.3 \\ 0.325 \end{pmatrix} = \begin{pmatrix} 0.8 & 0.2 & 0.25 \\ 0.1 & 0.6 & 0.25 \\ 0.1 & 0.2 & 0.5 \end{pmatrix} \cdot \begin{pmatrix} 0.25 \\ 0.25 \\ 0.5 \end{pmatrix}'$$

The first component is the desired probability.

Notice that the first method of the solution (without using the Markov process) led to the result faster and easier. But notice also how unclear it would become if we wanted to compute, say, the 22-nd or 30-th product. For the second method one can in a sense restrict the computations to the relevant parts of the matrices only instead of mindlessly multiplying the whole matrix. When using the Markov process, we have also directly obtained the probabilities that the 18-th product belongs to the class II and III. □

**3.G.21.** Repeated dice casting. Write down the transitional probabilistic matrix  $T$  for the Markov chain with states "maximum resulting number after  $n$  attempts" with the order of the states  $1, \dots, 6$ . Then determine  $T^n$  for every  $n \in \mathbb{N}$ .

**Solution.** We can immediately write

$$T = \begin{pmatrix} 1/6 & 0 & 0 & 0 & 0 & 0 \\ 1/6 & 2/6 & 0 & 0 & 0 & 0 \\ 1/6 & 1/6 & 3/6 & 0 & 0 & 0 \\ 1/6 & 1/6 & 1/6 & 4/6 & 0 & 0 \\ 1/6 & 1/6 & 1/6 & 1/6 & 5/6 & 0 \\ 1/6 & 1/6 & 1/6 & 1/6 & 1/6 & 1 \end{pmatrix}.$$

The first column is determined by the state 1 and probability  $1/6$  that it is preserved (that is, the next result is one) and probability  $1/6$  for transition into any of the other states  $2, \dots, 6$  (the result on the dice would be  $2, \dots, 6$ ). The second column is given by the state 2 and probabilities  $2/6$  that it is preserved (the result is 1 or 2) and probability for transition  $1/6$  for transition into any of the other states  $3, \dots, 6$  (the result would be  $3, \dots, 6$ ). The last column is derived from the fact that the state 6 is persistent. That is, if 6 has already been cast, no greater result is possible.

For  $n \in \mathbb{N}$ , we can directly determine  $T^n$ :

$$\begin{pmatrix} a^n & 0 & 0 & 0 & 0 & 0 \\ b^n - a^n & b^n & 0 & 0 & 0 & 0 \\ c^n - b^n & c^n - b^n & c^n & 0 & 0 & 0 \\ d^n - c^n & d^n - c^n & d^n - c^n & d^n & 0 & 0 \\ e^n - d^n & e^n - d^n & e^n - d^n & e^n - d^n & e^n & 0 \\ 1 - e^n & 1 - e^n & 1 - e^n & 1 - e^n & 1 - e^n & 1 \end{pmatrix}.$$

where  $a = 1/6, b = 2/6, c = 3/6, d = 4/6, e = 5/6$ .

The numbers in the first column correspond successively to the probabilities that  $n$ -times in a row the result is 1,  $n$ -times in a row the result is 1 or 2 and there was at least one 2 (therefore we subtract the probability given in the first row),  $n$ -times in a row the result is 1, 2 or 3 and at least once the result is 3, up to the last row where there is the probability that at least once during  $n$  throws the result is 6 (this can be easily derived from the probability of the complementary event). Similarly, in the fourth column are the non-zero probabilities of the events

"if  $n$ -times in a row the result is 1, 2, 3 or 4",

"if  $n$ -times in a row the result is 1, 2, 3, 4 or 5 and at least once it is 5"

"if at least once during  $n$  attempts the result is 6". Interpretation of the matrix  $T$  as the probabilistic transition matrix of a Markov process allows for a quick expression of the powers  $T^n, n \in \mathbb{N}$ .  $\square$

**3.G.22.** In this problem we deal with a certain property of an animal species which is determined independently of sex but just by a certain gene – a pair of alleles. Every individual gains one allele from each parent, randomly and independently. There are forms of the gene given by various alleles  $a, A$  – they form three possible states  $aa, aA = Aa$  and  $AA$  of the property.

- Assume that each individual of a certain population mates only with an individual of another population, where there appears only the property caused by the pair  $aA$ . Exactly one of their offspring (a randomly chosen one) will be left on the spot and he will also mate only with an individual of that specific population, and so on. Determine the probabilities of appearance of  $aa, aA, AA$  in the considered population after certain time.
- Solve the problem given in the case (a), if the other population is composed only of individuals with the pair  $AA$ .
- Randomly chosen two individuals of opposite sex are bred. From their progeny again randomly choose two of opposite sex and breed them. If this occurs for a long time, compute the probability that both bred individuals have a pair of alleles  $AA$ , or  $aa$ , when the process of breeding ends.
- Solve the problem from case (c) without the condition that the individuals have the same parent. Thus just breed random individuals from a population among them, then breed among their progeny, and so on.

**Solution.** Case (a). This is a Markov process given by the matrix

$$T = \begin{pmatrix} 1/2 & 1/4 & 0 \\ 1/2 & 1/2 & 1/2 \\ 0 & 1/4 & 1/2 \end{pmatrix}.$$

The order of the states corresponds to the order of the pairs of alleles  $aa$ ,  $aA$ ,  $AA$ . The numbers in the first column follow from the fact that an offspring of parents with alleles  $aa$  and  $aA$  has probability  $1/2$  for the pair  $aa$  and probability  $1/2$  for the pair  $aA$ . Similarly for the third column. The numbers in the second column follow from the fact that each of the four cases of the pairs of alleles  $aa$ ,  $aA$ ,  $Aa$ ,  $AA$  has the same probability for an individual whose both parents have the pair  $aA$ .

Note that there is a difference between counting probability — where we must distinguish between  $aA$  and  $Aa$  (which allele comes from which parent) — and investigating just the properties caused by the pairs  $aA$  and  $Aa$  which are then the same. For determining the resulting state it thus suffices to find the probabilistic vector associated with the eigenvalue 1 of the matrix  $T$ , because the matrix

$$T^2 = \begin{pmatrix} 3/8 & 1/4 & 1/8 \\ 1/2 & 1/2 & 1/2 \\ 1/8 & 1/4 & 3/8 \end{pmatrix}$$

satisfies the condition of the Perron-Frobenius theorem, that is, all of its elements are positive. The probabilistic vector is

$$\left( \frac{1}{4}, \frac{1}{2}, \frac{1}{4} \right)^T,$$

which gives the probabilities  $1/4$ ,  $1/2$ ,  $1/4$  of the appearance of the combinations  $aa$ ,  $aA$  and  $AA$  respectively after a very long (theoretically infinite) time.

Case (b). For the order of the pairs of alleles  $AA$ ,  $aA$ ,  $aa$  we obtain the probabilistic matrix

$$T = \begin{pmatrix} 1 & 1/2 & 0 \\ 0 & 1/2 & 1 \\ 0 & 0 & 0 \end{pmatrix}.$$

The eigenvalues are 1,  $1/2$  and 0. To these eigenvalues correspond respectively the eigenvectors

$$\begin{pmatrix} 1 \\ 0 \\ 0 \end{pmatrix}, \quad \begin{pmatrix} -1 \\ 1 \\ 0 \end{pmatrix}, \quad \begin{pmatrix} 1 \\ -2 \\ 1 \end{pmatrix}.$$

Therefore

$$\begin{aligned} T &= \begin{pmatrix} 1 & -1 & 1 \\ 0 & 1 & -2 \\ 0 & 0 & 1 \end{pmatrix} \cdot \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1/2 & 0 \\ 0 & 0 & 0 \end{pmatrix} \cdot \begin{pmatrix} 1 & -1 & 1 \\ 0 & 1 & -2 \\ 0 & 0 & 1 \end{pmatrix}^{-1} \\ &= \begin{pmatrix} 1 & -1 & 1 \\ 0 & 1 & -2 \\ 0 & 0 & 1 \end{pmatrix} \cdot \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1/2 & 0 \\ 0 & 0 & 0 \end{pmatrix} \cdot \begin{pmatrix} 1 & 1 & 1 \\ 0 & 1 & 2 \\ 0 & 0 & 1 \end{pmatrix}. \end{aligned}$$

From there for arbitrary  $n \in \mathbb{N}$  it follows that

$$\begin{aligned} T^n &= \begin{pmatrix} 1 & -1 & 1 \\ 0 & 1 & -2 \\ 0 & 0 & 1 \end{pmatrix} \cdot \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1/2 & 0 \\ 0 & 0 & 0 \end{pmatrix}^n \cdot \begin{pmatrix} 1 & 1 & 1 \\ 0 & 1 & 2 \\ 0 & 0 & 1 \end{pmatrix} \\ &= \begin{pmatrix} 1 & -1 & 1 \\ 0 & 1 & -2 \\ 0 & 0 & 1 \end{pmatrix} \cdot \begin{pmatrix} 1 & 0 & 0 \\ 0 & 2^{-n} & 0 \\ 0 & 0 & 0 \end{pmatrix} \cdot \begin{pmatrix} 1 & 1 & 1 \\ 0 & 1 & 2 \\ 0 & 0 & 1 \end{pmatrix}. \end{aligned}$$

Since  $\lim_{n \rightarrow \infty} 2^{-n} = 0$ ,

$$\begin{aligned} T^n &\approx \begin{pmatrix} 1 & -1 & 1 \\ 0 & 1 & -2 \\ 0 & 0 & 1 \end{pmatrix} \cdot \begin{pmatrix} 1 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix} \cdot \begin{pmatrix} 1 & 1 & 1 \\ 0 & 1 & 2 \\ 0 & 0 & 1 \end{pmatrix} \\ &= \begin{pmatrix} 1 & 1 & 1 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix} \end{aligned}$$

for large  $n$ . Thus if individuals of the original population procreate exclusively with the member of the specific population (the one which has only  $AA$ ), then necessarily after a sufficient amount of breeding there is a total elimination of the pairs  $aA$  and  $aa$ .

Case (c). There are 6 possible states (in this order)

$$\begin{aligned} AA, AA; \quad aA, AA; \quad aa, AA; \\ aA, aA; \quad aa, aA; \quad aa, aa, \end{aligned}$$

while these states are given by the genotypes of the parents. The matrix of the corresponding Markov chain is

$$T = \begin{pmatrix} 1 & 1/4 & 0 & 1/16 & 0 & 0 \\ 0 & 1/2 & 0 & 1/4 & 0 & 0 \\ 0 & 0 & 0 & 1/8 & 0 & 0 \\ 0 & 1/4 & 1 & 1/4 & 1/4 & 0 \\ 0 & 0 & 0 & 1/4 & 1/2 & 0 \\ 0 & 0 & 0 & 1/16 & 1/4 & 1 \end{pmatrix}.$$

If we consider for instance the situation (second column), where one of the parents has the pair  $AA$  and the other has  $aA$ , then each of the four cases (we are talking about the pairs of alleles of two randomly chosen offsprings)

$$AA, AA; \quad AA, aA; \quad aA, AA; \quad aA, aA$$

occurs with the same probability. The probability of staying in the second state is thus  $1/2$  and the probability for transition from the second state to the first is  $1/4$  and to the fourth state also  $1/4$ .

Again we determine the powers  $T^n$  for large  $n \in \mathbb{N}$ . Considering the form of the first and of the last column we find that 1 is an eigenvalue of the matrix  $T$  with corresponding eigenvectors

$$(1, 0, 0, 0, 0, 0)^T, \quad (0, 0, 0, 0, 0, 1)^T.$$

By considering only a four-dimensional submatrix of the matrix  $T$  (omitting the first and sixth row and column) we find the remaining eigenvalues

$$\frac{1}{2}, \quad \frac{1}{4}, \quad \frac{1 - \sqrt{5}}{4}, \quad \frac{1 + \sqrt{5}}{4}.$$

Recalling the solution of the exercise called the sweet-toothed gambler, we do not have to compute  $T^n$ . In that exercise we obtained the same eigenvectors corresponding to the eigenvalue 1 and the other eigenvalues also had their absolute value strictly smaller than 1 (the exact values were not used). Thus we obtain an identical conclusion – the process approaches the probabilistic vector

$$(a, 0, 0, 0, 0, 1 - a)^T,$$

where  $a \in [0, 1]$  is given by the initial state. Because there is a non zero number only at the first and sixth position of the resulting vector, the states

$$aA, AA; \quad aa, AA; \quad aA, aA; \quad aa, aA$$

disappear after many breedings. Notice that the probability that the process ends with  $AA, AA$  equals the relative ratio of the appearance of  $A$  in the initial state.

Case (d). Let the values  $a, b, c \in [0, 1]$  give, in this order, the relative ratios of the occurrence of alleles  $AA, aA, aa$  in the given population. We wish to obtain the expression of relative ratios of the pairs  $AA, aA, aa$  in the offspring of the population. If the choice of pairs for breeding is random, then for a suitably large population it can be expected that the relative ratio of breeding of individuals that both have  $AA$  is  $a^2$ . Similarly, the relative ratio for the pair  $aA$  and  $AA$  is  $2ab$ , and the relative ratio for  $aA$  (both of them) is  $b^2$  and so on. The offspring of the parents with pairs  $AA, AA$  must inherit  $AA$ . The probability that the offspring of the parents with pairs  $AA, aA$  has  $AA$  is  $1/2$  and the probability that the offspring of the parents with pairs  $aA, aA$  has  $AA$  is  $1/4$ . There are no other cases for an offspring with the pair  $AA$ . If one of the parents has the pair  $aa$ , then the offspring cannot have  $AA$ . The relative frequency of  $AA$  in the progeny is thus

$$a^2 \cdot 1 + 2ab \cdot \frac{1}{2} + b^2 \cdot \frac{1}{4} = a^2 + ab + \frac{b^2}{4}.$$

Similarly we set the relative frequencies of the pairs  $aA$  and  $aa$  in the progeny:

$$ab + bc + 2ac + \frac{b^2}{2}$$

and

$$c^2 + bc + \frac{b^2}{4}.$$

This process can be viewed as a mapping  $T$  that transforms the vector  $(a, b, c)^T$ . Hence

$$T : \begin{pmatrix} a \\ b \\ c \end{pmatrix} \mapsto \begin{pmatrix} a^2 + ab + b^2/4 \\ ab + bc + 2ac + b^2/2 \\ c^2 + bc + b^2/4 \end{pmatrix}.$$

Note that the domain (and also the codomain) of  $T$  are just the vectors

$$\begin{pmatrix} a \\ b \\ c \end{pmatrix}, \quad \text{where } a, b, c \in [0, 1], \quad a + b + c = 1.$$

We would like to describe the operation  $T$  by multiplying the vector by some constant matrix. But that is clearly not possible since the mapping  $T$  is not linear. Thus it is not a Markov process and the determination of what happens after a long time cannot be simplified as in the previous cases. But we can determine what happens if we apply the mapping  $T$  twice in succession. For the second step,

$$T : \begin{pmatrix} a^2 + ab + b^2/4 \\ ab + bc + 2ac + b^2/2 \\ c^2 + bc + b^2/4 \end{pmatrix} \mapsto \begin{pmatrix} t_2^1 \\ t_2^2 \\ t_2^3 \end{pmatrix}, \quad \text{where}$$

$$\begin{aligned} t_2^1 &= \left( a^2 + ab + \frac{b^2}{4} \right)^2 + \\ &\quad \left( a^2 + ab + \frac{b^2}{4} \right) \left( ab + bc + 2ac + \frac{b^2}{2} \right) \\ &\quad + \frac{1}{4} \left( ab + bc + 2ac + \frac{b^2}{2} \right)^2, \end{aligned}$$

$$\begin{aligned} t_2^2 &= \left( a^2 + ab + \frac{b^2}{4} \right) \left( ab + bc + 2ac + \frac{b^2}{2} \right) + \\ &\quad + \left( ab + bc + 2ac + \frac{b^2}{2} \right) \left( c^2 + bc + \frac{b^2}{4} \right) + \\ &\quad + 2 \left( a^2 + ab + \frac{b^2}{4} \right) \left( c^2 + bc + \frac{b^2}{4} \right) + \\ &\quad + \frac{1}{2} \left( ab + bc + 2ac + \frac{b^2}{2} \right)^2, \end{aligned}$$

$$t_2^3 = \left(c^2 + bc + \frac{b^2}{4}\right)^2 + \left(ab + bc + 2ac + \frac{b^2}{2}\right) \left(c^2 + bc + \frac{b^2}{4}\right) + \frac{1}{4} \left(ab + bc + 2ac + \frac{b^2}{2}\right)^2.$$

Using  $a + b + c = 1$ ,) it can be shown that

$$t_2^1 = a^2 + ab + \frac{b^2}{4}, \quad t_2^2 = ab + bc + 2ac + \frac{b^2}{2}, \quad t_2^3 = c^2 + bc + \frac{b^2}{4},$$

that is,

$$T : \begin{pmatrix} a^2 + ab + b^2/4 \\ ab + bc + 2ac + b^2/2 \\ c^2 + bc + b^2/4 \end{pmatrix} \mapsto \begin{pmatrix} a^2 + ab + b^2/4 \\ ab + bc + 2ac + b^2/2 \\ c^2 + bc + b^2/4 \end{pmatrix}.$$

We have obtained a surprising result that further application of the transform  $T$  does not change the vector obtained in the first step. This means that the appearance of the considered pairs is, after an arbitrary long time, the same as in the first generation of offspring. For a large population, we have thus shown that the evolution takes place during first generation unless there is a mutation or selection.  $\square$

**3.G.23.** Let there be two boxes, which contain between them  $n$  white and  $n$  black balls. Each box contains  $n$  balls. At regular time intervals a ball is taken from each box and moved to the other box. For this Markov process, find its probabilistic transition matrix  $T$ .

**Solution.** This problem is often used in physics as a model for blending two incompressible liquids (already introduced by D. Bernoulli in the year 1769) or analogously, as a model of diffusion of gases.

Let the states  $0, 1, \dots, n$  correspond to the number of white balls in the first box. This information already says how many black balls are in the first box (the remaining balls are then in the second box). If, for a certain step, the state changes from  $j \in \{1, \dots, n\}$  to  $j - 1$ , then from the first box a white ball was drawn and from the second a black ball was drawn. This happens with probability

$$\frac{j}{n} \cdot \frac{j}{n} = \frac{j^2}{n^2}.$$

The transition from state  $j \in \{0, \dots, n - 1\}$  to the state  $j + 1$  corresponds to drawing the black ball from the first box and a white ball from the second box, with probability

$$\frac{n - j}{n} \cdot \frac{n - j}{n} = \frac{(n - j)^2}{n^2}.$$

The system stays in state  $j \in \{1, \dots, n - 1\}$ , if from both boxes balls of the same colour are drawn, which has the same probability

$$\frac{j}{n} \cdot \frac{n - j}{n} + \frac{n - j}{n} \cdot \frac{j}{n} = \frac{2j(n - j)}{n^2}.$$

Notice that from the state 0 it is necessary (with probability 1) to go to the state 1 and similarly from the state  $n$  with probability one to the state  $n - 1$ . In summary we obtain the matrix  $n^2 T$ :

$$\begin{pmatrix} 0 & 1 & 0 & \cdots & 0 & 0 & 0 \\ n^2 & 2 \cdot 1(n - 1) & 2^2 & \ddots & 0 & 0 & 0 \\ 0 & (n - 1)^2 & 2 \cdot 2(n - 2) & \ddots & 0 & 0 & 0 \\ \vdots & \ddots & \ddots & \ddots & \ddots & \ddots & \vdots \\ 0 & 0 & 0 & \ddots & 2 \cdot (n - 2)2 & (n - 1)^2 & 0 \\ 0 & 0 & 0 & \ddots & 2^2 & 2 \cdot (n - 1)1 & n^2 \\ 0 & 0 & 0 & \cdots & 0 & 1 & 0 \end{pmatrix}$$

for the order of the states  $0, 1, \dots, n$ .

When using this model in physics we are of course interested in the distribution of balls in boxes after a certain time (the number of drawings). If the initial state is for instance 0, we can use the powers of the matrix  $T$  to observe with what probability the number of white balls in the first box is increasing. We can confirm the expected result that the initial distribution of the balls influences their distribution after a certain time in a very negligible way.

If we number the individual balls, we would instead of ball drawing draw some of the numbers  $1, 2, \dots, 2n$  and the ball whose number was draw would move to the other ball. We would obtain a Markov process with states  $0, 1, \dots, 2n$  (the number of balls in the first box), where we are not distinguishing the colour any more. This Markov chain is also very important in physics (P. and T. Ehrenfest introduced it in 1907). It is used as a model for interchange of heat between two isolated bodies.  $\square$

**3.G.24.** Two players,  $A$  and  $B$ , gamble for money repeatedly in a certain game, which can result only in a victory for one of the players. The winning probability for player  $A$  in each individual game is  $p \in [0, 1/2)$ . Both bet always only €1. Consequently after each game player  $B$  gives €1 to player  $A$  with probability  $p$ , and player  $A$  gives €1 to player  $B$  with probability  $1 - p$ . They play as long as both have some money. If player  $A$  has € $x$  at the start of the game, and player  $B$  has € $y$  at the start of the game, determine the probability that player  $A$  loses all the money he has.

**Solution.** This problem is called Ruining of a player. It is a special Markov chain (see also the exercise Sweet-toothed gambler) with many important applications. The probability in question is

$$(1) \quad \frac{1 - \left(\frac{p}{1-p}\right)^y}{1 - \left(\frac{p}{1-p}\right)^{x+y}}.$$

We investigate what this value is for specific choices of  $p, x, y$ . If player  $B$  wants to be almost sure and requires that the probability that player  $A$  loses with him €1 000 000 c is at least 0.999, then it suffices for him to have €346 c if  $p = 0.495$  (or €1 727 if  $p = 0.499$ ). Therefore it is possible in big casinos that "passionate" players play almost fair games.  $\square$

**3.G.25.** In a certain company there exist two competing departments. The management has decided that every week they will measure relative (with respect to the number of employees) incomes attained by these two departments. 2 employees will then be moved to the more successful department from the other department. This process will go on for as long as both departments have some employees. You have gained a position in this company and you can choose one of these two departments where you will work. You want to choose the department which will not be cancelled due to the employee movement. What will be your choice, if one of the departments has 40 employees, the other 10 employees and you estimate that the second one will have a greater income than the first one in 54 % of the cases?  $\circ$

Solutions of the exercises

3.A.2. The daily diet should contain 3.9 kg of hay and 4.3 kg of oat. The costs per foal are then €13.82.

3.B.10.

$$x_n = \frac{1}{\sqrt{21}} \left( \frac{3 + \sqrt{21}}{2} \right)^n - \frac{1}{\sqrt{21}} \left( \frac{3 - \sqrt{21}}{2} \right)^n.$$

3.B.11.  $x_n = 2\sqrt{3} \sin(n \cdot (\pi/6)) - 4 \cos(n \cdot (\pi/6))$ .

3.B.12.  $x_n = -3(-1)^n - 2 \cos(n \cdot (2\pi/3)) - 2\sqrt{3} \sin(n \cdot ((2\pi/3)))$ .

3.B.13.  $x_n = (-1)^n (-2n^2 + 8n - 7)$ .

3.E.2. yes, no, no, yes

3.F.1.

- The claim is true. ( $B := A^T A$ ,  $b_{ij} = (i\text{-th row of } A^T) \cdot (j\text{-th column of } A) = b_{ji} = (j\text{-th row of } A^T) \cdot (i\text{-th column of } A) = (j\text{-th column of } A) \cdot (i\text{-th row of } A^T)$ )
- The claim is not true. Consider for instance  $A = \begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix}$

3.F.3.

$$\begin{pmatrix} 1 & 0 & 0 \\ 1 & -2 & 0 \\ 0 & 1 & 1 \end{pmatrix} \begin{pmatrix} 1 & 1 & 0 \\ 0 & 1 & -1 \\ 0 & 0 & 0 \end{pmatrix}$$

3.G.5. The Leslie matrix of the given model is (the mortality of the first group is denoted by  $a$ )

$$\begin{pmatrix} 0 & 2 & 2 \\ a & 0 & 0 \\ 0 & 1 & 0 \end{pmatrix}.$$

The stagnation condition corresponds to the fact that the matrix has 1 for the eigenvalue, that is, the polynomial  $\lambda^3 - 2a\lambda - 2a$  has 1 as its root, that is,  $a = 1/4$ .

3.G.10. Again it is a special case of the Ruining of the player. It suffices to reformulate the statement accordingly. For  $p = 0.47$ ,  $y = 20$  and  $x = 20$  from (1) follows the result

$$0.917 \doteq \frac{1 - \left(\frac{0.47}{1-0.47}\right)^{20}}{1 - \left(\frac{0.47}{1-0.47}\right)^{40}}.$$

3.G.14.

$$\begin{pmatrix} 5 & 1 \\ 6 & 5 \end{pmatrix}.$$

The matrix has the dominant eigenvalue 1, the corresponding eigenvector is  $\left(\frac{6}{5}, 1\right)$ . Because the eigenvalue is dominant, the ratio of the viewers stabilises on 6 : 5.

3.G.17. As in (3.G.16) the game ends after three bets. Thus all the powers of  $A$ , starting with  $A^3$ , are identical.

$$A^{100} = A^3 = \begin{pmatrix} 1 & 7/8 & 3/4 & 1/2 & 0 \\ 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 \\ 0 & 1/8 & 1/4 & 1/2 & 1 \end{pmatrix}$$

3.G.25. You can use the result of the exercise called Ruining of the player. According to this exercise the probability that the first department is cancelled exercise equals to

$$\frac{1 - \left(\frac{0.46}{1-0.46}\right)^5}{1 - \left(\frac{0.46}{1-0.46}\right)^{25}} \doteq 0.56.$$

It was enough to substitute  $i p = 1 - 0.54$ ,  $y = 10/2$  and  $x = 40/2$  into (1). It is thus better to choose the smaller department.

## Analytic geometry

*position, incidence, projection*  
– and we return to matrices again...

### A. Affine geometry

**4.A.1.** Find a parametric equation for a line in  $\mathbb{R}^3$  given by the equations

$$\begin{aligned}x - 2y + z &= 2, \\2x + y - z &= 5.\end{aligned}$$

**Solution.** It is sufficient to solve the equation system. However, there is an alternative approach. Find a non-zero direction vector orthogonal to the normal vectors  $(1, -2, 1)$ ,  $(2, 1, -1)$ . The cross product

$$(1, -2, 1) \times (2, 1, -1) = (1, 3, 5)$$

is such a vector. The triple

$$[x, y, z] = [2, -1, -2]$$

satisfies the respective system, so a solution is

$$[2, -1, -2] + t(1, 3, 5), \quad t \in \mathbb{R}.$$

**4.A.2.** A plane in  $\mathbb{R}^4$  is given by its parametric equation

$$\varrho : [0, 3, 2, 5] + t(1, 0, 1, 0) + s(2, -1, -2, 2), \quad t, s \in \mathbb{R}$$

Find its implicit equation.

We return to the view on geometry that we had when we studied positions of points in the plane in the 5th part of the first chapter, c.f. 1.5.1. We are interested in the properties of objects in the Euclidean space, delimited by points, straight lines, planes etc. The essential point is to clarify how their properties are related to the notion of vectors, and whether they depend on the notion of the length of vectors.

Later in the book, we use linear algebra to study objects defined in a nonlinear way. To do this we need more from the theory of matrices. The results are important in discussions of the technique of optimization, or of searching for extrema of functions.

At the end of this chapter we show how the projectivization of affine spaces helps us to obtain a simplification and stability of algorithms typical for computer graphics.

### 1. Affine and Euclidean geometry

While clarifying the structure of solutions of linear equations in the first part of the previous chapter we find in paragraph 2.3.5 that the set of all solutions of a nonhomogeneous system of linear equations does not form a vector space. However, the solutions always arise in such a way that to one particular solution we can add the vector space of solutions to the corresponding homogeneous system. On the other hand, the difference of any two solutions of the nonhomogeneous system is always a solution of the homogeneous system. This behaviour is similar to the behaviour of linear difference equations. We see this already in paragraph 3.2.6.

**4.1.1. Affine spaces.** A hint as to how to deal with the theory is given already in the discussion of the geometry of the plane, c.f. paragraph 1.5.3 and further on. There we describe straight lines and points as sets of solutions of systems of linear equations. A line is considered as a one-dimensional subspace, although its points are described by two coordinates. Parametrically, the line is defined by the sum of a single point (that is, a pair of coordinates) and multiples of a fixed direction vector. We proceed now in the same way for arbitrary dimensions.

□

**Solution.** The task is to find a system of equations with 4 variables  $x, y, z, u$  (the dimension of the space is 4) which are satisfied by the coordinates of those points which lie in the plane. The desired system must contain  $2 = 4 - 2$  linearly independent equations. Solve the problem by elimination of parameters. The points  $[x, y, z, u] \in \varrho$  satisfy

$$\begin{aligned} x &= t + 2s, \\ y &= 3 - s, \\ z &= 2 + t - 2s, \\ u &= 5 + 2s, \end{aligned}$$

where  $t, s \in \mathbb{R}$ . Write the system as a matrix

$$\left( \begin{array}{cc|cccc|c} 1 & 2 & -1 & 0 & 0 & 0 & 0 \\ 0 & -1 & 0 & -1 & 0 & 0 & 3 \\ 1 & -2 & 0 & 0 & -1 & 0 & 2 \\ 0 & 2 & 0 & 0 & 0 & -1 & 5 \end{array} \right).$$

The first two columns are direction vectors of the plane, followed by the negative identity matrix. The last column is the vector of coordinates of the point  $[0, 3, 2, 5]$ . This is now a system in  $t, s, x, y, z, u$ . Transform the obtained matrix using elementary row operations in order to have as many zero-rows on the left-hand side of the first vertical line as possible. Adding  $(-1)$ -times the first row and  $(-4)$ -times the second row to the third row and adding twice the second row to the first row gives

$$\left( \begin{array}{cc|cccc|c} 1 & 2 & -1 & 0 & 0 & 0 & 0 \\ 0 & -1 & 0 & -1 & 0 & 0 & 3 \\ 0 & 0 & 1 & 4 & -1 & 0 & -10 \\ 0 & 0 & 0 & -2 & 0 & -1 & 11 \end{array} \right).$$

The bottom two rows, both with only zeros to the left of the first vertical line, imply

$$\begin{aligned} x + 4y - z - 10 &= 0, \\ -2y - u + 11 &= 0. \end{aligned}$$

Note that the original system can be written as

$$\left( \begin{array}{cccc|cc|c} 1 & 0 & 0 & 0 & 1 & 2 & 0 \\ 0 & 1 & 0 & 0 & 0 & -1 & 3 \\ 0 & 0 & 1 & 0 & 1 & -2 & 2 \\ 0 & 0 & 0 & 1 & 0 & 2 & 5 \end{array} \right),$$

where  $x, y, z, u$  remains on the left-hand side of the equations. A similar transformation gives

$$\left( \begin{array}{cccc|cc|c} 1 & 0 & 0 & 0 & 1 & 2 & 0 \\ 0 & 1 & 0 & 0 & 0 & -1 & 3 \\ -1 & -4 & 1 & 0 & 0 & 0 & -10 \\ 0 & 2 & 0 & 1 & 0 & 0 & 11 \end{array} \right)$$

from which

$$\begin{aligned} -x - 4y + z &= -10, \\ 2y + u &= 11. \end{aligned}$$

STANDARD AFFINE SPACE

*Standard affine space*  $\mathcal{A}_n$  is a set of all points in  $\mathbb{R}^n = \mathcal{A}_n$  together with an operation “+” which assigns the point

$$A + v = (a_1 + v_1, \dots, a_n + v_n) \in \mathbb{R}^n = \mathcal{A}_n$$

to a point  $A = (a_1, \dots, a_n) \in \mathcal{A}_n$  and a vector  $v = (v_1, \dots, v_n) \in \mathbb{R}^n = V$ .

This operation satisfies the following three properties:

- (1)  $A + 0 = A$  for all points  $A \in \mathcal{A}_n$  and the null vector  $0 \in V$ ,
- (2)  $A + (v + w) = (A + v) + w$  for all vectors  $v, w \in V$  and points  $A \in \mathcal{A}_n$ ,
- (3) for every two points  $A, B \in \mathcal{A}_n$  there exists exactly one vector  $v \in V$  such that  $A + v = B$ . This vector is denoted by  $v = B - A$ , sometimes also  $\overline{AB}$ .

The underlying vector space  $\mathbb{R}^n$  is called the *difference space* of the standard affine space  $\mathcal{A}_n$ .

Notice that care is needed about several formal ambiguities. In particular, the symbol “+” is used for two different operations. “+” is used for adding a vector from the difference space to a point in the affine space. “+” is also used for summing vectors in the difference space  $V = \mathbb{R}^n$ . Further, notice that the operation “-” assigns a vector to a couple of points and cannot be understood as inverse of the addition (although in the standard affine space it is given by the difference of the  $n$ -tuples  $B$  and  $A$ ). We do not introduce specific letters for the set of points in the affine space.  $\mathcal{A}_n$  denotes both this set of points as well as the whole structure defining the affine space.

Why distinguish between the set of points in the affine space  $\mathcal{A}_n$  and its difference space  $V$  when both spaces can be viewed as  $\mathbb{R}^n$ ? It is a fundamental formal step to understanding the geometry in  $\mathbb{R}^n$ : The issue is that geometric objects, namely straight lines, points, planes etc. do not depend directly on the vector space structure of the set  $\mathbb{R}^n$ . They do not depend at all on the fact that we work with  $n$ -tuples of scalars. We need to know only what it means to move “straight in a given direction”. For instance, we can consider the affine plane as an unbounded board without chosen coordinates, but with the possibility of moving about a given vector. When we switch to such an abstract view, we can discuss the “plane geometry” for two-dimensional subspaces, without the need to work with  $k$ -tuples of coordinates.

This point of view underlies the following definition:

**4.1.2. Definition.** The affine space  $\mathcal{A}$  with the difference space  $V$  is a set of *points*  $\mathcal{P}$ , together with the map

$$\mathcal{P} \times V \rightarrow \mathcal{P}, \quad (A, v) \mapsto A + v.$$

$V$  is a vector space. The map satisfies the properties (1)–(3) from the definition of the standard affine space.

For a fixed vector  $v \in V$ , there is a *translation*  $\tau_v : \mathcal{A} \rightarrow \mathcal{A}$  as the restricted map

$$\tau_v : \mathcal{P} \simeq \mathcal{P} \times \{v\} \rightarrow \mathcal{P}, \quad A \mapsto A + v.$$

As seen in this exercise, parameter elimination can be long-winded. It is not difficult to make a mistake along the way.

**Another solution** All that is needed are two linearly independent vectors perpendicular to  $(1, 0, 1, 0)$ ,  $(2, -1, -2, 2)$ . If we “guessed” that these vectors could be for example  $(0, 2, 0, 1)$ ,  $(-1, 0, 1, 2)$ , then putting  $x = 0$ ,  $y = 3$ ,  $z = 2$ ,  $u = 5$  to the equations

$$\begin{array}{rcccc} & 2y & & + & u & = & a, \\ -x & & + & z & + & 2u & = & b \end{array}$$

yields  $a = 11$ ,  $b = 12$ . The desired implicit expression is

$$\begin{array}{rcccc} & 2y & & + & u & = & 11, \\ -x & & + & z & + & 2u & = & 12. \end{array}$$

**Another solution** Since

$$\begin{array}{rcccc} x & = & & t & + & 2s, \\ y & = & 3 & & - & s, \\ z & = & 2 & + & t & - & 2s, \\ u & = & 5 & & + & 2s, \end{array}$$

Eliminate  $t$  to get

$$\begin{array}{rcccc} x - z & = & 2 - 4s, \\ y & = & 3 - s, \\ u & = & 5 + 2s, \end{array}$$

Eliminate  $s$  to obtain two equations, namely

$$\begin{array}{rcccc} z - x + 2u & = & 12 \\ u + 2y & = & 11, \end{array}$$

which solves the problem. □

**4.A.3.** Find a parametric equation of the plane passing through the points

$$A = [2, 1, 1], \quad B = [3, 4, 5], \quad C = [4, -2, 3].$$

Hence find a parametric equation of the open half-plane containing the point  $C$  and bounded by the line passing through the points  $A, B$ .

**Solution.** We need one point and two (linearly independent) vectors lying in the plane. It is enough to choose  $A$  together with the vectors  $B - A = (1, 3, 4)$  and  $C - A = (2, -3, 2)$ , which are clearly independent. A point  $[x, y, z]$  lies in the plane if and only if there exist numbers  $t, s \in \mathbb{R}$  so that

$$x = 2 + 1 \cdot t + 2 \cdot s, \quad y = 1 + 3 \cdot t - 3 \cdot s, \quad z = 1 + 4 \cdot t + 2 \cdot s.$$

Consequently a parametric equation is

$$[x, y, z] = [2, 1, 1] + t(1, 3, 4) + s(2, -3, 2), \quad t, s \in \mathbb{R}.$$

Setting  $s = 0$  gives a line passing through the points  $A$  and  $B$ .  $t = 0$  and  $s \geq 0$ , defines a ray passing through  $C$  with an initial point  $A$ . A particular but arbitrarily chosen  $t \in \mathbb{R}$  and variable  $s \geq 0$  gives a ray initiated on the border

By the *dimension* of an affine space  $\mathcal{A}$ , is meant the dimension of its difference space.

In the sequel, we do not distinguish accurately between  $\mathcal{A}$  and the set of points  $\mathcal{P}$ . We talk instead about points and vectors of the affine space  $\mathcal{A}$ .

It follows immediately from the axioms that for arbitrary points  $A, B, C$  in the affine space  $\mathcal{A}$

- (1)  $A - A = 0 \in V$
- (2)  $B - A = -(A - B)$
- (3)  $(C - B) + (B - A) = C - A$ .

Indeed, (1) follows from the fact that  $A + 0 = A$  and that such a vector is unique (the first and third defining property). By adding successively  $B - A$  and  $A - B$  to  $A$ , according to the second defining property we obtain  $A$  again. Add the null vector to prove (2). Similarly, (3) follows from the defining property 4.1.1 (2) and the uniqueness.

Notice that the choice of one fixed point  $A_0 \in \mathcal{A}$  determines a bijection between  $V$  and  $\mathcal{A}$ . So for a fixed basis  $\underline{u}$  in  $V$  there is a unique expression

$$A = A_0 + x_1 u_1 + \cdots + x_n u_n$$

for every point  $A \in \mathcal{A}$ . We talk about an *affine coordinate system*  $(A_0; u_1, \dots, u_n)$  given by the *origin of the affine coordinate system*  $A_0$  and the basis  $\underline{u}$  of the corresponding difference space. This is sometimes called an *affine frame*  $(A_0, \underline{u})$ .

To summarize: Affine coordinates of a point  $A$  in the frame  $(A_0, \underline{u})$  are the coordinates of the vector  $A - A_0$  in the basis  $\underline{u}$  of the difference space  $V$ .

The choice of an affine coordinate system identifies each  $n$ -dimensional affine space  $\mathcal{A}$  with the standard affine space  $\mathcal{A}_n$ .

**4.1.3. Affine subspaces.** If we consider some coordinate system on  $\mathcal{A}$  and choose only such points in  $\mathcal{A}$  which have some chosen coordinates equal to zero (for instance the last one), we obtain again a set which behaves as an affine space. This is the spirit of the following definition of the affine subspaces.

SUBSPACES OF AN AFFINE SPACE

**Definition.** The nonempty subset  $\mathcal{Q} \subset \mathcal{A}$  of an affine space  $\mathcal{A}$  with a difference space  $V$  is called an *affine subspace* in  $\mathcal{A}$  if the subset  $W = \{B - A; A, B \in \mathcal{Q}\} \subset V$  is a vector subspace and  $A + v \in \mathcal{Q}$  for any  $A \in \mathcal{Q}, v \in W$ .

It is important to include both of the conditions in the definition, since there are examples of sets which satisfy the first condition but not the second. One such set consists of a straight line in the plane with one point removed.

For an arbitrary set of points  $M \subset \mathcal{A}$  in an affine space with a difference space  $V$ , we define the vector space

$$Z(M) = \langle \{B - A; B, A \in M\} \rangle \subset V$$

of all vectors generated by the differences of points in  $M$ .

line, going through the half-plane in which the point  $C$  lies. That means that the desired open half-plane can be expressed parametrically as

$$[x, y, z] = [2, 1, 1] + t(1, 3, 4) + s(2, -3, 2), \quad t \in \mathbb{R}, s > 0.$$

□

**4.A.4.** Determine the relative position of the lines

$$p : [1, 0, 3] + t(2, -1, -3), \quad t \in \mathbb{R},$$

$$q : [1, 1, 3] + s(1, -1, -2), \quad s \in \mathbb{R}.$$

**Solution.** Search for common points of the given lines (subspaces intersection). We have a system

$$\begin{array}{rclcl} 1 & + & 2t & = & 1 & + & s, \\ 0 & - & t & = & 1 & - & s, \\ 3 & - & 3t & = & 3 & - & 2s. \end{array}$$

From the first two equations,  $t = 1, s = 2$ . This does not satisfy the third equation. Thus the system does not have a solution. The direction vector  $(2, -1, -3)$  of the line  $p$  is not a multiple of the direction vector  $(1, -1, -2)$  of the line  $q$ . Hence the lines are not parallel. Hence, the lines are skew. □

**4.A.5.** Find all numbers  $a \in \mathbb{R}$  so that the lines

$$p : [4, -4, 8] + t(2, 1, -4), \quad t \in \mathbb{R},$$

$$q : [a, 6, -5] + s(1, -3, 3), \quad s \in \mathbb{R}$$

intersect.

**Solution.** The lines intersect if and only if the system

$$\begin{array}{rclcl} 4 & + & 2t & = & a & + & s, \\ -4 & + & t & = & 6 & - & 3s, \\ 8 & - & 4t & = & -5 & + & 3s \end{array}$$

has a solution. Express the system as a matrix (the first column corresponding to  $t$ , the second to  $s$ ), and solve

$$\begin{aligned} \left( \begin{array}{cc|c} 2 & -1 & a-4 \\ 1 & 3 & 10 \\ -4 & -3 & -13 \end{array} \right) &\sim \left( \begin{array}{cc|c} 1 & 3 & 10 \\ 2 & -1 & a-4 \\ -4 & -3 & -13 \end{array} \right) \\ &\sim \left( \begin{array}{cc|c} 1 & 3 & 10 \\ 0 & -7 & a-24 \\ 0 & 1 & 3 \end{array} \right). \end{aligned}$$

The system has a solution if and only if the second row is a multiple of the third row. This property is satisfied only for  $a = 3$ . The point of intersection of the lines is  $[6, -3, 4]$ . □

In particular,  $V = Z(\mathcal{A})$ . Every affine subspace  $\mathcal{Q} \subset \mathcal{A}$  itself satisfies the axioms for an affine space with the difference space  $Z(\mathcal{Q})$ .

The intersection of any set of affine subspaces is either an affine subspace or is the empty set. This follows directly from the definitions.

The affine subspace  $\langle M \rangle$  in  $\mathcal{A}$  generated by a nonempty set  $M \subset \mathcal{A}$  is the intersection of all affine subspaces which contain all points of  $M$ .

#### AFFINE HULL AND PARAMETRIC DESCRIPTION

Affine subspaces can be described by their difference spaces after choosing a point  $A_0 \in M$  in a generating set  $M$ . Indeed, to generate the affine subspace, take the vector subspace  $Z(M) \subset Z(\mathcal{A})$  generated by all differences of points in  $M$ , and add this vector space to an arbitrary point in  $M$ , i.e.,  $\langle M \rangle = \{A_0 + v; v \in Z(M) \subset Z(\mathcal{A})\}$ . We talk about the *affine hull* of the set of points  $M$  in  $\mathcal{A}$ .

On the other hand, whenever a subspace  $U$  in the difference space  $Z(\mathcal{A})$  and a fixed point  $A \in \mathcal{A}$  is chosen, the subset  $A + U$ , created by all possible sums of  $A$  and all vectors in  $U$ , is an affine subspace. This approach leads to the notion of parametrization of subspaces:

Let  $\mathcal{Q} = A + Z(\mathcal{Q})$  be an affine subspace in  $\mathcal{A}_n$ . Let  $(u_1, \dots, u_k)$  be a basis of  $Z(\mathcal{Q}) \subset \mathbb{R}^n$ . Then the expression of the subspace

$$\mathcal{Q} = \{A + t_1u_1 + \dots + t_ku_k; t_1, \dots, t_k \in \mathbb{R}\}$$

is called the *parametric description* of the subspace  $\mathcal{Q}$ .

There is another way of prescribing affine spaces: If we choose affine coordinates, then the difference space may be described by a homogeneous system of linear equations in these coordinates. By inserting the coordinates of one point of the subspace  $\mathcal{Q}$  into the system of equations, we obtain the right-hand side of the non-homogeneous system with the same matrix. The subspace  $\mathcal{Q}$  is exactly the set of solutions of this system. The description of the subspace  $\mathcal{Q}$  by a system of equations in given coordinates is called an *implicit description* of the subspace  $\mathcal{Q}$ .

The following proposition says that we can prescribe all affine subspaces in this way. It shows the geometric nature of the solutions of systems of linear equations.

**4.1.4. Theorem.** Let  $(A_0; \underline{u})$  be an affine coordinate system in an  $n$ -dimensional affine space  $\mathcal{A}$ . In these coordinates, affine subspaces of dimension  $k$  in  $\mathcal{A}$  are exactly the sets of solutions of solvable systems of  $n - k$  linearly independent equations in  $n$  variables.

**PROOF.** Consider an arbitrary solvable system of  $n - k$  linearly independent equations  $\alpha_i(x) = b_i$ , where  $b_i \in \mathbb{R}$ ,  $i = 1, \dots, n - k$ . Suppose  $A = (a_1, \dots, a_n)^T \in \mathbb{R}^n$  is a fixed solution of this (non-homogeneous) system. Suppose also that  $U \subset \mathbb{R}^n$  is the vector space of all solutions of the homogenized system  $\alpha_i(x) = 0$ . Then the dimension of  $U$  is

**4.A.6.** In  $\mathbb{R}^3$ , determine the relative position of the line  $p$  defined implicitly by

$$\begin{aligned} x + y - z &= 4, \\ x - 2y + z &= -3 \end{aligned}$$

and the plane  $\varrho : y = 2x - 1$ .

**Solution.** A normal vector to the plane is  $\varrho$  is  $(2, -1, 0)$  (consider  $\varrho : 2x - y + 0z = 1$ ). Since

$$(1, 1, -1) + (1, -2, 1) = (2, -1, 0),$$

the normal vector to the plane  $\varrho$  is a linear combination of the  $p$  normal vectors. A vector defining the line lies in a subspace of the plane  $\varrho$ . It remains to discover whether or not they intersect. The system of equations

$$\begin{aligned} x + y - z &= 4, \\ x - 2y + z &= -3, \\ 2x - y &= 1 \end{aligned}$$

has infinitely many solutions, because the first two equations add to give the third one. So the line  $p$  lies in the plane  $\varrho$ .  $\square$

The following exercise is a typical vector spaces intersection exercise. The reader should be able to solve this. Otherwise we recommend not continuing with this book.

**4.A.7.** Find the intersection of the subspaces  $Q_1$  and  $Q_2$ , where

$$Q_1 : [4, -5, 1, -2] + t_1 [3, 5, 4, 2] + t_2 [2, 4, 5, 1] + t_3 [0, 3, 1, 2],$$

$$Q_2 : [4, 4, 4, 4] + s_1 [0, -6, -2, -4] + s_2 [-1, -5, -3, -3],$$

$$\text{for } t_1, t_2, t_3, s_1, s_2 \in \mathbb{R}.$$

**Solution.** The point  $X = [x_1, x_2, x_3, x_4] \in \mathbb{R}^4$  lies in  $Q_1$  if and only if

$$\begin{bmatrix} x_1 \\ x_2 \\ x_3 \\ x_4 \end{bmatrix} = \begin{bmatrix} 4 \\ -5 \\ 1 \\ -2 \end{bmatrix} + t_1 \begin{bmatrix} 3 \\ 5 \\ 4 \\ 2 \end{bmatrix} + t_2 \begin{bmatrix} 2 \\ 4 \\ 5 \\ 1 \end{bmatrix} + t_3 \begin{bmatrix} 0 \\ 3 \\ 1 \\ 2 \end{bmatrix}$$

for some numbers  $t_1, t_2, t_3 \in \mathbb{R}$ . The point  $X = [x_1, x_2, x_3, x_4] \in \mathbb{R}^4$  lies in  $Q_2$  if and only if

$$\begin{bmatrix} x_1 \\ x_2 \\ x_3 \\ x_4 \end{bmatrix} = \begin{bmatrix} 4 \\ 4 \\ 4 \\ 4 \end{bmatrix} + s_1 \begin{bmatrix} 0 \\ -6 \\ -2 \\ -4 \end{bmatrix} + s_2 \begin{bmatrix} -1 \\ -5 \\ -3 \\ -3 \end{bmatrix}$$

$k$ . The set of all solutions of the given system is of the form  $\{B; B = A + (y_1, \dots, y_n)^T, y = (y_1, \dots, y_n)^T \in U\} \subset \mathbb{R}^n$ , c.f. 2.3.5. So the corresponding affine subspace is described parametrically by the initial coordinates  $(A_0; \underline{u})$ .

Conversely, consider an arbitrary affine subspace  $\mathcal{Q} \subset \mathcal{A}_n$ . Choose a point  $B$  therein, and consider this point to be the origin of an affine coordinate system  $(B; \underline{v})$  for the affine space  $\mathcal{A}$ . Since  $\mathcal{Q} = B + Z(\mathcal{Q})$ , it is necessary to describe the difference space of the subspace  $\mathcal{Q}$  as a subspace of solutions of a homogeneous system of linear equations. Therefore, choose a basis  $\underline{v}$  of  $Z(\mathcal{A})$  such that the first  $k$  vectors form a basis of  $Z(\mathcal{Q})$ . In these coordinates, the vectors  $v \in Z(\mathcal{Q})$  are given by equations

$$\alpha_j(v) = 0, \quad j = k + 1, \dots, n.$$

The  $\alpha_i$  are linear forms from the dual basis to  $\underline{v}$ . They are the functions which assign to a vector the corresponding coordinates in the basis  $\underline{v}$ .

Hence the vector subspace  $Z(\mathcal{Q})$  of dimension  $k$  in the  $n$ -dimensional space  $\mathbb{R}^n$  is given as a solution of a homogeneous system of  $n - k$  independent equations. The description of the chosen affine subspace in the newly chosen coordinate system  $(B; \underline{v})$  is therefore given by a system of homogeneous linear equations.

It remains to consider the consequences of the transition from the former coordinate system  $(A; \underline{u})$  to the new adapted system  $(B; \underline{v})$ . It follows from a general consideration about transformations of coordinates in the following paragraph that the final description of the subspace is again a system of linear equations. This time it is non-homogeneous in general.  $\square$

**4.1.5. Coordinate transformations.** Any two arbitrarily chosen affine coordinate systems  $(A_0, \underline{u})$ ,  $(B_0, \underline{v})$  differ in the basis of the difference spaces and the origin of the latter one is translated about the vector  $(B_0 - A_0)$ . Hence the equations for the corresponding coordinate transformations can be read off from the rule for a transformation of a point  $X \in \mathcal{A}$

$$\begin{aligned} X &= B_0 + x'_1 v_1 + \dots + x'_n v_n \\ &= B_0 + (A_0 - B_0) + x_1 u_1 + \dots + x_n u_n. \end{aligned}$$

Let  $y = (y_1, \dots, y_n)^T$  denote the column of coordinates of the vector  $(A_0 - B_0)$  in the basis  $\underline{v}$ . Let  $M = (a_{ij})$  be the matrix expressing the basis  $\underline{u}$  in terms of the basis  $\underline{v}$ . Then

$$\begin{aligned} x'_1 &= y_1 + a_{11}x_1 + \dots + a_{1n}x_n \\ &\vdots \\ x'_n &= y_n + a_{n1}x_1 + \dots + a_{nn}x_n. \end{aligned}$$

In matrix notation

$$x' = y + M \cdot x.$$

Now, we can come back to the proof of the previous theorem. Suppose the system of linear equations in coordinates

for some  $s_1, s_2 \in \mathbb{R}$ . Hence if  $X$  lies in  $Q_1 \cap Q_2$  then the equation

$$\begin{aligned} & t_1 \begin{pmatrix} 3 \\ 5 \\ 4 \\ 2 \end{pmatrix} + t_2 \begin{pmatrix} 2 \\ 4 \\ 5 \\ 1 \end{pmatrix} + t_3 \begin{pmatrix} 0 \\ 3 \\ 1 \\ 2 \end{pmatrix} \\ &= \begin{pmatrix} 4-4 \\ 4+5 \\ 4-1 \\ 4+2 \end{pmatrix} + s_1 \begin{pmatrix} 0 \\ -6 \\ -2 \\ -4 \end{pmatrix} + s_2 \begin{pmatrix} -1 \\ -5 \\ -3 \\ -3 \end{pmatrix}. \end{aligned}$$

has a solution for  $t_1, t_2, t_3, s_1, s_2$ .

Move the vectors corresponding to  $s_1$  and  $s_2$  to the left-hand side. Write the equations in matrix form and reduce to echelon form. There follows

$$\begin{aligned} & \begin{pmatrix} 3 & 2 & 0 & 0 & 1 & 0 \\ 5 & 4 & 3 & 6 & 5 & 9 \\ 4 & 5 & 1 & 2 & 3 & 3 \\ 2 & 1 & 2 & 4 & 3 & 6 \end{pmatrix} \sim \begin{pmatrix} 3 & 2 & 0 & 0 & 1 & 0 \\ 0 & 2 & 9 & 18 & 10 & 27 \\ 0 & 7 & 3 & 6 & 5 & 9 \\ 0 & -1 & 6 & 12 & 7 & 18 \end{pmatrix} \\ & \sim \dots \sim \left( \begin{array}{cccccc|c} 3 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 2 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 2 & 0 & 3 & 0 \\ 0 & 0 & 0 & 0 & 1 & 0 & 0 \end{array} \right). \end{aligned}$$

So  $t_1 = t_2 = s_2 = 0$  and for  $s_1 = t \in \mathbb{R}$  we have  $t_3 = 3 - 2t$ . Note that for the determination of  $Q_1 \cap Q_2$ , it is sufficient to know either  $t_1, t_2, t_3$ , or  $s_1, s_2$ . So

$$\begin{bmatrix} x_1 \\ x_2 \\ x_3 \\ x_4 \end{bmatrix} = \begin{bmatrix} 4 \\ 4 \\ 4 \\ 4 \end{bmatrix} + s_1 \begin{pmatrix} 0 \\ -6 \\ -2 \\ -4 \end{pmatrix} + s_2 \begin{pmatrix} -1 \\ -5 \\ -3 \\ -3 \end{pmatrix} = \begin{bmatrix} 4 \\ 4 \\ 4 \\ 4 \end{bmatrix} + t \begin{pmatrix} 0 \\ -6 \\ -2 \\ -4 \end{pmatrix}.$$

This should be checked using  $t_1 = t_2 = 0$  and  $t_3 = 3 - 2t$ . The solution is a line lying in both planes. It is  $Q_1 \cap Q_2$ .  $\square$

**4.A.8.** Determine whether or not the points  $[0, 2, 1]$ ,  $[-1, 2, 0]$ ,  $[-2, 5, 2]$  and  $[0, 5, 4]$  in  $\mathbb{R}^3$  all lie in the same plane.

**Solution.** Consider the vectors  $[0, 2, 1] - [-1, 2, 0] = (1, 0, 1)$ ,  $[0, 2, 1] - [-2, 5, 2] = (2, -3, -1)$  and  $[0, 2, 1] - [0, 5, 4] = (0, -3, -3)$ . They are linearly dependent since the matrix

$$\begin{pmatrix} 1 & 0 & 1 \\ 2 & -3 & -1 \\ 0 & -3 & -3 \end{pmatrix},$$

has rank 2. Hence, the given points lie in a plane.  $\square$

**4.A.9.** Into how many parts can three planes slice the space ( $\mathbb{R}^3$ )? Give an example of planes in a suitable position for every case.

$(A_0; \underline{u})$  has the form

$$S \cdot x = b$$

where  $S$  is the matrix of the system. Then

$$S \cdot x = S \cdot M^{-1} \cdot (y + M \cdot x) - S \cdot M^{-1} \cdot y = b.$$

Thus in the new coordinates  $(B_0; \underline{v})$  considered above, the system has the form

$$(S \cdot M^{-1}) \cdot x' = b' = b + (S \cdot M^{-1}) \cdot y.$$

Therefore, if a subspace is described by a system of linear equations in one affine frame, then it is so described in all other affine frames. This completes the proof of the previous proposition.

**4.1.6. Examples of affine subspaces.** (1) The one-

dimensional (standard) affine space is the subset of all points of a real straight line  $\mathcal{A}_1$ . Its difference space is a one-dimensional vector space  $\mathbb{R}$ . The supporting set (i.e. the set of points in  $\mathcal{A}_1$ ) is also  $\mathbb{R}$ . The affine coordinates are obtained by the choice of an origin and a scale (i.e. a basis in the vector space  $\mathbb{R}$ ). All proper affine spaces are 0-dimensional. They are formed by all points of the real straight line  $\mathbb{R}$ .

(2) The two-dimensional (standard) affine space is a set of all points in the space  $\mathcal{A}_2$  with the difference space  $\mathbb{R}^2$ . The supporting set is  $\mathbb{R}^2$ . The affine coordinates are obtained by a choice of an origin and two linearly independent vectors (directions and scales). The proper subspaces are then all points and straight lines in the plane (0-dimensional and 1-dimensional). The lines are prescribed by the choice of a point and one vector from the corresponding difference space. The vector is a generator of direction as in the parametric definition of the straight line.

(3) The three-dimensional (standard) affine space is a set of all points in the space  $\mathcal{A}_3$  with the difference space  $\mathbb{R}^3$ . The affine coordinates are obtained by the choice of an origin and three linearly independent vectors (directions and scales). The proper affine subspaces are then all points, straight lines and planes (0-dimensional, 1-dimensional and 2-dimensional).

(4) Suppose there is given a nonzero vector of coefficients  $(a_1, \dots, a_n)$  and a scalar  $b \in \mathbb{R}$ . Compute the subspace of all solutions of one linear equation  $a \cdot x = b$  for the unknown point  $[x_1, \dots, x_n] \in \mathcal{A}_n$ . This is an affine subspace of dimension  $n - 1$ . We say that the subspace is of codimension 1, called a *hyperplane* in  $\mathcal{A}_n$ .

**4.1.7. Affine combinations of points.** We introduce an ana-

logue of the linear combination of vectors. Let  $A_0, \dots, A_k$  be points in the affine space  $\mathcal{A}$ . Their affine hull  $\langle \{A_0, \dots, A_k\} \rangle$  can be written as the set of points

$$\{A_0 + t_1(A_1 - A_0) + \dots + t_k(A_k - A_0); t_1, \dots, t_k \in \mathbb{R}\}.$$

**4.A.10.** Determine whether or not the point  $[2, 1, 0]$  lies within the convex hull of the points  $[0, 2, 1]$ ,  $[1, 0, 1]$ ,  $[3, -2, -1]$ ,  $[-1, 0, 1]$ .

**Solution.**  $[2, 1, 0]$  lies in the convex hull (see chapter 4.9) if and only if

$[2, 1, 0] = t_1[0, 2, 1] + t_2[1, 0, 1] + t_3[3, -2, -1] + t_4[-1, 0, 1]$  has a solution with  $t_1, t_2, t_3, t_4$ , all non-negative and  $t_1 + t_2 + t_3 + t_4 = 1$ . Equivalently,  $[2, 1, 0]$  lies in the convex hull if and only if

$$[2, 1, 0, 1] = t_1[0, 2, 1, 1] + t_2[1, 0, 1, 1] + t_3[3, -2, -1, 1] + t_4[-1, 0, 1, 1]$$

has a solution with  $t_1, t_2, t_3, t_4$ , all non-negative. Solving these four equations, gives  $(t_1, t_2, t_3, t_4) = (1, 0, 1/2, -1/2)$ , so the given point does not lie in the convex hull.  $\square$

**4.A.11.** In  $\mathbb{R}^3$ , a tetrahedron has vertices  $ABCD$ , where  $A = [4, 0, 2]$ ,  $B = [-2, -3, 1]$ ,  $C = [1, -1, -3]$ ,  $D = [2, 4, -2]$ .

- Determine its volume.
- Decide whether or not the point  $X = [0, -3, 0]$  lies inside the tetrahedron.

**Solution.** a) The volume of the tetrahedron is one sixth of volume of a parallelepiped, of which three edges from the point  $A$  are  $B - A = (-6, -3, -1)$ ,  $C - A = (-3, -1, -5)$  and  $D - A = (-2, 4, -4)$ . It is given by the absolute value of the determinant

$$\begin{vmatrix} -6 & -3 & -1 \\ -3 & -1 & -5 \\ -2 & 4 & -4 \end{vmatrix} = -124.$$

Thus, the volume of the tetrahedron is  $\frac{124}{6}$ .

b) Write  $X$  as an affine combination of its vertices, by solving the system of four linear equation in four unknowns  $a, b, c, d$  given by the equality  $X = aA + bB + cC + dD$ . The solution is  $X = \frac{1}{4}A + \frac{1}{2}B + \frac{1}{2}C - \frac{1}{4}D$ . Since the coefficient of  $D$  is negative,  $X$  does not lie in the convex hull of the points  $A, B, C$  and  $D$ . Hence the given point does not lie inside the tetrahedron.  $\square$

**4.A.12. Affine transformation of point coordinates**

The point  $X$  has coordinates expressed as  $[2, 2, 3]$  in an affine basis  $\{[1, 2, 3], (1, 1, 1), (1, -1, 2), (2, 1, 1)\}$  (in  $\mathbb{R}^3$ ).

Determine its coordinates in the standard basis, i.e. in the basis  $\{[0, 0, 0], (1, 0, 0), (0, 1, 0), (0, 0, 1)\}$ .

In any affine coordinates the same set can be written as

$$\{t_0A_0 + t_1A_1 + \dots + t_kA_k; t_i \in \mathbb{R}, \sum_{i=0}^k t_i = 1\}.$$

**AFFINE COMBINATIONS OF POINTS**

In general, by the formula  $t_0A_0 + t_1A_1 + \dots + t_kA_k$  with coefficients satisfying  $\sum_{i=0}^k t_i = 1$  is meant the set of all points  $A_0 + \sum_{i=1}^k t_i(A_i - A_0)$ . They are called the *affine combinations of points*.

The points  $A_0, \dots, A_k$  are in *general position* if they generate a  $k$ -dimensional affine subspace. This happens if and only if for each  $A_i$ , the vectors which arise as differences of this point  $A_i$ , and all other vectors  $A_j$ , are linearly independent. Observe that an assignment of a series of  $(\dim \mathcal{A}) + 1$  points in general position is equivalent to the definition of an affine frame with the origin in the first of them.

**4.1.8. Simplexes.** For points in an affine space, the affine combination is a similar construction to the linear combination for vectors in a vector space. Indeed, the affine subspace generated by points  $A_0, \dots, A_k$  equals the set of all affine combinations of its generators. The notion “to lie on the line between two points” can be generalized. In the two-dimensional case, imagine the interior of a triangle. In general proceed as follows:

**$k$ -DIMENSIONAL SIMPLEXES**

Let  $A_0, \dots, A_k$  be  $k + 1$  points in general position in an affine space  $\mathcal{A}$ . The set  $\Delta = \Delta(A_0, \dots, A_k)$  is defined as the set of all affine combinations of points  $A_i$  with nonnegative coefficients only. This is

$$\Delta = \{t_0A_0 + t_1A_1 + \dots + t_kA_k; 0 \leq t_i, \sum_{i=0}^k t_i = 1\},$$

called a  $k$ -dimensional *simplex* generated by the points  $A_i$ .

A one-dimensional simplex is a *line segment*, a two-dimensional simplex is a *triangle*, while a zero-dimensional simplex is a point.

Notice that each  $k$ -dimensional simplex has exactly  $k+1$  *faces* defined by equations  $t_i = 0, i = 0, \dots, k$ . The faces are also simplexes, and their dimension is  $k - 1$ . We talk about the *boundary* of the simplex. For instance, the boundary of a triangle is formed by the three edges, and the boundary of each edge is formed by the two vertices.

The description of a subspace as a set of affine combinations of points in general position is equivalent to the parametric description. We work similarly with the parametric description of simplexes.

**4.1.9. Convex sets.** The subset  $M$  of an affine space is called *convex* if and only if for any two points  $A, B \in M$  the set contains the line segment  $\Delta(A, B)$ . Directly from the definition, each convex set with  $k + 1$  points in general position contains also the entire simplex defined by these points

**Solution.** The coordinates  $[2, 2, 3]$  in the given basis are by the definition

$$[1, 2, 3] + 2 \cdot (1, 1, 1) + 2 \cdot (1, -1, 2) + 3 \cdot (2, 1, 1) = [11, 5, 12]$$

coordinates for  $X$  in the standard basis. □

**4.A.13. Affine transformation of mapping.** Find the affine mapping  $f$  in the coordinate system with the basis  $\underline{u} = \{(1, 1), (-1, 1)\}$  and origin  $[2, 0]$ , defined as

$$f(x_1, x_2) = \begin{pmatrix} 2 & 1 \\ 0 & 1 \end{pmatrix} \begin{pmatrix} x_1 \\ x_2 \end{pmatrix} + \begin{pmatrix} 1 \\ 1 \end{pmatrix}$$

in the standard basis in  $\mathbb{R}^2$ .

**Solution.** The change of the basis matrix from the basis  $\underline{u}$  to the standard basis is

$$\begin{pmatrix} 1 & -1 \\ 1 & 1 \end{pmatrix}.$$

The transformation matrix in the basis  $([2, 0], \underline{u})$  is obtained by first transforming the coordinates in the basis  $([2, 0], \underline{u})$  to the standard basis, i.e. to the basis  $([0, 0], (1, 0), (0, 1))$ . Then the transformation matrix  $f$  is applied in the standard basis. Finally it is transformed back to the coordinates in the basis  $([2, 0], \underline{u})$ . The transformation equations for changing the coordinates  $y_1, y_2$  in the basis  $([2, 0], \underline{u})$  to the coordinates  $x_1, x_2$  in the standard basis are

$$\begin{pmatrix} x_1 \\ x_2 \end{pmatrix} = \begin{pmatrix} 1 & -1 \\ 1 & 1 \end{pmatrix} \begin{pmatrix} y_1 \\ y_2 \end{pmatrix} + \begin{pmatrix} 2 \\ 0 \end{pmatrix}.$$

Hereby

$$\begin{aligned} \begin{pmatrix} y_1 \\ y_2 \end{pmatrix} &= \begin{pmatrix} 1 & -1 \\ 1 & 1 \end{pmatrix}^{-1} \left( \begin{pmatrix} x_1 \\ x_2 \end{pmatrix} - \begin{pmatrix} 2 \\ 0 \end{pmatrix} \right) \\ &= \begin{pmatrix} \frac{1}{2} & \frac{1}{2} \\ -\frac{1}{2} & \frac{1}{2} \end{pmatrix} \begin{pmatrix} x_1 \\ x_2 \end{pmatrix} + \begin{pmatrix} -1 \\ 1 \end{pmatrix}. \end{aligned}$$

Hence the desired mapping is

$$\begin{aligned} f(y_1, y_2) &= \begin{pmatrix} \frac{1}{2} & \frac{1}{2} \\ -\frac{1}{2} & \frac{1}{2} \end{pmatrix} \left[ \begin{pmatrix} 2 & 1 \\ 0 & 1 \end{pmatrix} \left( \begin{pmatrix} 1 & -1 \\ 1 & 1 \end{pmatrix} \begin{pmatrix} y_1 \\ y_2 \end{pmatrix} + \begin{pmatrix} 2 \\ 0 \end{pmatrix} \right) + \begin{pmatrix} 1 \\ 1 \end{pmatrix} \right] + \begin{pmatrix} -1 \\ 1 \end{pmatrix} \\ &= \begin{pmatrix} 2 & 0 \\ -1 & 1 \end{pmatrix} \begin{pmatrix} y_1 \\ y_2 \end{pmatrix} + \begin{pmatrix} 2 \\ -1 \end{pmatrix} \end{aligned}$$

**4.A.14.** Let there be a standard coordinate system in  $\mathbb{R}^3$  space. Agent K lives at the point  $S$  with coordinates  $[0, 1, 2]$ . The headquarters gave him a coordinate system with origin  $S$  and basis  $\{(1, 1, 0), (-1, 0, 1), (0, 1, 2)\}$ . Agent Bond lives at the point  $D$  with coordinates  $[1, 1, 1]$  and uses a coordinate

Examples of convex sets are

- (1) the empty set,
  - (2) affine subspaces,
  - (3) line segments, rays  $p = \{P + t \cdot v; t \geq 0\}$ ,
  - (4) more generally  $k$ -dimensional subspaces
- $$\alpha = \{P + t_1 \cdot v_1 + \dots + t_k \cdot v_k; t_1, \dots, t_k \in \mathbb{R}, t_k \geq 0\},$$
- (5) angles in two-dimensional subspaces
- $$\beta = \{P + t_1 \cdot v_1 + t_2 \cdot v_2; t_1 \geq 0, t_2 \geq 0\}.$$

The intersection of an arbitrary system of convex sets is a convex set. The intersection of all convex sets containing a given set  $M$  is called the *convex hull*  $\mathcal{K}(M)$  of the set  $M$ .

**Theorem.** The convex hull of any subset  $M \subset \mathcal{A}$  is

$$\mathcal{K}(M) = \{t_1 A_1 + \dots + t_s A_s; \sum_{i=1}^s t_i = 1, t_i \geq 0, A_i \in M\}$$

**PROOF.** Let  $S$  denote the set of all affine combinations on the right-hand side of the equation. To check that  $S$  is convex, choose two sets of parameters  $t_i, i = 1, \dots, s_1, t'_j, j = 1, \dots, s_2$  with the desired properties.

Without loss of generality, assume that  $s_1 = s_2$  and that the same points from  $M$  there appear in both combinations (otherwise simply add summands with zero coefficients). Consider an arbitrary point on the line segment given by the vertices defined by the two combinations:

$$\varepsilon(t_1 A_1 + \dots + t_s A_s) + (1 - \varepsilon)(t'_1 A_1 + \dots + t'_s A_s), \quad 0 \leq \varepsilon \leq 1.$$

Obviously any point of this line segment lies in  $S$ .

It remains to show that the convex hull of the points  $A_1, \dots, A_s$  cannot be smaller than  $S$ . The points  $A_i$  themselves correspond to the choice of parameters  $t_j = 0$  for all  $j \neq i$  and  $t_i = 1$ . Assume that the claim holds for all sets with at most  $s - 1$  points. Then the convex hull of the points  $A_1, \dots, A_{s-1}$  is (according to the assumption) formed exactly by the combinations from the right side of the equation to be proved, where  $t_s = 0$ . Now consider a point  $A = t_1 A_1 + \dots + t_s A_s \in S, t_s < 1$ , and affine combinations  $\varepsilon(t_1 A_1 + \dots + t_{s-1} A_{s-1}) + (1 - \varepsilon(1 - t_s)) A_s, 0 \leq \varepsilon \leq \frac{1}{1 - t_s}$ . It is a line segment with vertices given by parameters  $\varepsilon = 0$  (the point  $A_s$ ) and  $\varepsilon = 1/(1 - t_s)$  (a point in the convex hull of  $A_1, \dots, A_{s-1}$ ). The point  $A$  is an inner point of this line segment with the parameter  $\varepsilon = 1$ , and thus  $A$  lies in the convex hull of  $A_1, \dots, A_s$ . □

The convex hulls of finite sets are called *convex polyhedrons*. □

We have a  $k$ -dimensional *simplex* if and only if the vertices  $A_0, \dots, A_k$  defining the convex polyhedron are in general position. In the case of a simplex, the expression of any of its points as an affine combination of the defining vertices is unique.

Specific examples are the convex polyhedrons defined by one point and a finite number of vectors. Let  $u_1, \dots, u_k$  be

system with basis  $\{(0, 0, 1), (-1, 1, 2), (1, 0, 1)\}$ . Agent K has set an appointment with agent Bond in the old brickfield which is (according to K's coordinate system) at the point  $[1, 1, 0]$ . To where should Bond go (regarding his coordinate system)?

**Solution.** The change of basis matrix from agent K's basis to the Bond's basis (with the same origins) is

$$T = \begin{pmatrix} -4 & 2 & -1 \\ 1 & 0 & 1 \\ 2 & -1 & 1 \end{pmatrix}$$

The vector  $(0, 1, 2)$  thus has coordinates  $T \cdot (0, 1, 2)^T = (0, 2, 1)^T$ . Translate the origin (add the vector  $(-1, 0, 1)$ ) to obtain the result  $(-1, 2, 2)$ .  $\square$

**4.A.15.** Find a transversal of the lines (that is, a line passing through both given lines)

$$p: [1, 1, 1] + t(2, 1, 0), \quad q: [2, 2, 0] + t(1, 1, 1),$$

so that  $[1, 0, 0]$  lies on the transversal.

**Solution.** The transversal lies in the plane  $\rho$  defined by the point  $[1, 0, 0]$  and the line  $p$ . Hence it lies in the plane

$$[1, 1, 1] + t(2, 1, 0) + s(0, 1, 1).$$

Let the point  $Q$  be the intersection of this plane with the line  $q$ .  $Q$  is obtained by solving the system

$$\begin{aligned} 1 + 2t &= 2 + u \\ 1 + t + s &= 2 + u \\ 1 + s &= u \end{aligned}$$

The left-hand sides of the equations represent all three coordinates of an arbitrary point of the plane  $\rho$  respectively. The right-hand sides then represent the coordinates of an arbitrary point on  $q$  (the free variable is denoted  $u$  in order not to be ambiguous). Solving this system, yields  $s = 2$ ,  $t = 2$ ,  $u = 3$ . Putting  $u = 3$  into the line  $q$  equation, gives  $Q = [5, 5, 3]$ . The desired transversal is thus given by  $Q$  and the point  $[1, 0, 0]$ . The intersection of the transversal with  $p$  is at  $P = [7/3, 5/3, 1]$ .  $\square$

**4.A.16.** Find the common perpendicular between the two skew lines

$$\begin{aligned} p: & [3, 0, 3] + (0, 1, 2)t, \quad t \in \mathbb{R} \\ q: & [0, -1, -2] + (1, 2, 3)s \quad s \in \mathbb{R} \end{aligned}$$

arbitrary vectors in the difference space  $\mathbb{R}^n$ ,  $A \in \mathcal{A}_n$  a point. A parallelepiped  $\mathcal{P}_k(A; u_1, \dots, u_k) \subset \mathcal{A}_n$  is the set

$$\mathcal{P}_k(A; u_1, \dots, u_k) = \{A + c_1u_1 + \dots + c_ku_k; 0 \leq c_i \leq 1\}.$$

If the vectors  $u_1, \dots, u_k$  are independent, we talk about a  $k$ -dimensional parallelepiped  $\mathcal{P}_k(A; u_1, \dots, u_k) \subset \mathcal{A}_n$ . It is clear from the definition that parallelepipeds are convex. They are the convex hulls of their vertices.

**4.1.10. Examples of standard affine tasks.** (1) To find a parametric description of an implicitly given subspace and vice versa:

Find a particular solution of a non-homogeneous system and a fundamental solution of the homogenized system. Then obtain (in the coordinates in which the equations have been set) the desired parametric description. In the opposite direction, write the parametric description in coordinates and then eliminate the free parameters  $t_1, \dots, t_k$ . This results in the equations defining the given subspace implicitly.

(2) To find the subspace generated by several subspaces  $\mathcal{Q}_1, \dots, \mathcal{Q}_s$  (of different dimensions in general). To find a plane in  $\mathbb{R}_3$  given by a straight line and a point, or by three points). To define this subspace implicitly or parametrically:

The resulting subspace  $\mathcal{Q}$  is always determined by one fixed point  $A_i$  in a subspace  $\mathcal{Q}_i$  and by the sum of all difference spaces. For instance,

$$\mathcal{Q} = A_1 + (Z(\{A_1, \dots, A_k\}) + Z(\mathcal{Q}_1) + \dots + Z(\mathcal{Q}_s)).$$

If the subspaces are given implicitly, it is possible to convert them into parametric form first. Nevertheless, different methods are advantageous in some concrete situations. Notice that it is really necessary to use one point from each of the subspaces. For example, two parallel lines in a plane generate the whole plane, but they share the same one-dimensional difference space.

(3) To find the intersection of the subspaces  $\mathcal{Q}_1, \dots, \mathcal{Q}_s$ :

If they are given in the implicit form, it is sufficient to unify all equations into one system, omitting any linearly dependent ones. If the resulting system has no solution, then the intersection is empty. Otherwise, an implicit description of the affine subspace is obtained. This is the intersection we are searching for.

If parametric forms are given, we may search directly for common points as solutions of the appropriate equations, similarly to the way we find the intersections of vector spaces. If the number of subspaces is greater than two, we must search for the intersection step by step.

If one of the subspaces is defined parametrically and the other implicitly, it suffices to substitute the parametrized coordinates and to solve the resulting system of equations.

(4) To find a crossbar between two skew lines  $p, q$  in  $\mathcal{A}_3$  passing through a given point or having a given direction:

By a crossbar we mean a straight line which has nonempty intersection with both skew lines. Thus the resulting crossbar  $r$  is a one-dimensional affine subspace.

**Solution.** The direction of the common perpendicular is given by the cross product of the two direction vectors. So the direction of the common perpendicular is  $(1, -2, 1)$ . Form a linear equation system which expresses that a vector defined by two points, one lying on  $p$ , the other on  $q$ , is parallel to the direction  $(1, -2, 1)$ . We get the system  $P - Q = k(1, -2, 1)$ , or  $\underbrace{[3, 0, 3] + (0, 1, 2)t}_P - \underbrace{[0, -1, -2] + (1, 2, 3)s}_Q = k(1, -2, 1)$ .

Treat this equality component-wise to give

$$\begin{aligned} 3 - s &= k \\ 1 + t - 2s &= -2k \\ 5 + 2t - 3s &= k \end{aligned}$$

with the solution  $t = 1, s = 2, k = 1$ . Put  $t = 1$  into the line  $p$ , to obtain the point  $[3, 1, 5]$  on the common perpendicular. Put  $s = 2$  into the line  $q$  equation to obtain the point  $[3, 1, 5]$ . The common perpendicular is defined by the line joining these two points.  $\square$

### B. Euclidean geometry

**4.B.1.** Determine the distance between the lines in  $\mathbb{R}^3$ .

$$p : [1, -1, 0] + t(-1, 2, 3), \text{ and } q : [2, 5, -1] + t(-1, -2, 1).$$

**Solution.** The distance is defined as the distance of the orthogonal projection of arbitrary points on the respective lines to the orthogonal complement of the vector subspace generated by their directions. The orthogonal complement is spanned by the cross product:

$$\begin{aligned} \langle (-1, 2, 3), (-1, -2, 1) \rangle^\perp &= \langle (-1, 2, 3) \times (-1, -2, 1) \rangle \\ &= \langle (8, -2, 4) \rangle = \langle (4, -1, 2) \rangle. \end{aligned}$$

A transversal is (for example) the segment joining  $[1, -1, 0]$  to  $[2, 5, -1]$ . So the vector to be projected is  $[1, -1, 0] - [2, 5, -1] = (-1, -6, 1)$ . The distance between the lines is therefore:

$$\rho(p, q) = \frac{|(-1, -6, 1) \cdot (4, -1, 2)|}{\|(4, -1, 2)\|} = \frac{4}{\sqrt{21}}.$$

$\square$

**4.B.2.** Find a point  $A$  lying on the line

$$p : x + 2y + z - 1 = 0, \quad 3x - y + 4z - 29 = 0,$$

which is equidistant from both  $B = [3, 11, 4]$  and  $C = [-5, -13, -2]$ .

If we are given one point  $A \in r$ , then the affine subspace generated by  $p$  and  $A$  is either a straight line (if  $A \in p$ ) or a plane (if  $A \notin p$ ). In the first case, there are an infinite number of solutions, one for each point of  $q$ . In the second case, it suffices to find the intersection  $B$  of the plane  $\langle p \cup A \rangle$  with  $q$ , and  $r = \langle \{A, B\} \rangle$ . There is no solution if the intersection is empty. If  $q \subset \langle p \cup A \rangle$ , there are an infinite number of solutions. If the intersection has one element, there is exactly one solution.

If a direction  $u \in \mathbb{R}^n$  is given, then we consider the subspace  $Q$  generated by  $p$  and the difference space  $Z(p) + \langle u \rangle \subset \mathbb{R}^n$ . Again, we obtain an infinite number of solutions if  $q \subset Q$ . Otherwise we consider the intersection  $Q$  with  $q$  and we finish as before.

The solutions of other practical geometric problems are based mostly on the systematic use of the steps given above.

**4.1.11. Remarks on linear programming.** In the beginning of the third chapter in paragraphs 3.1.1–3.1.7, we dealt with practical problems which are given by systems of linear inequalities. Each single inequality

$$a_1x_1 + \dots + a_nx_n \leq b$$

defines a halfspace in the standard affine space  $\mathbb{R}^n$ . This is bounded by a hyperplane given by the corresponding equation (compare with the definition in paragraph 4.1.9(4)). Suppose we choose the parametric description of the bounding hyperplane

$$\{P + t_1v_1 + \dots + t_{n-1}v_{n-1}\}$$

with vectors  $v_1, \dots, v_{n-1}$  from the difference space. By completing these vectors by  $v$  to a basis of the whole  $\mathbb{R}^n$ , the value of

$$a_1x_1 + \dots + a_nx_n - b$$

on the linear combination  $t_1v_1 + \dots + t_{n-1}v_{n-1} + t_nv$  must be positive for all vectors with either a positive or a negative  $t_n$ .

At the same time, the set of all admissible vectors for the problem of the linear programming is always an intersection of a finite number of convex sets. Hence the set itself is either convex or empty.

If the intersection is both nonempty and bounded, then it is a convex polyhedron. As justified in 3.1.1 already, each linear form is either increasing or decreasing or constant along each parametrized straight line in the affine space. Thus if a given problem from linear programming is solvable and bounded, then it has the optimal solution at one of the vertices of the corresponding convex polyhedron. The reader should be able to imagine this claim in the case of two-dimensional or three-dimensional problems. Nevertheless, the straightforward explanation in these low dimensions holds for all finite-dimensional cases.

We have given a “geometric proof” of the existence part of the fundamental theorem 3.1.5. We have translated the initial problem into a finite problem of the given cost function.

**Solution.** First, express the line  $p$  parametrically. Solve the system

$$\begin{aligned} x + 2y + z &= 1, \\ 3x - y + 4z &= 29. \end{aligned}$$

Rewrite the system as an augmented matrix and perform row operations

$$\begin{aligned} \left( \begin{array}{ccc|c} 1 & 2 & 1 & 1 \\ 3 & -1 & 4 & 29 \end{array} \right) &\sim \left( \begin{array}{ccc|c} 1 & 2 & 1 & 1 \\ 0 & -7 & 1 & 26 \end{array} \right) \\ &\sim \left( \begin{array}{ccc|c} 1 & 0 & 9/7 & 59/7 \\ 0 & 1 & -1/7 & -26/7 \end{array} \right). \end{aligned}$$

The line  $p$  is thus described by

$$p : \left[ \frac{59}{7}, -\frac{26}{7}, 0 \right] + t \left( -\frac{9}{7}, \frac{1}{7}, 1 \right), \quad t \in \mathbb{R}.$$

It is convenient to avoid the fractions, by introducing the substitution  $t = 7s + 26$ .  $p$  is thus described by

$$p : [-25, 0, 26] + s(-9, 1, 7), \quad s \in \mathbb{R}.$$

The point  $A$  is obtained by requiring that the vectors

$$A - B = (-28 - 9s, -11 + s, 22 + 7s),$$

$$A - C = (-20 - 9s, 13 + s, 28 + 7s)$$

have the same length. Hence

$$\begin{aligned} \sqrt{(-28 - 9s)^2 + (-11 + s)^2 + (22 + 7s)^2} \\ = \sqrt{(-20 - 9s)^2 + (13 + s)^2 + (28 + 7s)^2}, \end{aligned}$$

or rather

$$\begin{aligned} (-28 - 9s)^2 + (-11 + s)^2 + (22 + 7s)^2 \\ = (-20 - 9s)^2 + (13 + s)^2 + (28 + 7s)^2. \end{aligned}$$

which has the unique solution  $s = -3$ . Therefore

$$A = [-25, 0, 26] - 3(-9, 1, 7) = [2, -3, 5].$$

□

**4.B.3.** Michael has a stick of length 4. Can he touch the lines  $p$  and  $q$  simultaneously with this stick, given that the stick must pass through  $[2, 1, 2]$ ?

$$p : [-1, 4, 1] + t(-1, 2, 0),$$

$$q : [4, 4, -1] + s(1, 2, -4)?$$

**Solution.** Compute the transversal of those lines passing through  $[2, 1, 2]$ . It is the segment joining  $[1, 0, 1]$  to  $[3, 2, 3]$ . Its length is  $\sqrt{12}$ , which is less than 4. So Michael can touch the lines as required. □

**4.1.12. Affine maps.** A map  $f : \mathcal{A} \rightarrow \mathcal{B}$  between affine spaces is called an *affine map* if there exists a linear map  $\varphi : Z(\mathcal{A}) \rightarrow Z(\mathcal{B})$  between their difference spaces such that for all  $A \in \mathcal{A}$ ,  $v \in Z(\mathcal{A})$  the following holds:

$$f(A + v) = f(A) + \varphi(v).$$

The maps  $f$  and  $\varphi$  are determined uniquely by this property, and by arbitrarily chosen images of  $(\dim \mathcal{A} + 1)$  points in general position.

For an arbitrary affine combination of points  $t_0A_0 + \dots + t_sA_s \in \mathcal{A}$  we obtain

$$\begin{aligned} f(t_0A_0 + \dots + t_sA_s) &= \\ &= f(A_0 + t_1(A_1 - A_0) + \dots + t_s(A_s - A_0)) \\ &= f(A_0) + t_1\varphi(A_1 - A_0) + \dots + t_s\varphi(A_s - A_0) \\ &= t_0f(A_0) + t_1f(A_1) + \dots + t_sf(A_s). \end{aligned}$$

On the other hand, if a map preserves affine combinations, we may use a specific combination of  $n + 1$  fixed vectors generating the affine frame. After choosing successively the only non-zero coefficients  $t_i = 1$ ,  $i = 1, \dots, s$ , we define the map  $\varphi$  between difference spaces by the relation  $\varphi(A_i - A_0) = f(A_i) - f(A_0)$ . The previous computation can be read in the opposite direction, so we can check the validity and linearity of  $\varphi$ . The assumption that the first and the last rows are equal implies that the second and the third rows are equal. So we have an affine map with the corresponding linear map  $\varphi$  between difference spaces which we described in the chosen affine frame by this procedure. Therefore:

**Theorem.** *Affine maps are exactly those maps which preserve the affine combinations of points.*

It is sufficient to check the invariance of affine combinations for all pairs of points since we can create an arbitrary affine combination from them. The affine combination of  $k + 2$  points  $A_0, \dots, A_{k+1}$  can be expressed as

$$r(t_0A_0 + \dots + t_kA_k) + sA_{k+1},$$

where  $\sum_{i=0}^k t_k = 1$  and  $r + s = 1$ . We choose a point which is an affine combination of  $k + 1$  points only. Then make its combination with the last one. In this way, any finite affine combination can be made step by step from the combination of pairs.

**4.1.13. Ratio of collinear points.** The affine combinations of pairs of points can be also expressed with the help of the *ratio of points* on a straight line. If  $C$  is given by an affine combination of points  $A$  and  $B \neq C$ ,  $C = rA + sB$ , then we say that the number

$$\lambda = (C; A, B) = -\frac{s}{r}$$

is the ratio of the point  $C$  with respect to the given points  $A$  and  $B$ . Since we can express  $C$  as

$$C = A + s(B - A) = B + r(A - B),$$

**4.B.4.** In Euclidean space  $\mathbb{R}^4$ , determine the distance between the point  $A = [2, -5, 1, 4]$  and the subspace defined by the equations

$$U : \begin{aligned} 4x_1 - 2x_2 - 3x_3 - 2x_4 + 12 &= 0, \\ 2x_1 - x_2 - 2x_3 - 2x_4 + 9 &= 0. \end{aligned}$$

**Solution.** Find first a parametric expression of the subspace  $U$ . For example,

$$B = [0, 3, 0, 3] \in U.$$

The distance between  $A$  and  $U$  equals the length of the orthogonal projection of the vector  $A - B$  to the orthogonal complement of the direction of the subspace  $U$ . However, the orthogonal complement of the  $U$  direction (it defines this subspace) – as set (of linear combination of normal vectors)

$$V := \{t(4, -2, -3, -2) + s(2, -1, -2, -2); t, s \in \mathbb{R}\}.$$

We need to find the orthogonal projection  $P_{A-B}$  of vector  $A - B$  to  $V$ , which lies in  $V$ , and thus

$$P_{A-B} = a(4, -2, -3, -2) + b(2, -1, -2, -2)$$

for certain  $a, b \in \mathbb{R}$ . Clearly,  $(A - B - P_{A-B}) \perp V$ , thus

$$((A - B) - P_{A-B}) \perp (4, -2, -3, -2),$$

$$((A - B) - P_{A-B}) \perp (2, -1, -2, -2).$$

By substitution of  $A - B$  and  $P_{A-B}$ ,

$$\begin{aligned} ((2, -8, 1, 1) - a(4, -2, -3, -2) - b(2, -1, -2, -2)) \\ \cdot (4, -2, -3, -2) = 0, \end{aligned}$$

$$\begin{aligned} ((2, -8, 1, 1) - a(4, -2, -3, -2) - b(2, -1, -2, -2)) \\ \cdot (2, -1, -2, -2) = 0; \end{aligned}$$

so

$$\begin{aligned} (2, -8, 1, 1) \cdot (4, -2, -3, -2) \\ -a(4, -2, -3, -2) \cdot (4, -2, -3, -2) \\ -b(2, -1, -2, -2) \cdot (4, -2, -3, -2) = 0, \end{aligned}$$

$$\begin{aligned} ((2, -8, 1, 1) \cdot (2, -1, -2, -2)) \\ -a(4, -2, -3, -2) \cdot (2, -1, -2, -2) \\ -b(2, -1, -2, -2) \cdot (2, -1, -2, -2) = 0. \end{aligned}$$

If we compute these dot products, we obtain the system

$$\begin{aligned} 19 - 33a - 20b &= 0, \\ 8 - 20a - 13b &= 0, \end{aligned}$$

the ratio  $\lambda$  is the ratio of the length of the oriented vectors  $C - A$  and  $C - B$ . In particular,  $\lambda = -1$  if and only if  $C$  is at the centre of the line segment joining  $A$  and  $B$  (i.e.  $r = s = \frac{1}{2}$  in the affine combination).

Hence the characterization of affine maps in terms of affine combinations has the following consequence:

**Corollary.** *Affine maps are exactly those maps for which the ratios are invariant.*

Needless to say that collinearity of points must be preserved in order to talk about the ratios.

**4.1.14. Changes of coordinates.** Under the choice of an affine coordinate system  $(A_0, \underline{u})$  on  $\mathcal{A}$  and a system  $(B_0, \underline{v})$  on  $\mathcal{B}$ , we obtain the coordinate expression of the affine map  $f : \mathcal{A} \rightarrow \mathcal{B}$ . It is sufficient to express the image  $f(A_0)$  of the origin of the coordinate system on  $\mathcal{A}$  in the coordinate system on  $\mathcal{B}$ . In other words, the vector  $f(A_0) - B_0$  with the basis  $\underline{v}$  is expressed as a column of coordinates  $y_0$ . Everything else is then given by multiplying by the matrix of the map  $\varphi$  in the chosen bases and by adding the outcome. Each affine map therefore has the following form in coordinates:

$$x \mapsto y_0 + Y \cdot x,$$

where  $y_0$  is as above, and  $Y$  is the matrix of the map  $\varphi$ .

As in the case of linear maps, the transformation of affine coordinates corresponds to the expression of the identity map in the chosen affine frames. The change of coordinate expression of an affine map caused by a change of the basis is computed by multiplying and adding matrices and vectors.

Consider the change of the frame

$$x = w + M \cdot x',$$

on the domain by a translation  $w$  and a matrix  $M$ . Further, let

$$y' = z + N \cdot y$$

describe a change of basis on the range space by a translation  $z$  and a matrix  $N$ . Then

$$\begin{aligned} y' &= z + N \cdot y = z + N \cdot (y_0 + Y \cdot x) \\ &= (z + N \cdot y_0 + N \cdot Y \cdot w) + (N \cdot Y \cdot M) \cdot x'. \end{aligned}$$

Hence the affine map in the new bases is given by the translation vector  $z + N \cdot y_0 + N \cdot Y \cdot w$  and matrix  $N \cdot Y \cdot M$ .

**4.1.15. Euclidean point spaces.** So far, we do not need the notions of distance and length for geometric considerations. But the length of vectors and the angle between vectors, as defined in the second chapter (see 2.3.18 and elsewhere), play a significant role in many practical problems.

with the only solution  $a = 3, b = -4$ . Hence

$$\begin{aligned} P_{A-B} &= 3(4, -2, -3, -2) - 4(2, -1, -2, -2) \\ &= (4, -2, -1, 2), \end{aligned}$$

where

$$\|P_{A-B}\| = \sqrt{4^2 + (-2)^2 + (-1)^2 + 2^2} = 5.$$

Hence the distance between  $A$  and  $U$  equals  $\|P_{A-B}\| = 5$ .

□

**4.B.5.** In the vector space  $\mathbb{R}^4$ , compute the distance  $v$  between the point  $[0, 0, 6, 0]$  and the vector subspace

$$U : [0, 0, 0, 0] + t_1(1, 0, 1, 1) + t_2(2, 1, 1, 0) + t_3(1, -1, 2, 3),$$

$t_1, t_2, t_3 \in \mathbb{R}$

**Solution.** We solve the problem by the least squares method. Write the generating vectors of  $U$  as the columns of the matrix

$$A = \begin{pmatrix} 1 & 2 & 1 \\ 0 & 1 & -1 \\ 1 & 1 & 2 \\ 1 & 0 & 3 \end{pmatrix}.$$

Substitute the point  $[0, 0, 6, 0]$  by the corresponding vector  $b = (0, 0, 6, 0)^T$ . Now solve  $A \cdot x = b$ . This is the linear equation system

$$\begin{aligned} x_1 + 2x_2 + x_3 &= 0, \\ x_2 - x_3 &= 0, \\ x_1 + x_2 + 2x_3 &= 6, \\ x_1 + 3x_3 &= 0, \end{aligned}$$

by the least squares method. (Note that the system does not have a solution – the distance would be 0 otherwise.) Multiply  $A \cdot x = b$  by the matrix  $A^T$  from the left-hand side. Then the augmented matrix  $A^T \cdot A \cdot x = A^T \cdot b$  is

$$\left( \begin{array}{ccc|c} 3 & 3 & 6 & 6 \\ 3 & 6 & 3 & 6 \\ 6 & 3 & 15 & 12 \end{array} \right).$$

By elementary row operations, transform the matrix to the normal form

$$\begin{aligned} \left( \begin{array}{ccc|c} 3 & 3 & 6 & 6 \\ 3 & 6 & 3 & 6 \\ 6 & 3 & 15 & 12 \end{array} \right) &\sim \left( \begin{array}{ccc|c} 3 & 3 & 6 & 6 \\ 0 & 3 & -3 & 0 \\ 0 & -3 & 3 & 0 \end{array} \right) \\ &\sim \left( \begin{array}{ccc|c} 1 & 1 & 2 & 2 \\ 0 & 1 & -1 & 0 \\ 0 & 0 & 0 & 0 \end{array} \right). \end{aligned}$$

Continue with backward elimination

$$\left( \begin{array}{ccc|c} 1 & 1 & 2 & 2 \\ 0 & 1 & -1 & 0 \\ 0 & 0 & 0 & 0 \end{array} \right) \sim \left( \begin{array}{ccc|c} 1 & 0 & 3 & 2 \\ 0 & 1 & -1 & 0 \\ 0 & 0 & 0 & 0 \end{array} \right).$$

EUCLIDEAN SPACES

The *standard Euclidean point space*  $\mathcal{E}_n$  is the affine space  $\mathcal{A}_n$  whose difference space is the standard *Euclidean space*  $\mathbb{R}^n$  with the scalar product

$$\langle x, y \rangle = y^T \cdot x.$$

The *Cartesian coordinate system* is the affine coordinate system  $(A_0; \underline{u})$  with the orthonormal basis  $\underline{u}$ .

The *Euclidean distance* between two points  $A, B \in \mathcal{E}_n$  is defined as the length of the vector  $\|B - A\|$ . This is denoted by  $\rho(A, B)$ .

*Euclidean subspaces* in  $\mathcal{E}_n$  are affine subspaces, where the corresponding difference spaces are considered with restricted scalar products.

By a *Euclidean point space*  $\mathcal{E}$  of dimension  $n$  is meant an affine space, whose difference space is a real  $n$ -dimensional Euclidean vector space. The notion of a Cartesian coordinate system has an obvious meaning. Since each choice of such a coordinate system identifies  $\mathcal{E}$  with the standard space  $\mathcal{E}_n$ , we deal with the standard Euclidean spaces and their subspaces, with no loss of generality.

From the geometric point of view, simple properties of the scalar product like the triangular inequality, the Cauchy inequality, Bessel's inequality, derived in the previous chapter (see 3.4.3), have useful consequences:

**4.1.16. Theorem.** For points  $A, B, C \in \mathcal{E}_n$  the following holds

- (1)  $\rho(A, B) = \rho(B, A)$
- (2)  $\rho(A, B) = 0$  if and only if  $A = B$
- (3)  $\rho(A, B) + \rho(B, C) \geq \rho(A, C)$
- (4) In each Cartesian coordinate system  $(A_0; \underline{e})$ , the distance between the points  $A = A_0 + a_1e_1 + \dots + a_n e_n$ ,  $B = A_0 + b_1e_1 + \dots + b_n e_n$  is  $\sqrt{\sum_{i=1}^n (a_i - b_i)^2}$ .
- (5) Given a point  $A$  and a subspace  $\mathcal{Q}$  in  $\mathcal{E}_n$ , there exists a point  $P \in \mathcal{Q}$  which minimizes the distance between  $A$  and points in  $\mathcal{Q}$ . The distance between  $A$  and  $P$  equals the length of the orthogonal projection of the vector  $A - B$  into  $Z(\mathcal{Q})^\perp$  for an arbitrary  $B \in \mathcal{Q}$ .
- (6) More generally, for subspaces  $\mathcal{Q}$  and  $\mathcal{R}$  in  $\mathcal{E}_n$  there exist points  $P \in \mathcal{Q}$  and  $Q \in \mathcal{R}$  which minimize the distance between points  $B \in \mathcal{Q}$  and  $A \in \mathcal{R}$ . The distance between the points  $P$  and  $Q$  is the length of the orthogonal projection of the vector  $A - B$  into  $Z(\mathcal{Q})^\perp$  for arbitrary points  $B \in \mathcal{Q}$  and  $A \in \mathcal{R}$ .

**PROOF.** The first three properties follow directly from the properties of the length of vectors in spaces with a scalar product. The fourth follows from the expression of the scalar product in an orthonormal basis.

Consider the relation for the minimal distances  $\rho(A, B)$  for  $B \in \mathcal{Q}$ . The vector  $A - B$  decomposes uniquely as  $A - B = u_1 + u_2$ , where  $u_1 \in Z(\mathcal{Q})$ ,  $u_2 \in Z(\mathcal{Q})^\perp$ . The component  $u_2$  does not depend on the choice of  $B \in \mathcal{Q}$ . This

The solution is

$$x = (2 - 3t, t, t)^T, \quad t \in \mathbb{R}.$$

Note that the existence of infinitely many solutions is caused by third vector generating  $U$ , which is redundant because

$$3(1, 0, 1, 1) - (2, 1, 1, 0) = (1, -1, 2, 3).$$

An arbitrary ( $t \in \mathbb{R}$ ) linear combination

$$(2-3t)(1, 0, 1, 1) + t(2, 1, 1, 0) + t(1, -1, 2, 3) = (2, 0, 2, 2)$$

corresponds to a point  $[2, 0, 2, 2]$  in the subspace  $U$ , which is the nearest point to  $[0, 0, 6, 0]$ . The required distance is therefore

$$\begin{aligned} v &= \|[2, 0, 2, 2] - [0, 0, 6, 0]\| = \sqrt{2^2 + 0 + (-4)^2 + 2^2} \\ &= 2\sqrt{6}. \end{aligned}$$

□

**4.B.6.** Compute the volume of the parallelepiped in  $\mathbb{R}^3$  with base in the plane  $z = 0$  and with edges given by pairs of vertices  $[0, 0, 0]$ ,  $[-2, 3, 0]$ ;  $[0, 0, 0]$ ,  $[4, 1, 0]$  and  $[0, 0, 0]$ ,  $[5, 7, 3]$ .

**Solution.** The parallelepiped is given by vectors  $(4, 1, 0)$ ,  $(-2, 3, 0)$ ,  $(5, 7, 3)$ . Its volume is the determinant

$$\begin{vmatrix} 4 & -2 & 5 \\ 1 & 3 & 7 \\ 0 & 0 & 3 \end{vmatrix} = 3 \begin{vmatrix} 4 & -2 \\ 1 & 3 \end{vmatrix} = 3 \cdot 14 = 42.$$

Note that if the order of vectors is changed, we would get result  $\pm 42$ , because the determinant gives the *oriented* volume of parallelepiped. Note further that the volume would not change if the third vector was  $[a, b, 3]$  for arbitrary  $a, b \in \mathbb{R}$ . Its surface depends only on orthogonal distance between planes of its upper and lower base and their area

$$\begin{vmatrix} 4 & -2 \\ 1 & 3 \end{vmatrix} = 14.$$

□

**4.B.7.** Let the points  $[0, 0, 1]$ ,  $[2, 1, 1]$ ,  $[3, 3, 1]$ ,  $[1, 2, 1]$  define a parallelogram. Determine the point  $X$  lying on the line  $p : [0, 0, 1] + (1, 1, 1)t$  so that the parallelepiped defined by the given parallelogram and a point  $X$  has volume of 1.

**Solution.** Form a determinant which gives the volume of a parallelepiped with  $X$  moving along line  $p$ :

$$\begin{vmatrix} t & t & t \\ 2 & 1 & 0 \\ 1 & 2 & 0 \end{vmatrix}.$$

The volume is  $3t$  which implies  $t = 1/3$ .

□

is because any potential change of  $B$  is apparent by adding a vector from  $Z(Q)$ .

Choose  $P = A + (-u_2) = B + u_1 \in Q$ . Then

$$\|A - B\|^2 = \|u_1\|^2 + \|u_2\|^2 \geq \|u_2\|^2 = \|A - P\|^2.$$

Hence the minimal distance is obtained for the point  $P$ . Its value is  $\|u_2\|$ .

The general result is obtained in a similar way. For the choice of arbitrary points  $A \in \mathcal{R}$  and  $B \in \mathcal{Q}$  their difference is given as a sum of vectors  $u_1 \in Z(\mathcal{R}) + Z(\mathcal{Q})$  and  $u_2 \in (Z(\mathcal{R}) + Z(\mathcal{Q}))^\perp$ . The component  $u_2$  does not depend on the choice of the points. By adding suitable vectors from the difference spaces of  $\mathcal{R}$  and  $\mathcal{Q}$ , points  $A'$  and  $B'$  are obtained so that the distance between them is  $\|u_2\|$ . □

We consider more elementary problems in affine geometry requiring the concept of distance.

**4.1.17. Examples of standard problems.** (1) To find the distance from the point  $A \in \mathcal{E}_n$  to the subspace  $Q \subset \mathcal{E}_n$ :

A method of solving such a problem is given in proposition 4.1.16.

(2) In  $\mathcal{E}_2$  to construct the straight line  $q$  through a given point  $A$  which forms a given angle with a given line  $p$ :

Recall that we work with angles between vectors in plane geometry already (see e.g. 2.3.21). Find a vector  $u \in \mathbb{R}^2$  lying in the difference space of the line  $p$ . Then choose a vector  $v$  having the prescribed angle with  $u$ . The desired line is given by the point  $A$  and the difference space  $\langle v \rangle$ . The problem has either one or two solutions.

(3) To find a line through a given point, perpendicular to a given line:

The procedure is introduced in the proof of the last but one item of proposition 4.1.16.

(4) In  $\mathcal{E}_3$  to determine the distance between two lines  $p, q$ :

Choose any point from each of the lines,  $A \in p, B \in q$ . The component of the vector  $A - B$  lying in the orthogonal complement  $(Z(p) + Z(q))^\perp$  has length equal to the distance between  $p$  and  $q$ .

(5) In  $\mathcal{E}_3$  to find the axis of two skew lines  $p$  a  $q$ :

By the axis we mean the crossbar which attains the minimal possible distance between the given skew lines in terms of the points of intersection. The procedure can be derived from the proof of proposition 4.1.16 (the last item). Let  $\eta$  be the subspace generated by a single point  $A \in p$  and the sum  $Z(p) + (Z(p) + Z(q))^\perp$ . Provided that the lines  $p$  and  $q$  are not parallel,  $\eta$  is a plane. Then the intersection  $\eta \cap q$  together with the difference space  $(Z(p) + Z(q))^\perp$  gives a parametric description of the desired axis. If the lines are parallel, the problem has an infinite number of solutions.

**4.B.8.** Let  $ABCDEFGH$  be a cube (with common notation, i.e. vectors  $E - A, F - B, G - C, H - D$  are orthogonal to the plane defined by vertices  $A, B, C, D$ ) in Euclidean space  $\mathbb{R}^3$ . Compute the angle  $\varphi$  between the vectors  $F - A$  and  $H - A$ .

**Solution.** This problem is solved using the formula for the angle between the vectors. Alternatively notice that the vertices  $A, F, H$  are the vertices of a triangle with all sides of the same length. Hence it is an equilateral triangle. Therefore  $\varphi = \pi/3$ .  $\square$

**4.B.9.** Let  $S$  be the midpoint of the edge  $AB$  of the cube  $ABCDEFGH$  (with common labelling). Compute the cosine of the angle between the lines  $ES$  and  $BG$ .

**Solution.** Dilation (homothety) is a mapping which preserves angles. So without loss of generality, the cube edge has length 1. The coordinate system can be placed so that  $A$  is at the origin,  $B = [1, 0, 0]$  and  $E = [0, 0, 1]$ . It follows that then:  $S = [1/2, 0, 0], G = [1, 1, 1], ES = (1/2, 0, -1)$  and  $BG = (0, 1, 1)$ . The desired cosine of the angle  $\varphi$  is then

$$\cos(\varphi) = \left| \frac{(1/2, 0, -1) \cdot (0, 1, 1)}{\|(1/2, 0, -1)\| \|(0, 1, 1)\|} \right| = \frac{\sqrt{2}}{\sqrt{5}}$$

**4.B.10.** Compute the angle between the line  $p$  given by the implicit equations

$$\begin{aligned} x + 3y + z &= 0, \\ -x - y + z &= 0 \end{aligned}$$

and plane the  $\varrho : x + y + 2z + 1 = 0$ .

**Solution.** The normal vector of the plane  $\varrho$  is  $(1, 1, 2)$ . Copy the first equation of the line  $p$ . Sum both of them, to obtain

$$\begin{aligned} x + 3y + z &= 0, \\ 2y + 2z &= 0. \end{aligned}$$

From this system  $y = -z$  and  $x = 2z$ . The vector  $(2, -1, 1)$  is therefore the direction vector of  $p$ . In other words,  $p$  passes through the origin, and

$$p : [0, 0, 0] + t(2, -1, 1), \quad t \in \mathbb{R}.$$

For the angle  $\varphi$  between the vectors  $(1, 1, 2), (2, -1, 1)$ ,

$$\cos \varphi = \frac{2 - 1 + 2}{\sqrt{6} \cdot \sqrt{6}} = \frac{1}{2}.$$

Hence  $\varphi = 60^\circ$ . However, this is the angle between the direction vector of  $p$  and the normal vector  $\varrho$ . The desired angle is the complement of this angle, so the solution is  $30^\circ = 90^\circ - 60^\circ$ .  $\square$

**4.1.18. Angles.** Various geometric notions like angles, orientation, volume etc. in the point spaces  $\mathcal{E}_n$  are defined in terms of suitable notions from Euclidean spaces. The angle between two vectors is defined at the end of the third part of the second chapter, see 2.3.21.

From the Cauchy inequality, it follows that  $0 \leq \frac{|u \cdot v|}{\|u\| \|v\|} \leq 1$ . So it makes sense to define the *angle*  $\varphi(u, v)$  between vectors  $u, v \in V$  in a real vector space with a scalar product given by the equation

$$\cos \varphi(u, v) = \frac{u \cdot v}{\|u\| \|v\|}, \quad 0 \leq \varphi(u, v) \leq 2\pi.$$

This is completely in accordance with the situation in two-dimensional Euclidean space  $\mathbb{R}^2$  and with the philosophy that the notion related to the two vectors is the issue of plane geometry.

In the Euclidean plane, we use also the geometric functions  $\cos$  and  $\sin$  defined by a pure geometric consideration. Therefore, the angle between two vectors in higher-dimensional spaces is measured in the plane which is generated by these two vectors (or it is zero).

In an arbitrary real vector space with a scalar product, it follows that

$$\begin{aligned} \|u - v\|^2 &= \|u\|^2 + \|v\|^2 - 2(u \cdot v) \\ &= \|u\|^2 + \|v\|^2 - 2\|u\| \|v\| \cos \varphi(u, v). \end{aligned}$$

This is the well known *cosine rule* from plane geometry.

In each orthonormal basis  $\underline{e}$  of the difference space  $V$  and vector  $u \in V$ , the square of the size of  $u$  is given by the usual formula

$$\|u\|^2 = \sum_i |u \cdot e_i|^2.$$

By dividing this equation by the number  $\|u\|^2$ ,

$$1 = \sum_i (\cos \varphi(u, e_i))^2,$$

which is the *law of direction cosines*  $\varphi(u, e_i)$  of the vector  $u$ .

Now we can derive definitions for angles between general subspaces in a Euclidean vector space from the definitions of angles between vectors. In particular, it must be decided how to deal with cases where the subspaces have a nontrivial intersection. For the angle between two lines, use the smaller of the two possible angles.

In the case of two nonparallel planes in  $\mathbb{R}^3$  we do not say that the angle is zero. They intersect and have one direction in common. Perhaps we take the two perpendicular lines to this common direction in the two planes and measure their angle.

The general cases are treated as follows:

**4.B.11.** In the real plane, find a line which passes through the point  $[-3, 0]$ , so that  $60^\circ$  is the angle between this line and the line

$$p : \sqrt{3}x + 3y + 5 = 0.$$

**Solution.** The given line has slope  $\frac{-1}{\sqrt{3}}$ . This is at angle  $-30^\circ$  from the positive  $x$  axis. Thus the required line is either at angle  $-90^\circ$  or angle  $30^\circ$  from the positive  $x$  axis. The former determines the vertical line  $x = -3$ . The latter determines the line with slope  $\frac{1}{\sqrt{3}}$  through  $[-3, 0]$ , hence has equation  $y\sqrt{3} = x + 3$ .  $\square$

**Solution.** (Alternative) Notice that there are two such lines. The general equation of a line in the plane has the form

$$ax + by + c = 0. \quad \text{Choose parameters so that } a^2 + b^2 = 1.$$

We find such numbers  $a, b, c \in \mathbb{R}$ , so that all the conditions are satisfied. Since the line passes through  $[-3, 0]$ ,  $c = 3a$ . The condition of the angle between lines equals  $60^\circ$  then gives

$$\frac{1}{2} = \cos 60^\circ = \frac{|\sqrt{3}a + 3b|}{\sqrt{12}}, \quad \text{tj. } \sqrt{3} = |\sqrt{3}a + 3b|.$$

Performing further operations

$$\pm 1 = a + \sqrt{3}b \quad \text{and exponentiation} \quad 1 = a^2 + 3b^2 + 2\sqrt{3}ab.$$

If we use  $a^2 + b^2 = 1$ , we get

$$0 = 2b^2 + 2\sqrt{3}ab, \quad \text{tj. } 0 = b(b + \sqrt{3}a).$$

Together (remember that  $c = 3a$  and  $a^2 + b^2 = 1$ )

$$a = \pm 1, \quad b = 0, \quad c = \pm 3; \quad a = \pm \frac{1}{2}, \quad b = \mp \frac{\sqrt{3}}{2}, \quad c = \pm \frac{3}{2}$$

We can easily check that lines determined by those coefficients

$$x + 3 = 0, \quad \frac{1}{2}x - \frac{\sqrt{3}}{2}y + \frac{3}{2} = 0$$

satisfy all the conditions.  $\square$

**4.B.12.** Determine the equation of all planes so that the angle between every such plane and the plane  $x + y + z - 1 = 0$  is  $60^\circ$ , and further, that they contain the line  $p : [1, 0, 0] + t(1, 1, 0)$ .  $\circ$

**4.B.13.** Determine the angle between the planes

$$\sigma : [1, 0, 2] + (1, -1, 1)t + (0, 1, -2)s$$

$$\rho : [3, 3, 3] + (1, -2, 0)t + (0, 1, 1)s$$

**Solution.** The line of intersection between the planes has direction vector  $(1, -1, 1)$ . The plane orthogonal to this vector

ANGLES BETWEEN SUBSPACES

**4.1.19. Definition.** Consider finite-dimensional subspaces  $U_1, U_2$  in a Euclidean vector space  $V$  of arbitrary dimension.

The angle between vector subspaces  $U_1, U_2$  is the real number  $\alpha = \varphi(U_1, U_2) \in [0, \frac{\pi}{2}]$  satisfying:

(1) If  $\dim U_1 = \dim U_2 = 1, U_1 = \langle u \rangle, U_2 = \langle v \rangle$ , then

$$\cos \alpha = \frac{|u \cdot v|}{\|u\| \|v\|}.$$

(2) If the dimensions of  $U_1, U_2$  are positive, and if  $U_1 \cap U_2 = \{0\}$ , then the angle is the minimum of all angles between the one-dimensional subspaces

$$\alpha = \min\{\varphi(\langle u \rangle, \langle v \rangle); 0 \neq u \in U_1, 0 \neq v \in U_2\}.$$

Such a minimum always exists.

(3) If  $U_1 \subset U_2$  or  $U_2 \subset U_1$  (in particular if one of them is empty), then  $\alpha = 0$ .

(4) If  $U_1 \cap U_2 \neq \{0\}$  and if  $U_1 \neq U_1 \cap U_2 \neq U_2$ , then

$$\alpha = \varphi(U_1 \cap (U_1 \cap U_2)^\perp, U_2 \cap (U_1 \cap U_2)^\perp).$$

The angle between affine subspaces  $\mathcal{Q}_1, \mathcal{Q}_2$  in a Euclidean point space  $\mathcal{E}_n$  is defined as the angle between their difference spaces  $Z(\mathcal{Q}_1), Z(\mathcal{Q}_2)$ .

Notice that the angle is always well defined. In the last case,

$$(U_1 \cap (U_1 \cap U_2)^\perp) \cap (U_2 \cap (U_1 \cap U_2)^\perp) = \{0\}$$

so we can determine the angle according to item (2). Notice also that in the case  $U_1 \cap U_2 = \{0\}$ , the subspaces  $U_1$  and  $U_2$  are perpendicular in terms of the former definitions if and only if the angle between them is  $\pi/2$ . However, if the intersection is nontrivial, then they cannot be perpendicular in the former sense.

In order to show the validity of the definition, it remains to show that the vectors  $u \in U_1, v \in U_2$  minimizing the expression for the angle always exist. First a special case:

**4.1.20. Lemma.** Let  $v$  be a vector in a Euclidean space  $V$  and  $U \subset V$  an arbitrary subspace. Denote by  $v_1 \in U, v_2 \in U^\perp$  the (uniquely determined) components of the vector  $v$ , i.e.  $v = v_1 + v_2$ . Then the angle  $\varphi$  between the subspace generated by  $v$  and the subspace  $U$  satisfies

$$\cos \varphi(\langle v \rangle, U) = \cos \varphi(\langle v \rangle, \langle v_1 \rangle) = \frac{\|v_1\|}{\|v\|}.$$

**PROOF.** By the Cauchy inequality,

$$\begin{aligned} \frac{|u \cdot v|}{\|u\| \|v\|} &= \frac{|u \cdot (v_1 + v_2)|}{\|u\| \|v\|} = \frac{|u \cdot v_1|}{\|u\| \|v\|} \\ &\leq \frac{\|u\| \|v_1\|}{\|u\| \|v\|} = \frac{\|v_1\|}{\|v\|} = \frac{\|v_1\|^2}{\|v\| \|v_1\|} = \frac{|v_1 \cdot v|}{\|v\| \|v_1\|}. \end{aligned}$$

has intersection with the given planes generated by the vectors  $(1, 0, -1)$  and  $(0, 1, 1)$ . The angle between these one-dimensional subspaces is  $60^\circ$ .  $\square$

**4.B.14.** A cube  $ABCD A' B' C' D'$  is given in standard notation. That is,  $ABCD$  and  $A' B' C' D'$  are faces and  $AA', BB'$  are edges. Compute the angle  $\varphi$  between  $AB'$  and  $AD'$ .

**Solution.** It can be assumed that the cube is of side 1 and placed in  $\mathbb{R}^3$  in such a way that the vertices  $A, B, C, D$  have coordinates respectively  $[0, 0, 0], [1, 0, 0], [1, 1, 0], [0, 1, 0]$  and the vertices  $A', B', C', D'$  have coordinates respectively  $[0, 0, 1], [1, 0, 1], [1, 1, 1], [0, 1, 1]$ . Thus  $AB' = B' - A = (1, 0, 1), AD' = D' - A = (0, 1, 1)$ . So

$$\cos(\varphi) = \frac{(1, 0, 1) \cdot (0, 1, 1)}{\|(1, 0, 1)\| \|(0, 1, 1)\|} = \frac{1}{2},$$

hence  $\varphi = 60^\circ$ .  $\square$

For further exercises on angles, see .

**4.B.15.** Prove that for every  $n \in \mathbb{N}$  and for all positive  $x_1, x_2, \dots, x_n \in \mathbb{R}$

$$n^2 \leq \left( \frac{1}{x_1} + \frac{1}{x_2} + \dots + \frac{1}{x_n} \right) \cdot (x_1 + x_2 + \dots + x_n).$$

For what arguments does equality hold?

**Solution.** It is sufficient to consider the Cauchy inequality

$$|u \cdot v| \leq \|u\| \|v\|$$

in Euclidean space  $\mathbb{R}^n$  for the vectors

$$u = \left( \frac{1}{\sqrt{x_1}}, \dots, \frac{1}{\sqrt{x_n}} \right), v = (\sqrt{x_1}, \dots, \sqrt{x_n}).$$

We get

$$(1) \quad n \leq \sqrt{\frac{1}{x_1} + \frac{1}{x_2} + \dots + \frac{1}{x_n}} \cdot \sqrt{x_1 + x_2 + \dots + x_n}.$$

We obtain the desired inequality squaring (1). The Cauchy inequality attains equality when vector  $u$  is a multiple of  $v$ , that is, when  $x_1 = x_2 = \dots = x_n$ .  $\square$

**4.B.16.** Vectors  $\underline{u} = (u_1, u_2, u_3)$  and  $\underline{v} = (v_1, v_2, v_3)$  are given. Find a third unit vector such that parallelepiped defined by these three vectors has the greatest possible volume.

**Solution.** Denote the desired vector by  $\underline{t} = (t_1, t_2, t_3)$ . By Proposition ?? the volume of the parallelepiped  $\mathcal{P}_3(0; \underline{u}, \underline{v}, \underline{t})$

for all vectors  $u \in U$ . This implies that

$$\cos \varphi(\langle v \rangle, \langle u \rangle) \leq \cos \varphi(\langle v \rangle, \langle v_1 \rangle) = \frac{\|v_1\|}{\|v\|}.$$

Thus the computed vector  $v_1$  represents the largest possible value of the cosine of angles between all choices of vectors in  $U$ . The cosine function is decreasing on the interval  $[0, \frac{\pi}{2}]$ . Hence the smallest possible angle is obtained in this way, and so the claim is proved.  $\square$

**4.1.21. Calculating angles.** The procedure in the previous lemma can be understood as follows. Choose the orthogonal projection of the one-dimensional subspace generated by  $v$  into the subspace  $U$ , and consider the ratio between  $v$  and its image. A similar procedure is used in the higher dimension. The problem is to recognize the directions whose projections give the desired (minimal) angle. This is clear in the previous example if we project the larger space  $U$  into the one-dimensional  $\langle v \rangle$  first, and then orthogonally back to  $U$ . The desired angle corresponds to the direction of the eigenvector of this map. The eigenvalue is the square of the cosine of the angle.

Let  $U_1, U_2$  be two arbitrary subspaces in a Euclidean vector space  $V$ ,  $U_1 \cap U_2 = \{0\}$ . Choose orthonormal bases  $\underline{e}$  and  $\underline{e}'$  of the whole space  $V$  such that  $U_1 = \langle e_1, \dots, e_k \rangle$ ,  $U_2 = \langle e'_1, \dots, e'_l \rangle$ .

Consider the orthogonal projection  $\varphi$  of the space  $V$  on  $U_2$ . Its restriction on  $U_1$  will be denoted by  $\varphi : U_1 \rightarrow U_2$  as before. Similarly, let  $\psi : U_2 \rightarrow U_1$  be the map which has arisen from the orthogonal projection on  $U_1$ . In the bases  $(e_1, \dots, e_k)$  and  $(e'_1, \dots, e'_l)$ , these maps have matrices  $A$  and  $B$ ,

$$\begin{pmatrix} e_1 \cdot e'_1 & \dots & e_k \cdot e'_1 \\ \vdots & & \vdots \\ e_1 \cdot e'_l & \dots & e_k \cdot e'_l \end{pmatrix}, \begin{pmatrix} e'_1 \cdot e_1 & \dots & e'_l \cdot e_1 \\ \vdots & & \vdots \\ e'_1 \cdot e_k & \dots & e'_l \cdot e_k \end{pmatrix},$$

respectively. Since  $e_i \cdot e'_j = e'_j \cdot e_i$  holds for all indices  $i, j$ ,  $B = A^T$ .

The composition of maps  $\psi \circ \varphi : U_1 \rightarrow U_1$  has therefore a symmetric positive semidefinite matrix  $A^T A$ , and  $\psi$  is adjoint to  $\varphi$ . Each such map has only nonnegative real eigenvalues. It has a diagonal matrix with these eigenvalues on the diagonal in a suitable orthonormal basis, see 3.4.7 a 3.4.9.

Now we can derive a general procedure for computing the angle  $\alpha = \varphi(U_1, U_2)$ .

**Theorem.** In the previous notation, let  $\lambda$  be the largest eigenvalue of the matrix  $A^T A$ . Then  $(\cos \alpha)^2 = \lambda$ .

**PROOF.** Let  $u \in U_1$  be the eigenvector of the map  $\psi \circ \varphi$  corresponding to the eigenvalue  $\lambda$ . Consider all eigenvalues  $\lambda_1, \dots, \lambda_k$  (including multiplicities), and let  $\underline{u} = (u_1, \dots, u_n)$  be the corresponding orthonormal basis of  $U_1$  containing the eigenvectors.  $\|u\| = 1$ , and assume that  $\lambda = \lambda_1, u = u_1$ .

We need to show that the angle between an arbitrary  $v \in U_1$  and  $U_2$  is at least as large as the angle between  $u$  and

is the absolute value of determinant

$$\begin{vmatrix} u_1 & v_1 & t_1 \\ u_2 & v_2 & t_2 \\ u_3 & v_3 & t_3 \end{vmatrix} = \begin{vmatrix} t_1 & t_2 & t_3 \\ u_1 & u_2 & u_3 \\ v_1 & v_2 & v_3 \end{vmatrix} = \underline{t} \cdot (\underline{u} \times \underline{v}) \leq \|\underline{t}\| \|\underline{u} \times \underline{v}\| \\ = \|\underline{u} \times \underline{v}\|.$$

The sign of the inequality follows from the Cauchy inequality. This becomes equality if and only if  $\underline{t} = c(\underline{u} \times \underline{v})$ ,  $c \in \mathbb{R}$ . The volume therefore could be at most equal to the area of paralleloid defined by vectors  $\underline{u}, \underline{v}$  (i.e. size of vector  $(\underline{u} \times \underline{v})$ ). Equality holds if and only if

$$t = \pm \frac{(\underline{u} \times \underline{v})}{\|(\underline{u} \times \underline{v})\|}.$$

□

**4.B.17.** Find the foot of the line passing through the point  $[0, 0, 7]$  and perpendicular to the plane

$$\rho : [0, 5, 3] + (1, 2, 1)t + (-2, 1, 1)s.$$

**4.B.18.** In Euclidean space  $\mathbb{R}^5$  determine the distance between the planes

$$\varrho_1 : [7, 2, 7, -1, 1] + t_1(1, 0, -1, 0, 0) + s_1(0, 1, 0, 0, -1), \\ \varrho_2 : [2, 4, 7, -4, 2] + t_2(1, 1, 1, 0, 1) + s_2(0, -2, 0, 0, 3),$$

where  $t_1, s_1, t_2, s_2 \in \mathbb{R}$ .

**Solution.** First compute the orthogonal complement to sum of vectors defining the planes. Form a matrix with rows as the direction vectors of the planes. Then transform this matrix into normal form.

$$\begin{pmatrix} 1 & 0 & -1 & 0 & 0 \\ 0 & 1 & 0 & 0 & -1 \\ 1 & 1 & 1 & 0 & 1 \\ 0 & -2 & 0 & 0 & 3 \end{pmatrix} \sim \dots \sim \begin{pmatrix} 1 & 0 & -1 & 0 & 0 \\ 0 & 1 & 0 & 0 & -1 \\ 0 & 0 & 1 & 0 & 1 \\ 0 & 0 & 0 & 0 & 1 \end{pmatrix}.$$

So the orthogonal complement is  $\langle(0, 0, 0, 1, 0)\rangle$ . The vector  $(0, 0, 0, 1, 0)$  lies within the orthogonal complement. Transform the matrix into normal form. This shows that the orthogonal complement is one-dimensional. The distance between planes is the length of the perpendicular projection of the vector  $A_1 - A_2$  into the subspace  $\langle(0, 0, 0, 1, 0)\rangle$  for arbitrary points  $A_1 \in \varrho_1, A_2 \in \varrho_2$ . Choose e.g.  $A_1 = [7, 2, 7, -1, 1], A_2 = [2, 4, 7, -4, 2]$ . The orthogonal projection  $A_1 - A_2 = (5, -2, 0, 3, -1)$  to  $\langle(0, 0, 0, 1, 0)\rangle$  is  $(0, 0, 0, 3, 0)$ . The length of  $(0, 0, 0, 3, 0)$  gives the desired distance 3. □

$U_2$ . Equivalently that the cosine of the corresponding angle cannot be greater. By the previous lemma, it is sufficient to discuss the angle between  $u$  and  $\varphi(u) \in U_2$ . Choose  $v \in U_1, v = a_1u_1 + \dots + a_ku_k, \sum_{i=1}^k a_i^2 = \|v\|^2 = 1$ . Then

$$\|\varphi(v)\|^2 = \varphi(v) \cdot \varphi(v) = (\psi \circ \varphi(v)) \cdot v \\ \leq \|\psi \circ \varphi(v)\| \|v\| = \|\psi \circ \varphi(v)\|.$$

Moreover, the previous lemma gives a formula for computing the angle  $\alpha$  between the vector  $v$  and the subspace  $U_2$

$$\cos \alpha = \frac{\|\varphi(v)\|}{\|v\|} = \|\varphi(v)\|.$$

Since  $\lambda_1$  is the largest eigenvalue, and the sum of squares of coordinates  $a_i^2$  is one,

$$(\cos \alpha)^2 = \|\varphi(v)\|^2 \leq \|\psi \circ \varphi(v)\| = \sqrt{\sum_{i=1}^k (\lambda_i a_i)^2} = \\ = \sqrt{\lambda_1^2 + \sum_{i=1}^k a_i^2 (\lambda_i^2 - \lambda_1^2)} \leq \sqrt{\lambda_1^2}.$$

If  $v = u$ , we have  $\|\varphi(v)\|^2 = \lambda_1^2 \|v\|^2 = \lambda_1^2$ , and thus the angle has the minimal value for this vector. □

**4.1.22. Calculating volume.** An indication of how to calculate volumes in plane geometry is given at the end of the fifth part of the first chapter (see 1.5.11). There the notion of orientation played a fundamental role. We can imagine orientation as the decision whether to look at the plane  $\mathbb{R}^2$  from above or from below. The distinction lies in the order of selecting standard basis vectors  $e_1$  and  $e_2$  on the unit circle. We proceed in the same way in general:

#### ORIENTATION OF A VECTOR SPACE

Two bases  $\underline{u}$  and  $\underline{v}$  of a real vector space  $V$  are said to determine the same *orientation* if the transformation matrix between them has a positive determinant. By the orientation of a vector space  $V$  is meant the equivalence class of bases  $\underline{u}$  with respect to the equivalence defined above, by the sign of the determinant. Equivalent bases in this sense are called compatible with the chosen orientation.

It follows that there exist exactly two orientations on every vector space. From each compatible basis there is a non compatible one by a transformation matrix with a negative determinant.

A vector space with a chosen orientation is called the *oriented vector space*.

The *oriented Euclidean (point) space* is a Euclidean point space whose difference space is oriented. In the sequel we consider the standard Euclidean space  $\mathcal{E}_n$  together with the orientation given by the standard basis of  $\mathbb{R}^n$ .

Let  $u_1, \dots, u_k$  be arbitrary vectors in the difference space  $\mathbb{R}^n, A \in \mathcal{E}_n$  a point. As an example of a convex set,

**4.B.19.** In Euclidean space  $\mathbb{R}^5$  determine the distance of planes

$$\sigma_1 : [0, 1, 2, 0, 0] + p_1 (2, 1, 0, 0, 1) + q_1 (-2, 0, 1, 1, 0),$$

$$\sigma_2 : [3, -1, 7, 7, 3] + p_2 (2, 2, 4, 0, 3) + q_2 (2, 0, 0, -2, -1),$$

where  $p_1, q_1, p_2, q_2 \in \mathbb{R}$ .

**Solution.** The sum of the directions  $\sigma_1, \sigma_2$  is generated by the direction vectors. Denote them by

$$u_1 = (2, 1, 0, 0, 1), \quad u_2 = (-2, 0, 1, 1, 0),$$

$$v_1 = (2, 2, 4, 0, 3), \quad v_2 = (2, 0, 0, -2, -1).$$

Find points  $X_1 \in \sigma_1, X_2 \in \sigma_2$ , that equal the distance between  $\sigma_1$  and  $\sigma_2$ . This requires

$$X_1 - X_2 = [0, 1, 2, 0, 0] - [3, -1, 7, 7, 3]$$

$$+ p_1 u_1 + q_1 u_2 - p_2 v_1 - q_2 v_2$$

and

$$\langle X_1 - X_2, u_1 \rangle = 0, \quad \langle X_1 - X_2, u_2 \rangle = 0,$$

$$\langle X_1 - X_2, v_1 \rangle = 0, \quad \langle X_1 - X_2, v_2 \rangle = 0.$$

Hence

$$\langle (-3, 2, -5, -7, -3), u_1 \rangle + p_1 \langle u_1, u_1 \rangle + q_1 \langle u_2, u_1 \rangle$$

$$- p_2 \langle v_1, u_1 \rangle - q_2 \langle v_2, u_1 \rangle = 0,$$

$$\langle (-3, 2, -5, -7, -3), u_2 \rangle + p_1 \langle u_1, u_2 \rangle + q_1 \langle u_2, u_2 \rangle$$

$$- p_2 \langle v_1, u_2 \rangle - q_2 \langle v_2, u_2 \rangle = 0,$$

$$\langle (-3, 2, -5, -7, -3), v_1 \rangle + p_1 \langle u_1, v_1 \rangle + q_1 \langle u_2, v_1 \rangle$$

$$- p_2 \langle v_1, v_1 \rangle - q_2 \langle v_2, v_1 \rangle = 0,$$

$$\langle (-3, 2, -5, -7, -3), v_2 \rangle + p_1 \langle u_1, v_2 \rangle + q_1 \langle u_2, v_2 \rangle$$

$$- p_2 \langle v_1, v_2 \rangle - q_2 \langle v_2, v_2 \rangle = 0.$$

By computing the dot products, we obtain the linear equation system

$$\begin{array}{cccccc} 6p_1 & - & 4q_1 & - & 9p_2 & - & 3q_2 & = & 7, \\ -4p_1 & + & 6q_1 & & & + & 6q_2 & = & 6, \\ 9p_1 & & & - & 33p_2 & - & q_2 & = & 31, \\ 3p_1 & - & 6q_1 & - & p_2 & - & 9q_2 & = & -11. \end{array}$$

Solve it by forming a matrix and performing elementary row operations.

$$\left( \begin{array}{cccc|c} 6 & -4 & -9 & -3 & 7 \\ -4 & 6 & 0 & 6 & 6 \\ 9 & 0 & -33 & -1 & 31 \\ 3 & -6 & -1 & -9 & -11 \end{array} \right) \sim \dots$$

the parallelepiped  $\mathcal{P}_k(A; u_1, \dots, u_k) \subset \mathcal{E}_n$  is given by

$$\mathcal{P}_k(A; u_1, \dots, u_k) = \{A + c_1 u_1 + \dots + c_k u_k; 0 \leq c_i \leq 1\}.$$

If the vectors  $u_1, \dots, u_k$  are linearly dependent, we have a  $k$ -dimensional parallelepiped  $\mathcal{P}_k(A; u_1, \dots, u_k) \subset \mathcal{E}_n$ . For given vectors  $u_1, \dots, u_k$  there are also parallelepipeds of lower dimension

$$\mathcal{P}_1(A; u_1), \dots, \mathcal{P}_k(A; u_1, \dots, u_k)$$

in Euclidean subspaces  $A + \langle u_1 \rangle, \dots, A + \langle u_1, \dots, u_k \rangle$  at our disposal.

If  $u_1, \dots, u_k$  are linearly independent, the volume is given by

$$\text{Vol } \mathcal{P}_k = 0.$$

Otherwise consider it as in the case of the Gram–Schmidt orthogonalization

$$\langle u_1, \dots, u_k \rangle =$$

$$= \langle u_1, \dots, u_{k-1} \rangle \oplus \langle u_1, \dots, u_{k-1} \rangle^\perp \cap \langle u_1, \dots, u_k \rangle.$$

In this decomposition,  $u_k$  is uniquely expressed as

$$u_k = u'_k + e_k$$

where  $e_k \perp \langle u_1, \dots, u_{k-1} \rangle$ .

The absolute value of the volume of a parallelepiped is defined inductively such that it is the product of the volume of the “base” and the “altitude”:  $|\text{Vol } \mathcal{P}_1(A; u_1)| = \|u_1\|$ ,

$$|\text{Vol } \mathcal{P}_k(A; u_1, \dots, u_k)| =$$

$$= \|e_k\| |\text{Vol } \mathcal{P}_{k-1}(A; u_1, \dots, u_{k-1})|.$$

If  $u_1, \dots, u_n$  is a basis compatible with the orientation of  $V$ , the (oriented) volume of the parallelepiped is defined by

$$\text{Vol } \mathcal{P}_n(A; u_1, \dots, u_n) = |\text{Vol } \mathcal{P}_n(A; u_1, \dots, u_n)|.$$

In the case of a non compatible basis we set

$$\text{Vol } \mathcal{P}_n(A; u_1, \dots, u_n) = -|\text{Vol } \mathcal{P}_n(A; u_1, \dots, u_n)|.$$

**Theorem.** Let  $\mathcal{Q} \subset \mathcal{E}_n$  be a Euclidean subspace, and let  $(e_1, \dots, e_k)$  be its orthonormal basis. For arbitrary vectors  $u_1, \dots, u_k \in Z(\mathcal{Q})$  and  $A \in \mathcal{Q}$  the following holds

$$(1) \text{Vol } \mathcal{P}_k(A; u_1, \dots, u_k) = \begin{vmatrix} u_1 \cdot e_1 & \dots & u_k \cdot e_1 \\ \vdots & & \vdots \\ u_1 \cdot e_k & \dots & u_k \cdot e_k \end{vmatrix}$$

$$(2) (\text{Vol } \mathcal{P}_k(A; u_1, \dots, u_k))^2 = \begin{vmatrix} u_1 \cdot u_1 & \dots & u_k \cdot u_1 \\ \vdots & & \vdots \\ u_1 \cdot u_k & \dots & u_k \cdot u_k \end{vmatrix}$$

**PROOF.** The matrix

$$A = \begin{pmatrix} u_1 \cdot e_1 & \dots & u_k \cdot e_1 \\ \vdots & & \vdots \\ u_1 \cdot e_k & \dots & u_k \cdot e_k \end{pmatrix}$$

$$\sim \left( \begin{array}{cccc|c} 1 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & -1 \\ 0 & 0 & 1 & 0 & -1 \\ 0 & 0 & 0 & 1 & 2 \end{array} \right).$$

The solution is  $(p_1, q_1, p_2, q_2) = (0, -1, -1, 2)$ . Consequently

$$\begin{aligned} X_1 - X_2 &= (-3, 2, -5, -7, -3) - u_2 + v_1 - 2v_2 \\ &= (-3, 4, -2, -4, 2). \end{aligned}$$

The length of the vector  $(-3, 4, -2, -4, 2)$  equals the distance between the planes  $\sigma_1, \sigma_2$  and is then

$$7 = \sqrt{(-3)^2 + 4^2 + (-2)^2 + (-4)^2 + 2^2}.$$

We solved this problem by a method different to that of the previous problem. We can use both methods in both cases. Try the former method for the case of  $\sigma_1, \sigma_2$ . Find the orthogonal complement of vector subspace generated by  $(2, 1, 0, 0, 1), (-2, 0, 1, 1, 0), (2, 2, 4, 0, 3), (2, 0, 0, -2, -1)$ . We get

$$\begin{aligned} &\left( \begin{array}{ccccc} 2 & 1 & 0 & 0 & 1 \\ -2 & 0 & 1 & 1 & 0 \\ 2 & 2 & 4 & 0 & 3 \\ 2 & 0 & 0 & -2 & -1 \end{array} \right) \sim \dots \\ &\sim \left( \begin{array}{ccccc} 1 & 0 & 0 & 0 & 3/2 \\ 0 & 1 & 0 & 0 & -2 \\ 0 & 0 & 1 & 0 & 1 \\ 0 & 0 & 0 & 1 & 2 \end{array} \right), \end{aligned}$$

The orthogonal complement is  $\langle(-3/2, 2, -1, -2, 1)\rangle$ , or rather  $\langle(3, -4, 2, 4, -2)\rangle$ . Note that the distance between  $\sigma_1$  and  $\sigma_2$  equals the size of the orthogonal projection of the vector (the difference of an arbitrary point in  $\sigma_1$  and an arbitrary point in  $\sigma_2$ )

$$u = (3, -2, 5, 7, 3) = [3, -1, 7, 7, 3] - [0, 1, 2, 0, 0]$$

to this orthogonal complement. Denote the orthogonal projection of  $u$  as  $p_u$  and choose  $v = (3, -4, 2, 4, -2)$ . Obviously  $p_u = a \cdot v$  for some  $a \in \mathbb{R}$  and

$$\langle u - p_u, v \rangle = 0, \quad \text{tj.} \quad \langle u, v \rangle - a \langle v, v \rangle = 0.$$

Computing gives  $49 - a \cdot 49 = 0$ . Therefore  $p_u = 1 \cdot v = v$  and the distance between the planes  $\sigma_1$  and  $\sigma_2$  equals

$$\|p_u\| = \sqrt{3^2 + (-4)^2 + 2^2 + 4^2 + (-2)^2} = 7.$$

The method of computing the distance using the orthogonal complement of sum of vector spaces proves to be a "faster way to the solution". It is the same for the planes  $\varrho_1$  and  $\varrho_2$ . The second method however reveals points where the distance can be measured (a pair of points in which the planes are the

has the coordinates of the vectors  $u_1, \dots, u_k$  in the chosen basis in columns, and

$$\begin{aligned} |A|^2 &= |A||A| = |A^T||A| = |A^T A| \\ &= \begin{vmatrix} u_1 \cdot u_1 & \dots & u_k \cdot u_1 \\ \vdots & & \vdots \\ u_1 \cdot u_k & \dots & u_k \cdot u_k \end{vmatrix}. \end{aligned}$$

Hence if (1) holds, then also (2) holds.

Directly from the definition, the unoriented volume equals the product

$$|\text{Vol } \mathcal{P}_k(A; u_1, \dots, u_k)| = \|v_1\| \|v_2\| \dots \|v_k\|,$$

where  $v_1 = u_1, v_2 = u_2 + a_1^2 v_1, \dots, v_k = u_k + a_1^k v_1 + \dots + a_{k-1}^k v_{k-1}$  is the result of the Gram-Schmidt orthogonalization. Thus

$$\begin{aligned} (\text{Vol } \mathcal{P}_k(A; u_1, \dots, u_k))^2 &= \begin{vmatrix} v_1 \cdot v_1 & 0 & \dots & 0 \\ \vdots & \ddots & & \\ 0 & 0 & \dots & v_k \cdot v_k \end{vmatrix} \\ &= \begin{vmatrix} v_1 \cdot v_1 & \dots & v_k \cdot v_1 \\ \vdots & & \vdots \\ v_1 \cdot v_k & \dots & v_k \cdot v_k \end{vmatrix}. \end{aligned}$$

Denote by  $B$  the matrix whose columns are formed by the coordinates of vectors  $v_1, \dots, v_k$  in the orthonormal basis  $\underline{e}$ . Since  $v_1, \dots, v_k$  have arisen from  $u_1, \dots, u_k$  as images under a linear transformation with an upper-triangular matrix  $C$  with ones on the diagonal,  $B = CA$  and  $|B| = |C||A| = |A|$ . But then  $|A|^2 = |B|^2 = |A||A|$ , and thus  $\text{Vol } \mathcal{P}_k(A; u_1, \dots, u_k) = \pm|A|$ . The resulting volume is zero if the vectors  $u_1, \dots, u_k$  are linearly dependent. Provided they are independent, the sign of the determinant is positive if and only if the basis  $u_1, \dots, u_k$  defines the same orientation as the basis  $\underline{e}$ .  $\square$

Consider a parallelepiped in a  $k$ -dimensional space, which is spanned by  $k$  vectors. Write down the coordinates (in an orthonormal basis) into the columns of a matrix. Then the volume of the parallelepiped is the determinant of the matrix.

The formula (2) above is called the *Gram determinant*. It is independent of the choice of basis and, therefore it is useful when  $k$  is lower than the dimension of the whole space.

We formulate the following important geometric consequence:

**4.1.23. Corollary.** *For each linear map  $\varphi : V \rightarrow V$  on a Euclidean space  $V$ ,  $\det \varphi$  equals the (oriented) volume of the image of the parallelepiped determined by vectors of an orthonormal basis. More generally, the image of the parallelepiped  $\mathcal{P}$ , determined by arbitrary  $\dim V$  vectors, has a volume equal to  $\det \varphi$ -multiple of the former volume.*

closest). Find such points in the case of planes  $\varrho_1, \varrho_2$ . Denote

$$\begin{aligned} u_1 &= (1, 0, -1, 0, 0), & u_2 &= (0, 1, 0, 0, -1), \\ v_1 &= (1, 1, 1, 0, 1), & v_2 &= (0, -2, 0, 0, 3). \end{aligned}$$

Points  $X_1 \in \varrho_1, X_2 \in \varrho_2$ , which are the "closest" (as commented above), are

$$\begin{aligned} X_1 &= [7, 2, 7, -1, 1] + t_1 u_1 + s_1 u_2, \\ X_2 &= [2, 4, 7, -4, 2] + t_2 v_1 + s_2 v_2, \end{aligned}$$

so

$$\begin{aligned} X_1 - X_2 &= [7, 2, 7, -1, 1] - [2, 4, 7, -4, 2] \\ &\quad + t_1 u_1 + s_1 u_2 - t_2 v_1 - s_2 v_2 \\ &= (5, -2, 0, 3, -1) \\ &\quad + t_1 u_1 + s_1 u_2 - t_2 v_1 - s_2 v_2. \end{aligned}$$

The dot products

$$\begin{aligned} \langle X_1 - X_2, u_1 \rangle &= 0, & \langle X_1 - X_2, u_2 \rangle &= 0, \\ \langle X_1 - X_2, v_1 \rangle &= 0, & \langle X_1 - X_2, v_2 \rangle &= 0 \end{aligned}$$

then lead to the linear equation system

$$\begin{array}{rcccc} 2t_1 & & & & = & -5, \\ & 2s_1 & & + & 5s_2 & = & 1, \\ & & -4t_2 & - & s_2 & = & -2, \\ -5s_1 & - & t_2 & - & 13s_2 & = & -1 \end{array}$$

with the unique solution  $t_1 = -5/2, s_1 = 41/2, t_2 = 5/2, s_2 = -8$ . We obtained

$$\begin{aligned} X_1 &= [7, 2, 7, -1, 1] - \frac{5}{2}u_1 + \frac{41}{2}u_2 \\ &= \left[ \frac{9}{2}, \frac{45}{2}, \frac{19}{2}, -1, -\frac{39}{2} \right], \\ X_2 &= [2, 4, 7, -4, 2] + \frac{5}{2}v_1 - 8v_2 \\ &= \left[ \frac{9}{2}, \frac{45}{2}, \frac{19}{2}, -4, -\frac{39}{2} \right]. \end{aligned}$$

The distance between the points  $X_1, X_2$  equals the distance between the planes  $\varrho_1, \varrho_2$  both of which are given by  $\|X_1 - X_2\| = \|(0, 0, 0, 3, 0)\| = 3$ .  $\square$

**4.B.20.** Find the intersection of the plane passing through the point  $A = [1, 2, 3, 4] \in \mathbb{R}^4$  and orthogonal to the plane

$$\varrho : [1, 0, 1, 0] + (1, 2, -1, -2)s + (1, 0, 0, 1)t, \quad s, t \in \mathbb{R}.$$

**Solution.** Find the plane orthogonal to  $\varrho$ . Its direction is orthogonal to the direction of  $\varrho$ , for vectors  $(a, b, c, d)$  within its direction we get linear equation system

$$\begin{aligned} (a, b, c, d) \cdot (1, 2, -1, -2) &= 0 &\equiv & a + 2b - c - 2d = 0 \\ (a, b, c, d) \cdot (1, 0, 0, 1) &= 0 &\equiv & a + d = 0. \end{aligned}$$

**4.1.24. Outer product and cross product.** The previous considerations are closely related to the tensor product of vectors. We do not go further in this technically more complicated topic now. But we do mention the outer product of  $n = \dim V$  vectors  $u_1, \dots, u_n \in V$ .

Let  $(u_{1j}, \dots, u_{nj})^T$  be coordinate expressions of vectors  $u_j$  in a chosen orthonormal basis  $V$ . Let  $M$  be a matrix with elements  $(u_{ij})$ . Then the determinant  $|M|$  does not depend on the choice of the basis with the same orientation. Its value is called the *outer product* of the vectors  $u_1, \dots, u_n$ , and is denoted by  $[u_1, \dots, u_n]$ . Hence the outer product is the oriented volume of the corresponding parallelepiped, see 4.1.22.

Although the outer product looks like a scalar quantity, the story gets more complicated once we allow for general basis of  $V$ . Then the determinant of the matrix  $M$  built of the coordinates of  $u_i$  changes by the determinants of the transition matrices. Such objects are called *densities* and we shall come back to them in chapter 9.

Several useful properties of the outer product follow directly from the definition

- (1) The map  $(u_1, \dots, u_n) \mapsto [u_1, \dots, u_n]$  is an antisymmetric  $n$ -linear map. It is linear in all arguments, and the interchange of any two arguments causes a change of sign.
- (2) The outer product is zero if and only if the vectors  $u_1, \dots, u_n$  are linearly dependent.
- (3) The vectors  $u_1, \dots, u_n$  form a positive basis if and only if the outer product is positive.

Consider a Euclidean vector space  $V$  of dimension  $n \geq 2$  and vectors  $u_1, \dots, u_{n-1} \in V$ . If these  $n-1$  vectors are substituted into the first  $n-1$  arguments of the  $n$ -linear map defined by the volume determinant as above, then there is one argument left over. This defines a linear form on  $V$ . Since the scalar product is available, each linear form corresponds to exactly one vector. This vector  $v \in V$  is called the *cross product* of the vectors  $u_1, \dots, u_{n-1}$ . For each vector  $w \in V$

$$\langle w, v \rangle = [u_1, \dots, u_{n-1}, w].$$

We denote the cross product by  $v = u_1 \times \dots \times u_{n-1}$ .

If the coordinates of the vectors in an orthonormal basis are  $v = (y_1, \dots, y_n)^T, w = (x_1, \dots, x_n)^T$  and  $u_j = (u_{1j}, \dots, u_{nj})^T$ , then the definition can be expressed as

$$y_1 x_1 + \dots + y_n x_n = \begin{vmatrix} u_{11} & \dots & u_{1(n-1)} & x_1 \\ \vdots & & \vdots & \vdots \\ u_{n1} & \dots & u_{n(n-1)} & x_n \end{vmatrix}.$$

Hence the vector  $v$  is determined uniquely. Its coordinates are calculated by the formal expansion of this determinant along the last column. The following properties of the cross product are direct consequences of the definition:

**Theorem.** For the cross product  $v = u_1 \times \dots \times u_{n-1}$

- (1)  $v \in \langle u_1, \dots, u_{n-1} \rangle^\perp$
- (2)  $v$  is nonzero if and only if the vectors  $u_1, \dots, u_{n-1}$  are linearly independent,

The solution is the two-dimensional vector space  $\langle(0, 1, 2, 0), (-1, 0, -3, 1)\rangle$ . The plane  $\tau$  orthogonal to  $\varrho$  passing through  $A$  has parametric equation

$$\tau : [1, 2, 3, 4] + (0, 1, 2, 0)u + (-1, 0, -3, 1)v, \quad u, v \in \mathbb{R}.$$

We can obtain the intersection of the planes from both parametric equations. It is given by the linear equation system

$$\begin{aligned} 1 + s + t &= 1 - v \\ 2s &= 2 + u \\ 1 - s &= 3 + 2u - 3v \\ -2s + t &= 4 + v, \end{aligned}$$

which has the unique solution (it must be so as matrix columns are linearly independent)  $s = -8/19, t = 34/19, u = -54/19, v = -26/19$ . Substitute the parameter values  $s$  and  $t$  into the parametric form of the plane  $\varrho$ , to obtain the intersection  $[45/19, -16/19, 11/19, 18/19]$ . (Needless to say, the same solution is obtained by substituting the values into  $\tau$ ).  $\square$

**4.B.21.** Find a line passing through point  $[1, 2] \in \mathbb{R}^2$  so that the angle between this line and the line

$$p : [0, 1] + t(1, 1)$$

is  $30^\circ$ .

**Solution.** The angle between two lines is the angle between their direction vectors. It is sufficient to find the direction vector  $\underline{v}$  of the line. One way to do so is to rotate the direction vector of  $p$  by  $30^\circ$ . The rotation matrix for the angle  $30^\circ$  is

$$\begin{pmatrix} \cos 30^\circ & -\sin 30^\circ \\ \sin 30^\circ & \cos 30^\circ \end{pmatrix} = \begin{pmatrix} \frac{\sqrt{3}}{2} & -\frac{1}{2} \\ \frac{1}{2} & \frac{\sqrt{3}}{2} \end{pmatrix}.$$

The desired vector  $\underline{v}$  is therefore

$$\underline{v} = \begin{pmatrix} \frac{\sqrt{3}}{2} & -\frac{1}{2} \\ \frac{1}{2} & \frac{\sqrt{3}}{2} \end{pmatrix} \begin{pmatrix} 1 \\ 1 \end{pmatrix} = \begin{pmatrix} \frac{\sqrt{3}}{2} - \frac{1}{2} \\ \frac{\sqrt{3}}{2} + \frac{1}{2} \end{pmatrix}.$$

We could perform the backward rotation as well. The line (one of two possible) has parametric equation

$$[1, 2] + \left( \frac{\sqrt{3}}{2} - \frac{1}{2}, \frac{\sqrt{3}}{2} + \frac{1}{2} \right) t.$$

$\square$

**4.B.22.** An octahedron has eight faces consisting of equilateral triangles. Determine  $\cos \alpha$ , where  $\alpha$  is the angle between two adjacent faces of a regular octahedron.

**Solution.** An octahedron is symmetric, therefore it does not matter which two faces are selected. By suitable

(3) the length  $\|v\|$  of the cross product equals the absolute value of the volume of parallelepiped  $\mathcal{P}(0; u_1, \dots, u_{n-1})$ ,

(4)  $(u_1, \dots, u_{n-1}, v)$  is a compatible basis of the oriented Euclidean space  $V$ .

**PROOF.** The first claim follows directly from the defining formula for  $v$ . Substituting an arbitrary vector  $u_j$  for  $w$  gives the scalar product  $v \cdot u_j$  on the left and the determinant with two equal columns on the right.

The rank of the matrix with  $n - 1$  columns  $u_j$  is given by the maximal size of a non-zero minor. The minors which define coordinates of the cross product are of degree  $n - 1$  and thus claim (2) is proved.

If the vectors  $u_1, \dots, u_{n-1}$  are linearly dependent, then (3) also holds. Suppose the vectors are linearly independent. Let  $v$  be their cross product, and choose an orthonormal basis  $(e_1, \dots, e_{n-1})$  of the space  $\langle u_1, \dots, u_{n-1} \rangle$ . It follows from what is proved that there exists a multiple  $(1/\alpha)v, 0 \neq \alpha \in \mathbb{R}$ , such that  $(e_1, \dots, e_k, (1/\alpha)v)$  is an orthonormal basis of  $V$ . The coordinates of the vectors in this basis are

$$u_j = (u_{1j}, \dots, u_{(n-1)j}, 0)^T, \quad v = (0, \dots, 0, \alpha)^T.$$

So the outer product  $[u_1, \dots, u_{n-1}, v]$  equals (see the definition of cross product)

$$\begin{aligned} [u_1, \dots, u_{n-1}, v] &= \begin{vmatrix} u_{11} & \dots & u_{1(n-1)} & 0 \\ \vdots & & \vdots & \vdots \\ u_{(n-1)1} & \dots & u_{(n-1)(n-1)} & 0 \\ 0 & \dots & 0 & \alpha \end{vmatrix} \\ &= \langle v, v \rangle = \alpha^2. \end{aligned}$$

By expanding the determinant along the last column,

$$\alpha^2 = \alpha \text{Vol } \mathcal{P}(0; u_1, \dots, u_{n-1}),$$

which proves the remaining two claims.  $\square$

In technical applications in  $\mathbb{R}^3$ , the cross product is often used. It assigns a vector to any pair of vectors.

**4.1.25. Affine and Euclidean properties.** Now we can consider which properties are related to the affine structure of the space and which properties we really need in the difference space.

All Euclidean transformations, i.e. bijective affine maps which preserve the distance between points, preserve also all objects we have studied (possibly up to the change of orientation). Moreover they preserve un-oriented angles, un-oriented volumes, angle between subspaces etc. If we want them to preserve also oriented angles, cross products, volumes, then we must also assume that the transformations preserve the orientation.

We ask: Which concepts are preserved under affine transformations?

Recall first that an affine transformation on an  $n$ -dimensional space  $\mathcal{A}$  is uniquely defined by mapping  $n + 1$  points in general position, that is, by mapping

scaling, the octahedron has edge length 1 and is placed in the standard Cartesian coordinate system  $\mathbb{R}^3$  so that its centroid is at  $[0, 0, 0]$ . Its vertices then are located at the points  $A = [\frac{\sqrt{2}}{2}, 0, 0]$ ,  $B = [0, \frac{\sqrt{2}}{2}, 0]$ ,  $C = [-\frac{\sqrt{2}}{2}, 0, 0]$ ,  $D = [0, -\frac{\sqrt{2}}{2}, 0]$ ,  $E = [0, 0, -\frac{\sqrt{2}}{2}]$  and  $F = [0, 0, \frac{\sqrt{2}}{2}]$ .

We compute the angle between the faces  $CDF$  and  $BCF$ . We need to find vectors orthogonal to their intersection and lying within respective faces, which means orthogonal to  $CF$ . They are altitudes from  $D$  and  $F$  to the edge  $CF$  in the triangles  $CDF$  and  $BCF$  respectively. The altitudes in an equilateral triangle are the same segments as the medians, so they are  $SD$  and  $SB$ , where  $S$  is midpoint of  $CF$ . Because the coordinates of points  $C$  and  $F$  are known,  $S$  has coordinates  $[-\frac{\sqrt{2}}{4}, 0, \frac{\sqrt{2}}{4}]$  and the vectors are  $SD = (\frac{\sqrt{2}}{4}, -\frac{\sqrt{2}}{2}, -\frac{\sqrt{2}}{4})$  and  $SB = (\frac{\sqrt{2}}{4}, \frac{\sqrt{2}}{2}, -\frac{\sqrt{2}}{4})$ . Together

$$\cos \alpha = \frac{(\frac{\sqrt{2}}{4}, -\frac{\sqrt{2}}{2}, -\frac{\sqrt{2}}{4}) \cdot (\frac{\sqrt{2}}{4}, \frac{\sqrt{2}}{2}, -\frac{\sqrt{2}}{4})}{\|(\frac{\sqrt{2}}{4}, -\frac{\sqrt{2}}{2}, -\frac{\sqrt{2}}{4})\| \|(\frac{\sqrt{2}}{4}, \frac{\sqrt{2}}{2}, -\frac{\sqrt{2}}{4})\|} = -\frac{1}{3}.$$

Therefore  $\alpha \doteq 132^\circ$ . □

**4.B.23.** In Euclidean space  $\mathbb{R}^5$  determine the angle  $\varphi$  between subspaces  $U, V$ , where

- (a)  $U : [3, 5, 1, 7, 2] + t(1, 0, 2, -2, 1), t \in \mathbb{R}$ ,  
 $V : [0, 1, 0, 0, 0] + s(2, 0, -2, 1, -1), s \in \mathbb{R}$ ;
- (b)  $U : [4, 1, 1, 0, 1] + t(2, 0, 0, 2, 1), t \in \mathbb{R}$ ,  
 $V : x_1 + x_2 + x_3 + x_5 = 7$ ;
- (c)  $U : 2x_1 - x_2 + 2x_3 + x_5 = 3$ ,  
 $V : x_1 + 2x_2 + 2x_3 + x_5 = -1$ ;
- (d)  $U : [0, 1, 1, 0, 0] + t(0, 0, 0, 1, -1), t \in \mathbb{R}$ ,  
 $V : [1, 0, 1, 1, 1] + r(1, -1, 2, 1, 0) + s(0, 1, 3, 2, 0)$   
 $+ p(1, 0, 0, 1, 0) + q(1, 3, 1, 0, 0),$   
 $r, s, p, q \in \mathbb{R}$ ;
- (e)  $U : [0, 2, 5, 0, 0] + t(2, 1, 3, 5, 3) + s(0, 3, 1, 4, -2)$   
 $+ r(1, 2, 4, 0, 3), t, s, r \in \mathbb{R}$ ,  
 $V : [0, 0, 0, 0, 0] + p(-1, 1, 1, -5, 0)$   
 $+ q(1, 5, 1, 13, -4), p, q \in \mathbb{R}$ ;
- (f)  $U : [1, 1, 1, 1, 1] + t(1, 0, 1, 1, 1)$   
 $+ s(1, 0, 0, 1, 1), t, s \in \mathbb{R}$ ,  
 $V : [1, 1, 1, 1, 1] + p(1, 1, 1, 1, 1) + q(1, 1, 0, 1, 1)$   
 $+ r(1, 1, 0, 1, 0), p, q, r \in \mathbb{R}$ .

**Solution.** Recall that the angle between affine subspaces is the same as the angle between vector spaces associated to

a one  $n$ -dimensional simplex. In the plane, this means choosing the image of any nondegenerate triangle. Preserved properties are properties related to subspaces and ratios. In particular, incidence properties of the type “a line passing through a point” or “a plane contains a line” etc. are preserved. Moreover, the collinearity of vectors is preserved. For every two collinear vectors, the ratio of their lengths is preserved independently of the scalar product defining the length. Similarly, the ratio of the volumes of two  $n$ -dimensional parallelepipeds is preserved under the transformations, since the determinant of the corresponding matrix changes by the same multiple.

These affine properties can be used in the plane to prove geometric statements. For instance, to prove the fact that the medians of a triangle intersect in a single point, and in one third of their lengths, it is sufficient to verify this only in the case of an isosceles right-angled triangle or only in the case of an equilateral triangle. Then this property holds for all triangles. Think about this argument!

## 2. Geometry of quadratic forms

After straight lines, the simplest objects in the analytic geometry of plane are the conic sections. These are given by quadratic equations in Cartesian coordinates. A conic is distinguished as a circle, ellipse, parabola or hyperbola, by examining the coefficients. There are two degenerate cases, namely a pair of lines or a point. We cannot distinguish a circle from an ellipse in affine geometry, therefore we begin with Euclidean geometry.

**4.2.1. Quadrics in  $\mathcal{E}_n$ .** In analogy with the equations of conic sections in plane, we start with objects in Euclidean point spaces. These are defined in a given orthonormal basis by quadratic equations, and are known as *quadrics*.

Choose a fixed Cartesian coordinate system in  $\mathcal{E}_n$ . This is a point and an orthonormal basis of the difference space. Consider a general quadratic equation for the coordinates  $(x_1, \dots, x_n)^T$  of a point  $A \in \mathcal{E}_n$

$$(1) \quad \sum_{i,j=1}^n a_{ij}x_i x_j + \sum_{i=1}^n a_i x_i + a = 0,$$

where it may be assumed by symmetry that  $a_{ij} = a_{ji}$  without loss of generality. This equation can be written as

$$f(u) + g(u) + a = 0$$

for a quadratic form  $f$  (i.e. the restriction of a symmetric bilinear form  $F$  to pairs of equal arguments), a linear form  $g$ , and a scalar  $a \in \mathbb{R}$ . We assume that at least one coefficient  $a_{ij}$  is nonzero. Otherwise the equation is linear and describes a hyperplane.

Notice that the equation (1) keeps the same shape under every Euclidean (or affine) coordinate transformation, i.e., it splits again into quadratic, linear and constant parts.

them. Therefore the translation caused by the point addition can be omitted.

Case (a). Since  $U$  and  $V$  are one-dimensional spaces, the angle  $\varphi \in [0, \pi/2]$  is given by formula

$$\cos \varphi = \frac{|(1,0,2,-2,1) \cdot (2,0,-2,1,-1)|}{\|(1,0,2,-2,1)\| \cdot \|(2,0,-2,1,-1)\|} = \frac{5}{\sqrt{10} \cdot \sqrt{10}}.$$

Therefore  $\cos \varphi = 1/2$  and  $\varphi = \pi/3$ .

Case (b). The subspace  $U$  has direction vector  $(2, 0, 0, 2, 1)$  and the subspace  $V$  has normal vector  $(1, 1, 1, 0, 1)$ . The angle between them  $\psi = \pi/3$  is derived from the formula

$$\cos \psi = \frac{(2,0,0,2,1) \cdot (1,1,1,0,1)}{\|(2,0,0,2,1)\| \cdot \|(1,1,1,0,1)\|} = \frac{3}{3 \cdot 2}.$$

Notice that  $\varphi = \pi/2 - \psi = \pi/6$ , because  $\varphi$  is complement to  $\psi$ .

Case (c). The hyperplanes  $U$  and  $V$  are defined by normal vectors  $u = (2, -1, 2, 0, 1)$  and  $v = (1, 2, 2, 0, 1)$ . The angle  $\varphi$  equals to angle between the direction vectors  $u$  and  $v$ . Therefore (see (a))

$$\cos \varphi = \frac{|(2,-1,2,0,1) \cdot (1,2,2,0,1)|}{\|(2,-1,2,0,1)\| \cdot \|(1,2,2,0,1)\|} = \frac{1}{2}, \quad \text{tj.} \quad \varphi = \frac{\pi}{3}.$$

Case (d). Denote

$$u = (0, 0, 0, 1, -1), \quad v_1 = (1, -1, 2, 1, 0),$$

$$v_2 = (0, 1, 3, 2, 0), \quad v_3 = (1, 0, 0, 1, 0), \quad v_4 = (1, 3, 1, 0, 0)$$

and denote the orthogonal projection of  $u$  into the vector subspace of  $V$  (subspace generated by  $v_1, v_2, v_3, v_4$ ) by  $p_u$ .

Now

$$p_u = av_1 + bv_2 + cv_3 + dv_4 \quad \text{for some } a, b, c, d \in \mathbb{R}$$

and

$$\langle p_u - u, v_1 \rangle = 0, \quad \langle p_u - u, v_2 \rangle = 0,$$

$$\langle p_u - u, v_3 \rangle = 0, \quad \langle p_u - u, v_4 \rangle = 0.$$

Substituting for  $p_u$  gives the linear equation system

$$7a + 7b + 2c = 1,$$

$$7a + 14b + 2c + 6d = 2,$$

$$2a + 2b + 2c + d = 1,$$

$$6b + c + 11d = 0.$$

The solution is  $(a, b, c, d) = (-8/19, 7/19, 13/19, -5/19)$ .

$$(1) \quad \cos \varphi = \frac{\|p_u\|}{\|u\|}$$

and so

$$p_u = -\frac{8}{19}v_1 + \frac{7}{19}v_2 + \frac{13}{19}v_3 - \frac{5}{19}v_4 = (0, 0, 0, 1, 0),$$

$$\cos \varphi = \frac{\|p_u\|}{\|u\|} = \frac{\|(0, 0, 0, 1, 0)\|}{\|(0, 0, 0, 1, -1)\|} = \frac{1}{\sqrt{2}} = \frac{\sqrt{2}}{2}.$$

Hence  $\varphi = \pi/4$ .

Case (e). Determine the intersection of the vector subspaces associated with the given affine subspaces. The

**4.2.2. Quadratic forms.** Begin the discussion of equation (1) with its quadratic part, i.e. bilinear symmetric form  $F : \mathbb{R}^n \times \mathbb{R}^n \rightarrow \mathbb{R}$ . Similarly, think of a general symmetric bilinear form on an arbitrary vector space with scalar product.

For an arbitrary basis on this vector space, the value  $f(x)$  on vector  $x = x_1e_1 + \dots + x_n e_n$  is given by the equation

$$(1) \quad f(x) = F(x, x) = \sum_{i,j} x_i x_j F(e_i, e_j) = x^T \cdot A \cdot x$$

where  $A = (a_{ij})$  is a symmetric matrix with elements  $a_{ij} = F(e_i, e_j)$ . We call such maps  $f$  *quadratic forms*, and the formula from above for the value of the form in terms of the chosen coordinates is called the *analytic formula* for the form.

In general, by a quadratic form is meant the restriction  $f(x)$  of a symmetric bilinear form  $F(x, y)$  to arguments of the type  $(x, x)$ . Evidently, the whole bilinear form  $F$  can be reconstructed from the values  $f(x)$  since

$$f(x+y) = F(x+y, x+y) = f(x) + f(y) + 2F(x, y).$$

If we change the basis  $e_i$  to a different basis  $e'_1, \dots, e'_n$ , we get different coordinates  $x = S \cdot x'$  for the same vector (here  $S$  is the corresponding transformation matrix), and so

$$f(x) = (S \cdot x')^T \cdot A \cdot (S \cdot x') = (x')^T \cdot (S^T \cdot A \cdot S) \cdot x'.$$

Assume now that the vector space is equipped with a scalar product. Then the previous computation can be formulated as follows. The matrix of the bilinear form  $F$ , which is the same as the matrix of  $f$ , transforms under a change of coordinates in such a way that for orthogonal changes it coincides with the transformation of a matrix of a linear map (i.e., then  $S^{-1} = S^T$ ). This result can be interpreted as the following observation:

**Proposition.** *Let  $V$  be a real vector space with a scalar product. Then formula*

$$\varphi \mapsto F, \quad F(u, u) = \langle \varphi(u), u \rangle$$

*defines a bijection between symmetric linear maps and quadratic forms on  $V$ .*

**PROOF.** Each bilinear form with a fixed second argument becomes a linear form  $F(\cdot, u)$ . In the presence of a scalar product, it is given by the formula  $F(v, u) = v \cdot w$  for a suitable vector  $w$ . Put  $\varphi(u) = w$ . Directly from the coordinate expression (1) displayed above,  $\varphi$  is the linear map with symmetric matrix  $A$ . Hence it is selfadjoint.

On the other hand, each symmetric map  $\varphi$  defines a symmetric bilinear form  $F$  by formula  $F(u, v) = \langle \varphi(u), v \rangle = \langle u, \varphi(v) \rangle$ , and this is also a quadratic form.  $\square$

It is immediate that for each quadratic form  $f$  there exists an orthonormal basis of the difference space in which  $f$  has a diagonal matrix. The values on the diagonal are determined uniquely up to their order.

Due to the identification of quadratic forms with linear maps, the *rank of the quadratic form* can be defined as the

vector  $(x_1, x_2, x_3, x_4, x_5)$  is in the vector subspace of  $U$ , if and only if

$$(x_1, x_2, x_3, x_4, x_5) = t(2, 1, 3, 5, 3) + s(0, 3, 1, 4, -2) + r(1, 2, 4, 0, 3)$$

for some  $t, s, r \in \mathbb{R}$ . Similarly,  $(x_1, x_2, x_3, x_4, x_5) \in V$  if and only if

$$(x_1, x_2, x_3, x_4, x_5) = p(-1, 1, 1, -5, 0) + q(1, 5, 1, 13, -4)$$

for some  $p, q \in \mathbb{R}$ . We look for such  $t, s, r, p, q \in \mathbb{R}$ , so that

$$t(2, 1, 3, 5, 3) + s(0, 3, 1, 4, -2) + r(1, 2, 4, 0, 3) = p(-1, 1, 1, -5, 0) + q(1, 5, 1, 13, -4).$$

It is a homogeneous linear equation system. It is solved in matrix form (order of variables is  $t, s, r, p, q$ )

$$\begin{pmatrix} 2 & 0 & 1 & 1 & -1 \\ 1 & 3 & 2 & -1 & -5 \\ 3 & 1 & 4 & -1 & -1 \\ 5 & 4 & 0 & 5 & -13 \\ 3 & -2 & 3 & 0 & 4 \end{pmatrix} \sim \dots \sim \begin{pmatrix} 1 & 3 & 2 & -1 & -5 \\ 0 & 2 & 1 & -1 & -3 \\ 0 & 0 & 1 & -1 & 1 \\ 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 \end{pmatrix}.$$

The vectors defining  $V$  are linear combination of the vectors of  $U$ . So  $V$  is subset of  $U$ , and hence  $\varphi = 0$ .

Case (f). Find the intersection of  $U$  and  $V$ . Search for numbers  $t, s, p, q, r \in \mathbb{R}$  such that

$$t(1, 0, 1, 1, 1) + s(1, 0, 0, 1, 1) = p(1, 1, 1, 1, 1) + q(1, 1, 0, 1, 1) + r(1, 1, 0, 1, 0).$$

The solution is  $(t, s, p, q, r) = (-a, a, -a, a, 0)$ ,  $a \in \mathbb{R}$ . The intersection  $Z(U) \cap Z(V)$  of vector spaces  $U$  and  $V$  contains the vectors

$$(0, 0, -a, 0, 0) = -a(1, 0, 1, 1, 1) + a(1, 0, 0, 1, 1) = -a(1, 1, 1, 1, 1) + a(1, 1, 0, 1, 1) + 0(1, 1, 0, 1, 0),$$

where  $a \in \mathbb{R}$ .  $Z(U) \cap Z(V)$  is generated by  $(0, 0, 1, 0, 0)$  and its orthogonal complement  $(Z(U) \cap Z(V))^\perp$  is generated by vectors  $(1, 0, 0, 0, 0), (0, 1, 0, 0, 0), (0, 0, 0, 1, 0), (0, 0, 0, 0, 1)$ .

We obtain

$$Z(U) \cap Z(V) \neq \{0\}, \quad Z(U) \cap Z(V) \neq Z(U), \\ Z(U) \cap Z(V) \neq Z(V).$$

The angle  $\varphi$  is defined as the angle between the subspaces  $Z(U) \cap (Z(U) \cap Z(V))^\perp$  and  $Z(V) \cap (Z(U) \cap Z(V))^\perp$ .

rank of its matrix in any basis. The rank equals the dimension of the image of the corresponding map  $\varphi$ .

**4.2.3. Classification of quadrics.** We return to the equation (1). The above results enable us to rewrite this equation as

$$\sum_{i=1}^n \lambda_i x_i^2 + \sum_{i=1}^n b_i x_i + b = 0.$$

Hence we may assume that the quadric is given in this form.

In the next step, we “complete the square” for the coordinates  $x_i$  with  $\lambda_i \neq 0$ , which “absorbs” the squares together with the linear terms in the same variable. So only linear terms are left corresponding to variables for which the coefficient of the quadratic term is zero. We have

$$\sum_{i=1}^n \lambda_i (x_i - p_i)^2 + \sum_j b_j x_j + c = 0.$$

where the summation over  $j$  is only for  $j$  satisfying  $\lambda_j = 0$ .

This corresponds to a translation of the origin about the vector with coordinates  $p_i$ . To such a choice of basis of the difference space the desired diagonal form is in the quadratic part. In the identification of quadratic forms with linear maps derived above, this means that  $\varphi$  is diagonal on the orthogonal complement of its kernel. If there are also some linear terms left, the orthonormal basis of the difference space can be adjusted for the kernel of  $\varphi$  so that the corresponding linear form is a multiple of the first term of the dual basis. Hence the final formula reads

$$\sum_{i=1}^k \lambda_i y_i^2 + b y_{k+1} + c = 0,$$

where  $k$  is the rank of matrix of quadratic form  $f$ . If  $b \neq 0$ , it can be arranged that the constant  $c$  in the equation is zero by a further change of the origin.

Hence the linear term may (but does not have to) appear only in the case that the rank of  $f$  is less than  $n$ , while  $c \in \mathbb{R}$  may be nonzero only if  $b = 0$ . The resulting equations are called the *canonical analytic formulas* for quadrics.

**4.2.4. The case of  $\mathcal{E}_2$ .** As an example of the previous procedure, we discuss the simplest case of a non-trivial dimension, namely dimension two. The original equation has the form

$$a_{11}x^2 + a_{22}y^2 + 2a_{12}xy + a_1x + a_2y + a = 0.$$

By a suitable choice of a basis of the difference space, and the subsequent completion of the square, it is written in the form (using the same notation  $x, y$  for the new coordinates):

$$a_{11}x^2 + a_{22}y^2 + a_1x + a_2y + a = 0$$

where  $a_i$  is nonzero only in the case that  $a_{ii}$  is zero. By the last step of the general procedure, exactly one of the following equations is involved (notice the equations of quadrics are determined up to a multiple):

It is now established that

$$\begin{aligned} Z(U) \cap (Z(U) \cap Z(V))^\perp &= \langle (1, 0, 0, 1, 1) \rangle, \\ Z(V) \cap (Z(U) \cap Z(V))^\perp &= \langle (1, 1, 0, 1, 1), (1, 1, 0, 1, 0) \rangle. \end{aligned}$$

It is enough to express  $Z(U)$  as a linear combination of vectors  $(0, 0, 1, 0, 0)$ ,  $(1, 0, 0, 1, 1)$  and  $Z(V)$  by the vectors  $(0, 0, 1, 0, 0)$ ,  $(1, 1, 0, 1, 1)$ ,  $(1, 1, 0, 1, 0)$ . Since the dimension of  $Z(U) \cap (Z(U) \cap Z(V))^\perp$  is 1, we can use the formula (1), where  $u = (1, 0, 0, 1, 1)$  and  $p_u$  is the orthogonal projection of  $u$  into  $Z(V) \cap (Z(U) \cap Z(V))^\perp$ . Then

$$p_u = a(1, 1, 0, 1, 1) + b(1, 1, 0, 1, 0)$$

and

$$\langle p_u - u, (1, 1, 0, 1, 1) \rangle = 0, \quad \langle p_u - u, (1, 1, 0, 1, 0) \rangle = 0,$$

which leads to the linear equation system

$$\begin{aligned} 4a + 3b &= 3, \\ 3a + 3b &= 2 \end{aligned}$$

with the unique solution  $a = 1, b = -1/3$ . Thus

$$p_u = \left(\frac{2}{3}, \frac{2}{3}, 0, \frac{2}{3}, 1\right).$$

From (1) it follows that

$$\cos \varphi = \frac{\|(2/3, 2/3, 0, 2/3, 1)\|}{\|(1, 0, 0, 1, 1)\|} = \frac{\sqrt{7}}{3}. \quad \varphi \doteq 0.49 \ (\approx 28^\circ).$$

□

### C. Geometry of quadratic forms

**4.C.1.** Determine the polar basis of the form  $f : \mathbb{R}^3 \rightarrow \mathbb{R}$ ,  $f(x_1, x_2, x_3) = 3x_1^2 + 2x_1x_2 + x_2^2 + 4x_2x_3 + 6x_3^2$ .

**Solution.** Its matrix is

$$A = \begin{pmatrix} 3 & 1 & 0 \\ 1 & 1 & 2 \\ 0 & 2 & 6 \end{pmatrix}.$$

According to step (1) of the Lagrange algorithm (see Theorem 4.2.5), perform the following operations

$$\begin{aligned} f(x_1, x_2, x_3) &= \frac{1}{3}(3x_1 + x_2)^2 + \frac{2}{3}x_2^2 + 4x_2x_3 + 6x_3^2 \\ &= \frac{1}{3}y_1^2 + \frac{3}{2}\left(\frac{2}{3}y_2 + 2y_3\right)^2 \\ &= \frac{1}{3}z_1^2 + \frac{3}{2}z_2^2. \end{aligned}$$

The form has rank 2 and the matrix changing the basis to the polar basis  $\underline{w}$  is obtained by a combination of following transformations:  $z_3 = y_3 = x_3$ ,  $z_2 = \frac{2}{3}y_2 + 2y_3 = \frac{2}{3}x_2 + 2x_3$  and  $z_1 = y_1 = 3x_1 + x_2$ , so the change of basis matrix is

$$T = \begin{pmatrix} 3 & 1 & 0 \\ 0 & \frac{2}{3} & 2 \\ 0 & 0 & 1 \end{pmatrix}.$$

$0 = x^2/a^2 + y^2/b^2 + 1$	empty set
$0 = x^2/a^2 + y^2/b^2 - 1$	ellipse
$0 = x^2/a^2 - y^2/b^2 - 1$	hyperbola
$0 = x^2/a^2 - 2py$	parabola
$0 = x^2/a^2 + y^2/b^2$	point
$0 = x^2/a^2 - y^2/b^2$	2 concurrent lines
$0 = x^2 - a^2$	2 parallel lines
$0 = x^2$	2 identical lines
$0 = x^2 + a^2$	empty set

The origin of the Cartesian coordinates is the *center* of the studied conic. The new orthonormal basis of the difference space gives the direction of *semiaxes*. The final coefficients  $a, b$  then give the lengths of the semiaxes in the nondegenerate directions.

**4.2.5. Affine point of view.** In the previous two paragraphs,

we searched for essential properties and standardized analytical descriptions of objects defined in Euclidean spaces by quadratic equations. We sought the simplest equations which can be obtained by a suitable choice of coordinates. A geometric formulation of the result is that for two different quadrics, given in different Cartesian coordinates, there exists a *Euclidean transformation* on  $\mathcal{E}_n$  (that is, an affine bijective map preserving lengths) if and only if the above algorithm leads to the same analytic formulas, up to the order of coordinates. Moreover, the Cartesian coordinates in which the objects are given by the resulting canonical formulas, can be obtained directly. Hence the explicit expression of the corresponding coordinate transformation is also obtained. It is always a composition of a translation, rotation and reflection with respect to a hyperplane.

Of course, we may ask to what extent we can do the same in affine spaces, where we can choose any coordinate system. For example, in the plane we cannot distinguish the circle from the ellipse. On the other hand, we can distinguish from the hyperbola and between all other types of conics. In particular, all hyperbolas merge into one etc. We postpone discussion of this issue to the third part of this chapter, except for the case of quadratic forms.

Consider a quadratic form  $f$  on a vector space  $V$  and its analytic formula  $f(u) = x^T Ax$  with respect to a chosen basis on  $V$ . Then for the vector  $u = x_1u_1 + \dots + x_nu_n$ , the form  $f$  can be written as

$$f(x_1, \dots, x_n) = \sum_{ij} a_{ij}x_ix_j,$$

It is already shown that  $A$  is diagonal for a suitable choice of basis. In other words that  $F(u_i, u_j) = 0$  for  $i \neq j$  for a suitable symmetric form  $F$ . Each such basis is called the *polar basis* of the quadratic form  $f$ . A scalar product can always be chosen for such a purpose. Nevertheless, without the use of the scalar product, there is a much simpler algorithm for finding a polar basis among all other bases. At the same time, there is relevant information to be found about the affine

We computed the polar coordinates, expressed them in standard basis and wrote them as rows of the matrix (the columns of this matrix are vectors of the standard basis in the polar basis). The polar basis vector coordinates are the columns of the matrix  $T^{-1}$ .

$$T^{-1} = \begin{pmatrix} \frac{1}{3} & \frac{-1}{3} & 1 \\ 0 & \frac{3}{2} & -3 \\ 0 & 0 & 1 \end{pmatrix},$$

The polar basis is therefore  $((\frac{1}{3}, 0, 0), (-\frac{1}{2}, \frac{3}{2}, 0), (1, -3, 1))$ . □

**4.C.2.** Determine the polar basis of the form  $f : \mathbb{R}^3 \rightarrow \mathbb{R}^3$ .  
 $f(x_1, x_2, x_3) = 2x_1x_3 + x_2^2$ .

**Solution.** The matrix is of the form

$$A = \begin{pmatrix} 0 & 0 & 1 \\ 0 & 1 & 0 \\ 1 & 0 & 0 \end{pmatrix}.$$

Change the order of the variables:  $y_1 = x_2, y_2 = x_1, y_3 = x_3$ . It is then trivial to apply step (1) of Lagrange algorithm (there are no common terms). However for the next step, case (4) sets in. Introduce the transformation  $z_1 = y_1, z_2 = y_2, z_3 = y_3 - y_2$ .

$$f(x_1, x_2, x_3) = z_1^2 + 2z_2(z_3 + z_2) = z_1^2 + \frac{1}{2}(2z_2 + z_3)^2 - \frac{1}{2}z_3^2.$$

Together,  $z_1 = y_1 = x_2, z_2 = y_2 = x_1, z_3 = y_3 - y_2 = x_3 - x_1$ . The matrix  $T$  for change to polar basis is

$$T = \begin{pmatrix} 0 & 1 & 0 \\ 1 & 0 & 0 \\ -1 & 0 & 1 \end{pmatrix} \quad \text{and} \quad T^{-1} = \begin{pmatrix} 0 & 1 & 0 \\ 1 & 0 & 0 \\ 0 & 1 & 1 \end{pmatrix}.$$

The polar basis is therefore  $((0, 1, 0), (1, 0, 1), (0, 1, 1))$ . □

**4.C.3.** Find the polar basis of the quadratic form  $f : \mathbb{R}^3 \rightarrow \mathbb{R}$ , which in the standard basis is defined as

$$f(x_1, x_2, x_3) = x_1x_2 + x_1x_3.$$

properties of the quadratic form. The algorithmic procedure in the proof of the next theorem is known as the *Lagrange algorithm*.

**Theorem.** Let  $V$  be a real vector space of dimension  $n$ ,  $f : V \rightarrow \mathbb{R}$  a quadratic form. Then there exist a polar basis for  $f$  on  $V$ .

**PROOF.** (1) Let  $A$  be the matrix of  $f$  in basis  $\underline{u} = (u_1, \dots, u_n)$  on  $V$ , and assume  $a_{11} \neq 0$ . Then we may write  
 $f(x_1, \dots, x_n) = a_{11}x_1^2 + 2a_{12}x_1x_2 + \dots + a_{22}x_2^2 + \dots$   
 $= a_{11}^{-1}(a_{11}x_1 + a_{12}x_2 + \dots + a_{1n}x_n)^2$   
 + terms not containing  $x_1$ .

Hence we can transform the coordinates (i.e. change the basis) such that in the new coordinates

$$x'_1 = a_{11}x_1 + a_{12}x_2 + \dots + a_{1n}x_n, x'_2 = x_2, \dots, x'_n = x_n.$$

This corresponds to the new basis

$$v_1 = a_{11}^{-1}u_1, v_2 = u_2 - a_{11}^{-1}a_{12}u_1, \dots, v_n = u_n - a_{11}^{-1}a_{1n}u_1$$

(As an exercise, compute the transformation matrix). In the new basis the corresponding symmetric bilinear form satisfies  $g(v_i, v_i) = 0$  for all  $i > 1$  (compute it!). Thus  $f$  has the form  $a_{11}^{-1}x_1'^2 + h$  in the new coordinates, where  $h$  is a quadratic form independent of the variable  $x_1$ .

It is often easier to choose  $v_1 = u_1$  in the new basis. Then  $f = f_1 + h$ , where  $f_1$  depends only on  $x'_1$ , while  $x'_1$  does not appear in  $h$ , but  $g(v_1, v_1) = a_{11}$ .

(2) Assume that after step (1),  $h$  is a matrix of rank less than  $n$  with a nonzero coefficient of  $x_2'^2$ . Then the same procedure can be repeated to obtain the expression  $f = f_1 + f_2 + h$ , where  $h$  contains only the variables with index greater than two. Proceed in this way until a diagonal form is obtained after  $n - 1$  steps, or in (say) the  $i$ -th step, the element  $a_{ii}$  is zero.

(3) If the last possibility occurs, and there exists some other element  $a_{jj} \neq 0$  with  $j > i$ , then it suffices to exchange the  $i$ -th and the  $j$ -th vector of the basis. Then continue according to the previous procedure.

(4) Assume that the situation is  $a_{jj} = 0$  for all  $j \geq i$ . If there is no element  $a_{jk} \neq 0$  with  $j \geq i, k \geq i$ , then we are finished, since then the matrix is diagonal. If  $a_{jk} \neq 0$ , then we use the transformation  $v_j = u_j + u_k$  and we keep the other vectors of basis unchanged (i.e.  $x'_k = x_k - x_j$ , the other remain without change). Then  $h(v_j, v_j) = h(u_j, u_j) + h(u_k, u_k) + 2h(u_k, u_j) = 2a_{jk} \neq 0$  and we can continue as for case (1). □

**4.2.6. Affine classification of quadratic forms.**

The vectors in the basis obtained from the Lagrange algorithm can be rescaled by scalars such that the coefficients of the squares of variables are only the scalars 1, -1 and 0. Moreover, the following *law of inertia* says that the number of one's and minus one's does not depend on the choices in the course of the algorithm. These numbers are called the *signature of a quadratic form*.

**Solution.** By an application of the Lagrange algorithm:

$$\begin{aligned}
 f(x_1, x_2, x_3) &= 2x_1x_2 + x_2x_3 \\
 \text{substitution } y_2 &= x_2 - x_1, y_1 = x_1, y_3 = x_3 \\
 &= 2x_1(x_1 + y_2) + (x_1 + y_2)x_3 \\
 &= 2x_1^2 + 2x_1y_2 + x_1x_3 + y_2x_3 \\
 &= \frac{1}{2}(2x_1 + y_2 + \frac{1}{2}x_3)^2 - \frac{1}{2}y_2^2 - \frac{1}{8}x_3^2 + y_2x_3 \\
 \text{substitution } y_1 &= 2x_1 + y_2 + \frac{1}{2}x_3 \\
 &= \frac{1}{2}y_1^2 - \frac{1}{2}y_2^2 - \frac{1}{8}x_3^2 + y_2x_3 \\
 &= \frac{1}{2}y_1^2 - 2(\frac{1}{2}y_2 - \frac{1}{2}x_3)^2 + \frac{3}{8}x_3^2 \\
 \text{substitution } y_3 &= \frac{1}{2}y_2 - \frac{1}{2}x_3 \\
 &= \frac{1}{2}y_1^2 - 2y_3^2 + \frac{3}{8}x_3^2.
 \end{aligned}$$

With the coordinates  $y_1, y_3, x_3$ , the quadratic form has a diagonal shape, which means that the basis associated with those coordinates is the polar basis of the form. If we want to express the basis, we need to obtain the matrix which changes the basis from polar to standard. By definition of the change of basis matrix, its columns are the polar basis vectors. Either we express the old variables  $(x_1, x_2, x_3)$  by new variables  $(y_1, y_3, x_3)$ , or equivalently we express the new ones by the old ones (which is easier). In the latter case, we need to compute inverse matrix.

$y_1 = 2x_1 + y_2 + \frac{1}{2}x_3 = 2x_1 + (x_2 - x_1) + \frac{1}{2}x_3$  and  $y_3 = \frac{1}{2}y_2 - \frac{1}{2}x_3 = -\frac{1}{2}x_1 + \frac{1}{2}x_3 - \frac{1}{2}x_3$ . The matrix for changing the basis from the polar basis to the standard basis is

$$T = \begin{pmatrix} 2 & 1 & \frac{1}{2} \\ -\frac{1}{2} & \frac{1}{2} & -\frac{1}{2} \\ 0 & 0 & 1 \end{pmatrix}.$$

The inverse matrix is

$$T^{-1} = \begin{pmatrix} \frac{1}{3} & -\frac{2}{3} & -\frac{1}{2} \\ \frac{1}{3} & \frac{4}{3} & \frac{1}{2} \\ 0 & 0 & 1 \end{pmatrix}.$$

Hence one of the polar bases of the given quadratic forms is (see the columns of the matrix),  $\{(1/3, 1/3, 0), (-2/3, 4/3, 0), (-1/2, 1/2, 1)\}$ .  $\square$

**4.C.4.** Determine the type of conic section defined by

$$3x_1^2 - 3x_1x_2 + x_2 - 1 = 0.$$

As before, there is a complete description of quadratic forms in the sense that two such forms may be transformed each one into the other by an affine transformation if and only if they have the same signature.

**Theorem.** For each nonzero quadratic form of rank  $r$  on a real vector space  $V$  there exists a natural number  $p$ , and  $r$  independent linear forms  $\varphi_1, \dots, \varphi_r \in V^*$  such that  $0 \leq p \leq r$  and  $f(u)$  becomes

$$(\varphi_1(u))^2 + \dots + (\varphi_p(u))^2 - (\varphi_{p+1}(u))^2 - \dots - (\varphi_r(u))^2.$$

Otherwise put, there exists a polar basis, in which  $f$  has an analytic formula

$$f(x_1, \dots, x_n) = x_1^2 + \dots + x_p^2 - x_{p+1}^2 - \dots - x_r^2.$$

The number  $p$  of positive diagonal coefficients in the matrix of the given quadratic form (and thus the number  $r - p$  of negative coefficients) does not depend on the choice of polar basis.

Two symmetric matrices  $A, B$  of dimension  $n$  are matrices of the same quadratic form in different bases if and only if they have the same rank and the same number of positive coefficients in the polar basis.

**PROOF.** By completing the squares,  $f(x_1, \dots, x_n) = \lambda_1x_1^2 + \dots + \lambda_rx_r^2$ ,  $\lambda_i \neq 0$ , in a basis on  $V$ . Assume moreover that the first  $p$  coefficients  $\lambda_i$  are positive. Then the transformation  $y_1 = \sqrt{\lambda_1}x_1, \dots, y_p = \sqrt{\lambda_p}x_p, y_{p+1} = \sqrt{-\lambda_{p+1}}x_{p+1}, \dots, y_r = \sqrt{-\lambda_r}x_r, y_{r+1} = x_{r+1}, \dots, y_n = x_n$  yields the desired formula. The forms  $\varphi_i$  are exactly the forms from the dual basis in  $V^*$  to the obtained polar basis.

It remains to prove that  $p$  does not depend on the procedure. Assume that there is a formula for the same form  $f$  in the polar bases  $\underline{u}, \underline{v}$ , i.e.

$$\begin{aligned}
 f(x_1, \dots, x_n) &= x_1^2 + \dots + x_p^2 - x_{p+1}^2 - \dots - x_r^2 \\
 f(y_1, \dots, y_n) &= y_1^2 + \dots + y_q^2 - y_{q+1}^2 - \dots - y_r^2.
 \end{aligned}$$

Denote the subspace generated by the first  $p$  vectors of the first basis by  $P = \langle u_1, \dots, u_p \rangle$ , and similarly  $Q = \langle v_{q+1}, \dots, v_n \rangle$ . Then for each  $u \in P$ ,  $f(u) > 0$  while for  $v \in Q$ ,  $f(v) \leq 0$ . Hence necessarily  $P \cap Q = \{0\}$ , and therefore  $\dim P + \dim Q \leq n$ . Hence  $p + (n - q) \leq n$ , so that  $p \leq q$ . By interchanging the subspaces,  $q \leq p$ , and so  $p = q$ .

Thus  $p$  is independent of the choice of the polar basis. Consequently for two matrices with the same rank and the same number of positive coefficients in the diagonal form of the corresponding quadratic form, the analytic formulas are the same.  $\square$

While discussing symmetric maps we talked about definite and semidefinite maps. The same discussion has an obvious meaning also for symmetric bilinear forms and quadratic forms. A quadratic form  $f$  on a real vector space  $V$  is called

- (1) *positive definite* if  $f(u) > 0$  for all vectors  $u \neq 0$ ,
- (2) *positive semidefinite* if  $f(u) \geq 0$  for all vectors  $u \in V$ ,

**Solution.** Complete the squares:

$$\begin{aligned} 3x_1^2 - 3x_1x_2 + x_2 - 1 &= \frac{1}{3}(3x_1 - \frac{3}{2}x_2)^2 - \frac{3}{4}x_2^2 + x_2 - 1 \\ &= \frac{1}{3}y_1^2 - \frac{4}{3}(\frac{3}{4}x_2 - \frac{1}{2})^2 + \frac{1}{3} - 1 \\ &= \frac{1}{2}y_1^2 - \frac{4}{3}y_2^2 - \frac{2}{3}. \end{aligned}$$

According to the list 4.2.4, the given conic section is a hyperbola.  $\square$

**4.C.5.** By completing the squares, express the quadric

$$-x^2 + 3y^2 + z^2 + 6xy - 4z = 0$$

in such a way that one can determine its type from it.

**Solution.** Complete the square. Deal first with all terms involving an  $x$ . Obtain the equation

$$-(x - 3y)^2 + 9y^2 + 3y^2 + z^2 - 4z = 0.$$

There are no "unwanted" terms containing  $y$ , so repeat the procedure for  $z$ . This gives

$$-(x - 3y)^2 + 12y^2 + (z - 2)^2 - 4 = 0.$$

Conclude that there is a transformation of variables that leads to the equation (we can divide by 4 if desired)

$$-\bar{x}^2 + \bar{y}^2 + \bar{z}^2 - 1 = 0.$$

$\square$

We can tell the type of the conic section without transforming its equation to the form listed in 4.2.4. Every conic section can be expressed as

$$a_{11}x^2 + 2a_{12}xy + a_{22}y^2 + 2a_{13}x + 2a_{23}y + a_{33} = 0.$$

Determinants  $\Delta = \det A = \begin{vmatrix} a_{11} & a_{12} & a_{13} \\ a_{12} & a_{22} & a_{23} \\ a_{13} & a_{32} & a_{33} \end{vmatrix}$  and

$\delta = \begin{vmatrix} a_{11} & a_{12} \\ a_{12} & a_{22} \end{vmatrix}$  are invariants of conic sections which means that they are not changed by Euclidean transformations (rotation and translation). Furthermore, the different types of conic sections have different signs of those determinants.

- $\Delta \neq 0$  for non-degenerate conic sections:  
 ellipse for  $\delta > 0$ , hyperbola for  $\delta < 0$  and parabola for  $\delta = 0$   
 For a real ellipse (not imaginary), it is necessary that  $(a_{11} + a_{22})\Delta < 0$ .
- $\Delta = 0$  for degenerate conic sections, or pairs of lines.

The signs (or zero-value) of the determinants are really invariant to the coordinate transformation. Denote  $X = \begin{pmatrix} x \\ y \\ 1 \end{pmatrix}$

- (3) *negative definite* if  $f(u) < 0$  for all vectors  $u \neq 0$ ,
- (4) *negative semidefinite* if  $f(u) \leq 0$  for all vectors  $u \in V$ ,
- (5) *indefinite* if  $f(u) > 0$  and  $f(v) < 0$  for two vectors  $u, v \in V$ .

The same names are used for symmetric matrices corresponding to quadratic forms. By the signature of a symmetric matrix is meant the signature of the corresponding quadratic form.

SYLVESTER CRITERION

**4.2.7. Theorem.** A symmetric real matrix  $A$  is positive definite if and only if all its leading principal minors are positive.

A symmetric real matrix  $A$  is negative definite if and only if  $(-1)^i |A_i| > 0$  for all leading principal submatrices  $A_i$ .

**PROOF.** The claim about negative definite forms follows immediately from the first part of the theorem. Just observe that  $A$  is positive definite if and only if  $-A$  is negative definite.

Suppose that the form  $f$  is positive definite. Then  $A = P^T E P = P^T P$  for a suitable regular matrix  $P$ . Hence  $|A| = |P|^2 > 0$ . Let  $\underline{u}$  be a chosen basis in which the form  $f$  has matrix  $A$ . The restrictions of  $f$  to the subspaces  $V_k = \langle u_1, \dots, u_k \rangle$  are positive definite forms  $f_k$  again, and the corresponding matrices in the bases  $u_1, \dots, u_k$  are the leading principal submatrices  $A_k$ . Thus  $|A_k| > 0$ , too.

In order to prove the other implication, analyse in detail the form of the transformations used in completing the square in the Lagrange algorithm. The transformation used in the first step always has an upper triangular matrix  $T$ . By rescaling, see the proof of Theorem 4.2.5, the matrix may have ones on the diagonal:

$$T = \begin{pmatrix} 1 & -\frac{a_{12}}{a_{11}} & \dots & -\frac{a_{n2}}{a_{11}} \\ 0 & 1 & \dots & 0 \\ \vdots & & \ddots & \vdots \end{pmatrix}.$$

Such a matrix of the transformation from basis  $\underline{u}$  to basis  $\underline{v}$  has several useful properties. In particular, its leading principal submatrices  $T_k$  formed by the first  $k$  rows and columns are the transformation matrices of a subspace  $P_k = \langle u_1, \dots, u_k \rangle$  from basis  $(u_1, \dots, u_k)$  to basis  $(v_1, \dots, v_k)$ . The leading principal submatrices  $A_k$  of the matrix  $A$  of the form  $f$  are matrices of restrictions of the form  $f$  to  $P_k$ . Therefore, the matrices  $A_k$  and  $A'_k$  of restrictions to  $P_k$  in basis  $\underline{u}$  and  $\underline{v}$  respectively satisfy  $A_k = T_k^T A'_k T_k$ , where  $T$  is the transformation matrix from  $\underline{u}$  to  $\underline{v}$ . The inverse matrix to an upper triangular matrix with one's on the diagonal is again an upper triangular matrix with one's on the diagonal. Hence we may similarly express  $A'$  in terms of  $A$ . Thus the determinants of the matrices  $A_k$  and  $A'_k$  are equal by Cauchy formula. We may conclude:

and denote  $A$  as the matrix of the quadratic form. Then the corresponding conic section has equation  $X^T A X = 0$ . The standard form is obtained by rotation and translation. This is by a transformation to new coordinates  $x', y'$  satisfying

$$\begin{aligned} x &= x' \cos \alpha - y' \sin \alpha + c_1 \\ y &= x' \sin \alpha + y' \cos \alpha + c_2, \end{aligned}$$

or, in matrix form, for the new coordinates  $X' = \begin{pmatrix} x' \\ y' \\ 1 \end{pmatrix}$ ,

$$(1) \quad X = \begin{pmatrix} x \\ y \\ 1 \end{pmatrix} = \begin{pmatrix} \cos \alpha & -\sin \alpha & c_1 \\ \sin \alpha & \cos \alpha & c_2 \\ 0 & 0 & 1 \end{pmatrix} \begin{pmatrix} x' \\ y' \\ 1 \end{pmatrix} = M X'.$$

Put  $X = M X'$  into the conic section equation to obtain the equation in new coordinates

$$\begin{aligned} X^T A X &= 0 \\ (M X')^T A (M X') &= 0 \\ X'^T M^T A M X' &= 0. \end{aligned}$$

Denote by  $A'$  the matrix of the quadratic form in new coordinates. Then  $A' = M^T A M$ , where matrix  $M = \begin{pmatrix} \cos \alpha & -\sin \alpha & c_1 \\ \sin \alpha & \cos \alpha & c_2 \\ 0 & 0 & 1 \end{pmatrix}$  has unit determinant, so

$$\det A' = \det M^T \det A \det M = \det A = \Delta.$$

Necessarily, the determinant  $A_{33}$ , which is the algebraic complement of  $a_{33}$ , is invariant to the coordination transformation. For rotation only,  $\det A' = \det M^T \det A \det M$ .

In this case the matrix  $M = \begin{pmatrix} \cos \alpha & -\sin \alpha & 0 \\ \sin \alpha & \cos \alpha & 0 \\ 0 & 0 & 1 \end{pmatrix}$

and  $\det A'_{33} = \det A_{33} = \delta$ . For translation only,

$M = \begin{pmatrix} 1 & 0 & c_1 \\ 0 & 1 & c_2 \\ 0 & 0 & 1 \end{pmatrix}$  and this subdeterminant remains unchanged.

**4.C.6.** Determine the type of conic section

$$2x^2 - 2xy + 3y^2 - x + y - 1 = 0.$$

**Solution.** The determinant

$$\Delta = \begin{vmatrix} 2 & -1 & -\frac{1}{2} \\ -1 & 3 & \frac{1}{2} \\ -\frac{1}{2} & \frac{1}{2} & -1 \end{vmatrix} = -\frac{23}{4} \neq 0,$$

hence it is a non-degenerate conic section. Moreover  $\delta = 5 > 0$ , therefore it is an ellipse. Furthermore  $(a_{11} + a_{22})\Delta = (2 + 3) \cdot (-\frac{23}{4}) < 0$ , so it is real ellipse.  $\square$

**Claim.** Let  $f$  be a quadratic form on  $V$ ,  $\dim V = n$ . Let  $\underline{u}$  be a basis of  $V$  such that the items (3) and (4) from the Lagrange algorithm while finding the polar basis are not needed. Then the analytic formula

$$f(x_1, \dots, x_n) = \lambda_1 x_1^2 + \lambda_2 x_2^2 + \dots + \lambda_r x_r^2$$

is obtained where  $r$  is the rank of the form  $f$ ,  $\lambda_1, \dots, \lambda_r \neq 0$  and for the leading principal submatrices of the (former) matrix  $A$  of quadratic form  $f$ ,  $|A_k| = \lambda_1 \lambda_2 \dots \lambda_k$ ,  $k \leq r$ .

After each step in this procedure, the resulting matrix contains zeros under the diagonal in the already processed columns. At the same time, all the principal minors remain the same.

Consequently if the leading principal minors are nonzero, then the next diagonal term in  $A$  is nonzero and we do not need other steps than completing the squares. Moreover,  $\lambda_i = |A_i|/|A_{i-1}|$ . This proves the following:

**Corollary (Jacobi theorem).** Let  $f$  be a quadratic form of rank  $r$  on a vector space  $V$  with matrix  $A$  for the basis  $\underline{u}$ . Steps other than completing the square are not required if and only if the leading principal submatrices of  $A$  satisfy  $|A_1| \neq 0, \dots, |A_r| \neq 0$ . Then there exists a polar basis in which  $f$  has the analytic formula

$$f(x_1, \dots, x_n) = |A_1| x_1^2 + \frac{|A_2|}{|A_1|} x_2^2 + \dots + \frac{|A_r|}{|A_{r-1}|} x_r^2.$$

Hence if all leading principal minors are positive, then  $f$  is positive definite by the Jacobi theorem and the Sylvester criterion is proved.  $\square$

**3. Projective geometry**

In many elementary texts on analytic geometry, the authors finish with the affine and Euclidean objects described above. The affine and Euclidean geometries are sufficient for many practical problems, but not for all problems.

For instance in processing an image from a camera, angles are not preserved and parallel lines may (but do not have to) intersect.

Moreover, it is often difficult to distinguish very small angles from zero angles, and thus it would be convenient to have tools which do not need such distinguishing.

The basic idea of projective geometry is to extend affine spaces by points at infinity. This permits an easy way to deal with linear objects such as points, lines, planes, projections, etc.

**4.3.1. Projective extension of affine plane.** We begin with the simplest interesting case, namely geometry in a plane. If we imagine the points in the plane  $\mathcal{A}_2$  as the plane  $z = 1$  in  $\mathbb{R}^3$ , then each point  $P$  in the affine plane is represented by a vector  $u = (x, y, 1) \in \mathbb{R}^3$ . So it is represented also by a one-dimensional subspace  $\langle u \rangle \subset \mathbb{R}^3$ . On the other hand, almost every one-dimensional subspace in  $\mathbb{R}^3$  intersects the plane in exactly one point  $P$ . The vectors of such a subspace are given by coordinates  $(x, y, z)$  uniquely up to a common

**4.C.7.** Determine the type of conic section  $x^2 - 4xy - 5y^2 + 2x + 4y + 3 = 0$ .

**Solution.** The determinant  $\Delta = \begin{vmatrix} 1 & -2 & 1 \\ -2 & -5 & 2 \\ 1 & 2 & 3 \end{vmatrix} = -34 \neq 0$ ,

furthermore  $\delta = \begin{vmatrix} 1 & -2 \\ -2 & -5 \end{vmatrix} = -9 < 0$ , it is therefore a hyperbola.  $\square$

**4.C.8.** Determine the equation and type of conic section passing through the points

$$[-2, -4], [8, -4], [0, -2], [0, -6], [6, -2].$$

**Solution.** Input the coordinates of the points into the general conic section equation

$$a_{11}x^2 + a_{22}y^2 + 2a_{12}xy + a_1x + a_2y + a = 0$$

There follows the linear equation system

$$\begin{aligned} 4a_{11} + 16a_{22} + 16a_{12} - 2a_1 - 4a_2 + a &= 0, \\ 64a_{11} + 16a_{22} - 64a_{12} + 8a_1 - 4a_2 + a &= 0, \\ 4a_{22} - 2a_2 + a &= 0, \\ 36a_{22} - 6a_2 + a &= 0, \\ 36a_{11} + 4a_{22} - 24a_{12} + 6a_1 - 2a_2 + a &= 0. \end{aligned}$$

In matrix form we perform operations

$$\begin{aligned} &\begin{pmatrix} 4 & 16 & 16 & -2 & -4 & 1 \\ 64 & 16 & -64 & 8 & -4 & 1 \\ 0 & 4 & 0 & 0 & -2 & 1 \\ 0 & 36 & 0 & 0 & -6 & 1 \\ 36 & 4 & -24 & 6 & -2 & 1 \end{pmatrix} \sim \dots \\ &\sim \begin{pmatrix} 4 & 16 & 16 & -2 & -4 & 1 \\ 0 & 4 & 0 & 0 & -2 & 1 \\ 0 & 0 & 64 & -8 & 12 & -9 \\ 0 & 0 & 0 & 24 & -36 & 27 \\ 0 & 0 & 0 & 0 & 3 & -2 \end{pmatrix} \sim \dots \\ &\sim \begin{pmatrix} 48 & 0 & 0 & 0 & 0 & -1 \\ 0 & 12 & 0 & 0 & 0 & -1 \\ 0 & 0 & 64 & 0 & 0 & 0 \\ 0 & 0 & 0 & 24 & 0 & 3 \\ 0 & 0 & 0 & 0 & 3 & -2 \end{pmatrix}. \end{aligned}$$

Then

$$a_{11} = 1, \quad a_{22} = 4, \quad a_{12} = 0, \quad a_1 = -6, \quad a_2 = 32.$$

The conic section has equation

$$x^2 + 4y^2 - 6x + 32y + 48 = 0.$$

Complete the terms  $x^2 - 6x$ ,  $4y^2 + 32y$  to squares. The result is

$$(x - 3)^2 + 4(y + 4)^2 - 25 = 0,$$

scalar multiple. Only the subspaces corresponding to vectors  $(x, y, 0)$  do not intersect the plane.

PROJECTIVE PLANE

**Definition.** The projective plane  $\mathcal{P}_2$  is the set of all one-dimensional subspaces in  $\mathbb{R}^3$ . The homogeneous coordinates of a point  $P = (x : y : z)$  in the projective plane are triples of real numbers given up to a common scalar multiple, at least one of which must be nonzero. A straight line in the projective plane is defined as a set of one-dimensional subspaces (i.e. points in  $\mathcal{P}_2$ ) which generate a two-dimensional subspace (i.e. a plane) in  $\mathbb{R}^3$ .

For a concrete example, consider two parallel lines in the affine plane  $\mathbb{R}^2$

$$L_1 : y - x - 1 = 0, \quad L_2 : y - x + 1 = 0.$$

If the points of lines  $L_1$  and  $L_2$  are finite points in projective space  $\mathcal{P}_2$ , then their homogeneous coordinates  $(x : y : z)$  satisfy equations

$$L_1 : y - x - z = 0, \quad L_2 : y - x + z = 0.$$

the intersection  $L_1 \cap L_2$  is the point  $(1 : 1 : 0) \in \mathcal{P}_2$  in this context. It is the point at infinity corresponding to the common direction vector of the lines.

**4.3.2. Affine coordinates in the projective plane.** If we begin with the projective plane and if we want to see

the affine plane as its “finite” part, then instead of the plane  $z = 1$  we may take another plane  $\sigma$  in  $\mathbb{R}^3$  which does not pass through the origin  $0 \in \mathbb{R}^3$ . Then the finite points are those one-dimensional subspaces which have a nonempty intersection with the plane  $\sigma$ .

Consider the two parallel lines from the previous paragraph. Let us choose the plane  $y = 1$  to obtain two lines in the affine plane

$$L'_1 : 1 - x - z = 0, \quad L'_2 : 1 - x + z = 0$$

The “infinite” points of the former affine plane are given by  $z = 0$ . The lines  $L'_1$  and  $L'_2$  intersect at the “finite” point  $(x, z) = (1, 0)$ . This corresponds to the geometric concept that two parallel lines  $L_1, L_2$  in the affine plane meet at infinity, at the point  $(1 : 1 : 0)$ , but this point becomes finite in different affine coordinates.

**4.3.3. Projective spaces and transformations.** In a natural way one can generalize the procedure in the

affine plane for each finite dimension.

By choosing an arbitrary affine hyperplane  $\mathcal{A}_n$  in the vector space  $\mathbb{R}^{n+1}$  which does not pass through origin, we may identify the points  $P \in \mathcal{A}_n$  with one-dimensional subspaces generated by these points. The remaining one-dimensional subspaces determine a hyperplane parallel to  $\mathcal{A}_n$ . They are called *infinite points* in the projective extension  $\mathcal{P}_n$  of the affine plane  $\mathcal{A}_n$ .

The set of infinite points in  $\mathcal{P}_n$  is always a projective space of dimension one less. An affine straight line has only

or rather

$$\frac{(x - 3)^2}{5^2} + \frac{(y + 4)^2}{\left(\frac{5}{2}\right)^2} - 1 = 0.$$

The conic section is an ellipse with centre at  $[3, -4]$ .  $\square$

**4.C.9. Other characteristics and concepts of conic sections.**

The *axis of a conic section* is a line of reflection symmetry for the conic section. From the canonical form of a conic section in polar basis (4.2.4) it can be shown that an ellipse and a hyperbola both have two axes ( $x = 0$  and  $y = 0$ ). A parabola has one axis ( $x = 0$ ). The intersection of a conic section and its axis is called a *conic section vertex*.

The numbers  $a, b$  from the canonical form of a conic section (which express the distance between vertices and the origin) are called the *length of semi-axes*. In the case of an ellipse and hyperbola, the axes intersect at the origin. This is a point of central symmetry for the conic section, called the *centre of the conic section*.

For practical problems involving conic sections, it is often easiest to describe them in parametric form. Often, this avoids contending with messy square roots.

Every point  $P$  on the parabola  $y^2 = 4ax$ ,  $a > 0$ , can be described by  $P = (x, y) = (at^2, 2at)$ , for real  $t$ . The standard parametric form for the parabola is the pair of equations

$$x = at^2 \quad y = 2at,$$

(Note that the roles of  $x$  and  $y$  are interchanged, so that the axis of symmetry is the line  $y = 0$ .) The tangent line at  $(at^2, 2at)$  has slope  $\frac{1}{t}$  and equation  $t(y - 2at) = (x - at^2)$ . The point  $F = (a, 0)$  on the axis is called the focus of the parabola, and the line  $x = -a$  is called the directrix. Each point on the parabola is equidistant from the focus and the directrix. This property can be used to define a parabola.

Every point  $P$  on the ellipse  $\frac{x^2}{a^2} + \frac{y^2}{b^2} = 1$  can be described by  $P = (x, y) = (a \cos \theta, b \sin \theta)$ , where  $0 < b \leq a$ . The standard parametric form for the ellipse is the pair of equations

$$x = a \cos \theta, \quad y = b \sin \theta.$$

The tangent line at  $P$  has slope  $-\frac{b \cos \theta}{a \sin \theta}$  and consequently has equation  $(a \cos \theta)(y - b \sin \theta) = -b \cos \theta(x - a \cos \theta)$ . The positive number  $e$ , defined by  $b^2 = a^2(1 - e^2)$  is called the eccentricity of the ellipse. If  $e = 0$ , the ellipse becomes a circle or radius  $a = b$ . Otherwise  $0 < e < 1$ . The two points  $F_1 = (ae, 0)$  and  $F_2 = (-ae, 0)$  are the foci of the ellipse, and the lines  $x = \pm a/e$  are the directrices.

one infinite point in its projective extension (both ends of the line “intersect” at infinity and thus the projective line looks like a circle). The projective plane has a projective line of infinite points, the three-dimensional projective space has a projective plane of infinite points etc.

More generally, we can define the *projectivization of a vector space*. For an arbitrary vector space  $V$  of dimension  $n + 1$ , we define

$$\mathcal{P}(V) = \{P \subset V; P \subset V, \dim V = 1\}.$$

By choosing a basis  $\underline{u}$  in  $V$  we obtain *homogeneous coordinates* on  $\mathcal{P}(V)$ . For a  $P \in \mathcal{P}(V)$  we use the nonzero vector  $u \in V$  and the coordinates of this vector in a basis  $\underline{u}$ . The points of the projective space  $\mathcal{P}(V)$  are called *geometric points*. Their generators in  $V$  are called *arithmetic representatives*.

In the chosen projective coordinates, we fix one of them to be one. Thus we exclude all points of the projective extension which have this coordinate equal to zero. We have an embedding of  $n$ -dimensional affine space  $\mathcal{A}_n \subset \mathcal{P}(V)$ . This is precisely the construction used in the example on the projective plane.

**4.3.4. Perspective projection.**

The advantages of projective geometry show up well in the case of perspective projection  $\mathbb{R}^3 \rightarrow \mathbb{R}^2$ . Imagine that an observer sitting in the origin observes “one half of the world”, that is, the points  $(X, Y, Z) \in \mathbb{R}^3$  with  $Z > 0$ . The observer sees the image “projected” on the screen given by plane  $Z = f > 0$ .

picture missing!

Thus a point  $(X, Y, Z)$  in the “real world” projects to a point  $(x, y)$  on the screen as follows:

$$x = -f \frac{X}{Z}, \quad y = -f \frac{Y}{Z}.$$

This is a nonlinear formula. The accuracy of calculations are problematic when  $Z$  is small.

By extending this transformation to a map between projective spaces, we have  $(X : Y : Z : W) \mapsto (x : y : z) = (-fX : -fY : Z)$ , which is well defined for all  $Z > 0$ . That

Every point  $P$  on the hyperbola  $\frac{x^2}{a^2} - \frac{y^2}{b^2} = 1$ ,  $0 < a$ ,  $0 < b$ , can be described by  $P = (x, y) = (a \cosh \theta, b \sinh \theta)$ . The standard parametric form for the hyperbola is the pair of equations

$$x = a \cosh \theta, \quad y = b \sinh \theta.$$

The tangent line at  $P$  has slope  $\frac{b \cosh \theta}{a \sinh \theta}$  and consequently has equation  $(a \cosh \theta)(y - b \sinh \theta) = b \cosh \theta(x - a \cosh \theta)$ . The positive number  $e$ , defined by  $b^2 = a^2(e^2 - 1)$  is called the eccentricity of the hyperbola. Necessarily,  $e > 1$ . The two points  $F_1 = (ae, 0)$  and  $F_2 = (-ae, 0)$  are the foci of the ellipse, and the lines  $x = \pm a/e$  are the directrices. A hyperbola has two asymptotes. In standard form, the equations are  $y = \pm(b/a)x$ .

**4.C.10. Existence of foci.** For an ellipse with lengths of semi-axes  $a > b$ , show that the sum of the distances from any point on the ellipse to the two foci is constant, namely  $2a$ .

**Solution.** If  $P = (a \cos \theta, b \sin \theta)$  and  $F_1 = (ae, 0)$ , then

$$\begin{aligned} |PF_1|^2 &= (a \cos \theta - ae)^2 + b^2 \sin^2 \theta \\ &= a^2 \cos^2 \theta - 2a^2 e \cos \theta + a^2 e^2 + a^2(1 - e^2) \sin^2 \theta \\ &= a^2[-2e \cos \theta + e^2 - e^2(1 - \cos^2 \theta)] \\ &= a^2(1 - e \cos \theta)^2. \end{aligned}$$

So  $|PF_1| = a(1 - e \cos \theta)$ . Similarly  $|PF_2| = a(1 + e \cos \theta)$ . Hence  $|PF_1| + |PF_2| = 2a$ .  $\square$

**Solution.** (Alternative). Consider the points  $X = [x, y]$ , which satisfy the property  $|F_1 X| + |F_2 X| = 2a$ . Coordinate-wise, this implies the equation

$$\sqrt{(x + ae)^2 + y^2} + \sqrt{(x - ae)^2 + y^2} = 2a$$

Rewrite this as

$$\sqrt{(x + ae)^2 + y^2} = 2a - \sqrt{(x - ae)^2 + y^2}$$

Square, simplify and square again to get

$$(1 - e^2)x^2 + y^2 = a^2(1 - e^2).$$

Substitute  $b^2 = a^2(1 - e^2)$  and divide by  $b^2$  to obtain

$$\frac{x^2}{a^2} + \frac{y^2}{b^2} = 1.$$

which is the ellipse in standard form.  $\square$

**Remark.**

is, a map described by a simple linear formula

$$\begin{pmatrix} x \\ y \\ z \end{pmatrix} = \begin{pmatrix} f & 0 & 0 & 0 \\ 0 & f & 0 & 0 \\ 0 & 0 & 1 & 0 \end{pmatrix} \cdot \begin{pmatrix} X \\ Y \\ Z \\ W \end{pmatrix}$$

This simple expression defines the perspective projection for finite points in  $\mathbb{R}^3 \subset \mathcal{P}_3$  which we substitute as points with  $W = 1$ . In this way we eliminate problems with points whose image runs to infinity. Indeed, if the  $Z$ -coordinate of a real point is close to zero, then the value of the third homogeneous coordinate of the image is close to zero, i.e. it corresponds to a point close to infinity.

**4.3.5. Affine and projective transformations.** Each in-

jective linear map  $\varphi : V_1 \rightarrow V_2$  between vector spaces maps one-dimensional subspaces to one-dimensional subspaces. Therefore, we have a map on projectivizations  $T : \mathcal{P}(V_1) \rightarrow \mathcal{P}(V_2)$ . Such maps are called *projective maps*. In the literature, the notion *collineation* is used if this map is invertible.

Otherwise put, the projective map is a map between projective spaces such that in each system of homogeneous coordinates on the domain and image, it is given by the multiplication by a matrix. More generally if the auxiliary linear map is not injective, then we need to define the projective map only outside of its kernel, that is, on points whose homogeneous coordinates do not map to zero.

Since injective maps  $V \rightarrow V$  of a vector space to itself are invertible, all projective maps of projective space  $\mathcal{P}_n$  to itself are invertible. They are also called *regular collineations* or *projective transformations*. In homogeneous coordinates, they correspond to invertible matrices of dimension  $n + 1$ . Two such matrices define the same projective transformation if and only if one is a (nonzero) multiple of the other.

If we choose the first coordinate as the one whose vanishing defines infinite points, then the transformations preserving infinite points are given by matrices whose first row vanishes up to its first element. If we wish to switch to affine coordinates of finite points, (i.e the first coordinate is fixed at one), the first element in the first row also equals one. Hence the matrices of collineations preserving finite points of the affine space have the form:

$$\begin{pmatrix} 1 & 0 & \cdots & 0 \\ b_1 & a_{11} & \cdots & a_{1n} \\ \vdots & \vdots & \ddots & \vdots \\ b_n & a_{n1} & \cdots & a_{nn} \end{pmatrix}$$

where  $b = (b_1, \dots, b_n)^T \in \mathbb{R}^n$  and  $A = (a_{ij})$  is an invertible matrix of dimension  $n$ . The action of such a matrix on the vector  $(1, x_1, \dots, x_n)$  is exactly a general affine transformation, where  $b$  is the translation and  $A$  is its linear part. Thus the affine maps are exactly those collineations which preserve the hyperplane of points at infinity.  $\square$

Similarly, the *hyperbola foci* are the points  $F_1, F_2$ , which satisfy  $||F_2X| - |F_1X|| = 2a$  for an arbitrary  $X$  on the hyperbola. You can check this in the same way as above for the ellipse, with  $F_1 = [ae, 0], F_2 = [-ae, 0], ae = \sqrt{a^2 + b^2}$ .

**Parabola focus** If the parabola has equation  $x^2 = 2py$ , the focus is the point  $F$  with coordinates  $F = [0, \frac{p}{2}]$ . It is characterized by the fact that the distance between this point and an arbitrary  $X$  on parabola is equal to the distance between  $X$  and line  $y = -\frac{p}{2}$ .

**4.C.11.** Find the foci of the ellipse  $x^2 + 2y^2 = 2$ .

**Solution.** From the equation that semi-axes lengths are  $a = \sqrt{2}$  and  $b = 1$ . Compute (see 4.C.10):  $ae = \sqrt{a^2 - b^2} = 1$  The foci coordinates are at  $[-1, 0]$  and  $[1, 0]$ . □

**4.C.12.** Prove that the product of the distances between the foci of an ellipse and any tangent line is constant. Find the value of the constant.

**Solution.** Every point  $T$  on the ellipse has coordinates  $T = (x, y)$  where  $x = a \cos \theta, y = b \sin \theta$  for some  $\theta$ . The tangent line to the ellipse at  $T$  has equation

$$y - b \sin \theta = -\frac{b \cos \theta}{a \sin \theta}(x - a \cos \theta).$$

$$a(\sin \theta)(y - b \sin \theta) = -b(\cos \theta)(x - a \cos \theta).$$

This meets the  $x$ -axis at the point  $(a/\cos \theta, 0)$ . The distance from the focus  $F_1$  to the tangent line is  $D_1 = [a/\cos \theta - ae] \sin \varphi$  where  $\tan \varphi = \pm \frac{b \cos \theta}{a \sin \theta}$ . Eliminate

**4.3.6. Determining collineations.** In order to define an affine map, it is necessary and sufficient to define an image of the affine frame. In the above description of affine transformations as special cases of projective maps, this corresponds to a suitable choice of an image of a suitable arithmetic basis of the vector space  $V$ .

In general it is not true that the image of an arithmetic basis of  $V$  determines the collineation uniquely. The basic problem is illustrated by a simple example of affine plane.

Choose four points  $A, B, C, D$  in the plane such that no three of them lie on a line. Then choose their images in the collineation as follows:

Choose arbitrarily their four images  $A', B', C', D'$  with the same property, and choose their homogeneous coordinates  $u, v, w, z, u', v', w', z'$  in  $\mathbb{R}^3$ . The vectors  $z$  and  $z'$  can be written as linear combinations

$$z = c_1u + c_2v + c_3w, \quad z' = c'_1u' + c'_2v' + c'_3w',$$

where all six coefficients must be nonzero, otherwise there exist three points not in general position.

Now choose new arithmetic representatives  $\tilde{u} = c_1u, \tilde{v} = c_2v$  and  $\tilde{w} = c_3w$  of points  $A, B$  and  $C$  respectively. Similarly  $\tilde{u}' = c'_1u', \tilde{v}' = c'_2v'$  and  $\tilde{w}' = c'_3w'$  for points  $A', B'$  and  $C'$ . This choice defines a unique linear map  $\varphi$  which maps successively

$$\varphi(\tilde{u}) = \tilde{u}', \quad \varphi(\tilde{v}) = \tilde{v}', \quad \varphi(\tilde{w}) = \tilde{w}'.$$

But then,

$$\varphi(z) = \varphi(\tilde{u} + \tilde{v} + \tilde{w}) = \tilde{u}' + \tilde{v}' + \tilde{w}' = z',$$

and so the constructed collineation maps the points which we have chosen in advance. The linear map  $\varphi$  is given uniquely by the construction, thus the collineation is given uniquely by this choice.

The argument holds also in the case when some of the chosen points are infinite (i.e. one or two). The same phenomenon can be explained even more easily by the regular collineation of a projective line. These are defined by pairwise different images of three pairwise different points.

The procedure works in an arbitrary dimension  $n$ . Then we say that  $n + 2$  points are in *general position* if no  $n + 1$  of them lie in the same hyperplane. We also call these points linearly independent, forming a *geometric basis* of projective space.

**Theorem.** A regular collineation on  $n$ -dimensional projective space is uniquely determined by linearly independent images of  $n + 2$  linearly independent points.

**PROOF.** The proof is exactly the same as in dimension two. We recommend writing it in detail as an exercise. □

**4.3.7. Cross-ratio.** Recall that affine maps preserve ratios of lengths of line segments on each line. Technically, we defined this ratio as for three points  $A, B$  and  $C \neq B, C = rA + sB$  as  $\lambda = (C; A, B) = -\frac{s}{r}$ .

$\varphi$  to get

$$\begin{aligned} D_1^2 &= a^2(1 - e \cos \theta)^2 \left[ \frac{b^2}{a^2 \sin^2 \theta + b^2 \cos^2 \theta} \right] \\ &= (1 - e \cos \theta)^2 \left[ \frac{b^2}{\sin^2 \theta + (1 - e^2) \cos^2 \theta} \right] \\ &= (1 - e \cos \theta)^2 \left[ \frac{b^2}{1 - e^2 \cos^2 \theta} \right] \\ &= b^2(1 - e \cos \theta) \left[ \frac{1}{1 + e \cos \theta} \right] \end{aligned}$$

Since  $D_2$  is the same as  $D_1$  with  $e$  replaced by  $-e$ , it follows that  $D_1 D_2 = b^2$ .  $\square$

**Solution.** (Alternative). Consider the polar basis. The ellipse matrix has diagonal shape  $\text{diag}(\frac{1}{a^2}, \frac{1}{b^2}, -1)$  and the tangent equation at  $X=[x_0, y_0]$  is  $\frac{x_0}{a^2}x + \frac{y_0}{b^2}y = 1$ . The distance between  $F_1, F_2 = [\mp ae, 0]$  and this line equals

$$\frac{1 \pm ae \frac{x_0}{a^2}}{\sqrt{\frac{x_0^2}{a^4} + \frac{y_0^2}{b^4}}}$$

Its product is

$$\frac{1 - e^2 \frac{x_0^2}{a^4}}{\frac{x_0^2}{a^4} + \frac{y_0^2}{b^4}}$$

If we substitute  $a^2 e^2 = a^2 - b^2$  and  $\frac{y_0^2}{b^2} = 1 - \frac{x_0^2}{a^2}$  (the point  $X$  is lying on the ellipse), we find that the previous term equals  $b^2$ .  $\square$

**4.C.13. Projective approach to conic section.** Projective space gives an ability to approach the conic section from a new perspective (compare with 4.3.11). We can understand conic sections in  $\mathcal{E}_2$  defined by the quadratic form

$f(x, y) = a_{11}x^2 + 2a_{12}xy + a_{22}y^2 + 2a_{13}x + 2a_{23}y + a_{33}$  as a set of points in projective plane  $\mathcal{P}^2$  with homogenous coordinates  $(x : y : z)$ , which are the zero points of the homogenous quadratic form

$$f(x, y, z) = a_{11}x^2 + 2a_{12}xy + a_{22}y^2 + 2a_{13}xz + 2a_{23}yz + a_{33}z^2.$$

Or rather  $f(v) = v^T Av$ , where  $v$  is a column vector with coordinates  $(x, y, z)$  and matrix  $A$  is symmetric matrix  $(a_{ij})$ . By theorem 4.2.6, there exists a basis in which this quadratic form has one of the following equations

$$f(x, y, z) = x^2 + y^2 + z^2, \quad f(x, y, z) = x^2 + y^2 - z^2.$$

In the former case there is only one solution of  $f(x, y, z) = 0$  and therefore the original form does not represent a real conic section. The second quadratic form represents a cone in  $\mathbb{R}^3$ . We obtain the corresponding conic section by moving back to inhomogeneous coordinates. That means intersecting the

For central projection the ratios are not preserved. Moreover, even the relative position of points on a line is not necessarily preserved. On the contrary we may determine uniquely a projective transformation by choosing arbitrarily images of three pairwise different points on a projective line. However, one can show relatively easily that the ratio of such ratios for two distinct points  $C$  is preserved:

Consider four distinct points  $A, B, C, D$  in projective space with arithmetic coordinates  $x, y, w, z$  respectively which lie on a projective line. Since these four vectors lie in the subspace generated by  $\langle x, y \rangle$ , we may write  $w$  and  $z$  as linear combinations

$$w = t_1 x + s_1 y, \quad z = t_2 x + s_2 y.$$

Define the *cross-ratio of four points*  $(A, B, C, D)$  as

$$\rho = \frac{s_1 t_2}{t_1 s_2}.$$

The definition is valid, since although the vectors  $x$  and  $y$  are determined up to a scalar multiple, these multiples cancel out in the definition.

Each projective transformation preserves cross-ratios: Indeed, if the transformation is given in arithmetic coordinates by a matrix  $A$ , we have images  $A \cdot w = t_1 A \cdot x + s_1 A \cdot y$ , and similarly for  $Az$ . Therefore the four images have the same cross-ratio.

We discuss the characterization of projective transformations. These are exactly those maps which preserve cross-ratios. But this is not a very practical characterization, since it contains implicitly the claim that these maps map projective lines to projective lines.

We shall not go into details here, but one can prove a much stronger statement. A map of arbitrarily small open area in affine space  $\mathbb{R}^n$  (e.g. a ball without boundary) into the same affine space which maps lines to lines is actually a restriction of a uniquely determined projective transformation of the projective extension  $\mathcal{P}\mathbb{R}^{n+1}$  of the former affine space  $\mathbb{R}^n$ . Thus these transformations also preserve cross-ratios.

**4.3.8. Duality.** Projective hyperplanes in an  $n$ -dimensional projective space  $\mathcal{P}(V)$  are defined as the projectivizations of  $n$ -dimensional vector subspaces in the vector space  $V$ . Hence in homogeneous coordinates, they are defined as kernels of linear forms  $\alpha \in V^*$  which in turn are determined up to a scalar multiple.

Thus in a chosen arithmetic basis, a projective hyperplane is given by a row vector  $\alpha = (\alpha_0, \dots, \alpha_n)$ . But the forms  $\alpha$  are given uniquely up to a scalar multiple. Therefore, each hyperplane in  $V$  is identified with exactly one geometric point in the projectivization of the dual space  $\mathcal{P}(V^*)$ . We call such a space the *dual projective space*, and we talk about a duality between points and hyperplanes.

On forms, the linear map defining a given collineation acts by the multiplication of row vectors from the right by the same matrix

$$\alpha = (\alpha_0, \dots, \alpha_n) \mapsto \alpha \cdot A.$$

cone with the plane which has the equation  $z = 1$  in the original basis. Immediately we obtain the conic section classification from 4.29., which corresponds to the intersecting cone in  $\mathbb{R}^3$  with different planes. Non-degenerate sections are depicted. Degenerate sections are those which pass through the vertex of the cone.

We define the following useful terms for a conic section in projective plane :

Points  $P, Q \in \mathcal{P}^2$  corresponding to one-dimensional subspaces  $\langle p \rangle, \langle q \rangle$  (generated by vectors  $p, q \in \mathbb{R}^3$ ) are called *polar conjugated* with respect to conic section  $f$ , if  $F(p, q) = 0$ , or rather  $p^T A q = 0$ .

Point  $P = \langle p \rangle$  is called *singular point* of conic section  $f$ , when it is polar conjugated with respect to  $f$  with all points of the plane, so  $F(p, x) = 0 \quad \forall x \in \mathcal{P}^2$ . In other words,  $A p = 0$ . Hence the matrix  $A$  of the conic section does not have maximal rank and therefore defines a degenerate conic section. Non-degenerate conic sections do not contain singular points.

The set of all points  $X = \langle x \rangle$  are called polar conjugated with  $P = \langle p \rangle$  polar of the point  $P$  with respect to the conic section  $f$ . It is therefore the set of points for which  $F(p, x) = p^T A x = 0$ . Because the polar is given by a linear combination of coordinates, it is always (in the non-singular case) a line. The following explains the geometric interpretation of polar.

**4.C.14. Polar characterization.** Consider a non-degenerate conic section  $f$ . The polar of a point  $P \in f$  with respect to  $f$  is the tangent to  $f$  with the touch point  $P$ . The polar of the point  $P \notin f$  is the line defined by the touch points of the tangents to  $f$  passing through  $P$ .

**Solution.** First consider  $P \in f$ . Suppose that the polar of  $P$ , defined by  $F(p, x) = 0$ , intersects  $f$  in  $Q = \langle q \rangle \neq P$ . Then  $F(p, q) = 0$  and  $f(q) = F(q, q) = 0$ . For an arbitrary point  $X = \langle x \rangle$  lying on  $P$  and  $Q$ ,  $x = \alpha p + \beta q$  for some  $\alpha, \beta \in \mathbb{R}$ .

Viewing the coordinates  $\alpha_i$  as columns, this corresponds to the action of the dual map with the matrix  $A^T$ . But the dual map maps forms in the opposite direction, from the “target space” to the “initial one”. Therefore the inverse map for the collineation of  $f$  is required in order to study the effect of regular collineations on points and their dual hyperplanes. The inverse is given by the matrix  $A^{-1}$ . Hence the matrix for the action of the corresponding collineation on forms is  $(A^T)^{-1}$ . Since the inverse matrix equals the algebraically adjoint matrix  $A_{\text{alg}}^*$ , up to the multiplication by the inverse of determinant, (see equation (1) on page 91) we can work directly with the projective transformation of the space  $\mathcal{P}(V^*)$  given by the matrix  $(A_{\text{alg}}^*)^T$  (or without transposing if we multiply row vectors from the right).

The projective point  $X$  belongs to the hyperplane  $\alpha$  if the arithmetic coordinates satisfy  $\alpha \cdot x = 0$ . It still holds after acting with an arbitrary collineation, since

$$(\alpha \cdot A^{-1}) \cdot (A \cdot x) = \alpha \cdot x = 0.$$

**4.3.9. Fixed points, centers and axes.** Consider a regular collineation  $f$  given in an arithmetic basis of projective space  $\mathcal{P}(V)$  by a matrix  $A$ .

By the *fixed point* of the collineation  $f$ , we mean a point  $A$  which is mapped to itself. That is,  $f(A) = A$ . By the *fixed hyperplane* of collineation  $f$  is meant a hyperplane  $\alpha$  which is mapped to itself. That is,  $f(\alpha) \subset \alpha$ .

Hence the arithmetic representatives of fixed points are exactly the eigenvectors of the matrix  $A$ .

In the geometry of the plane, we meet many types of collineations: reflection through a point, reflection across a line, translation, homothety etc. Perhaps we remember also some types of projections, e.g. the projection of a plane in  $\mathbb{R}^3$  to another from a center  $S \in \mathbb{R}^3$ .

Note also that there appear fixed lines next to fixed points in all cases of such affine maps. For example, the reflection through a point preserves also all lines passing through this point. In the case of a translation the infinite points behave similarly.

Now we discuss this phenomenon in an arbitrary dimension. First, we define a classical notion related to the incidence of points and hyperplanes.

A set of hyperplanes passing through a point  $A \in \mathcal{P}(V)$  is a set of all hyperplanes which contain the point  $A$ . For each point  $A$  the corresponding set of hyperplanes itself is a hyperplane in the dual space  $\mathcal{P}(V^*)$ . It is given by one homogeneous linear equation in arithmetic coordinates.

For a collineation  $f : \mathcal{P}(V) \rightarrow \mathcal{P}(V)$ , a point  $S \in \mathcal{P}(V)$ , is called the *center of collineation*  $f$ , if all hyperplanes in the set determined by  $S$  are fixed hyperplanes. A hyperplane  $\alpha$  is called the *axis of collineation*  $f$  if all its points are fixed points.

It follows that the axis of a collineation is the center of the dual collineation, while the set of hyperplanes defining the center of collineation is the axis of the dual collineation.

Because of the bilinearity and symmetry of  $F$ ,

$$f(x) = F(x, x) = \alpha^2 F(p, p) + 2\alpha\beta F(p, q) + \beta^2 F(q, q) = 0.$$

So every point  $X$  of the line lies on the conic section  $f$ . However, when the conic section contains a line, it has to be degenerate, which is a contradiction.

The claim for  $P \notin f$  follows from the corollary of the symmetry of the bilinear form  $F$ . When the  $Q$  lies on the polar of  $P$ , then  $P$  lies on the polar of  $Q$ .

□

Using polar conjugates we can find the axes and the centre of the conic sections without using the Lagrange algorithm.

Consider the conic section matrix as a block matrix

$$A = \begin{pmatrix} \bar{A} & a \\ a^T & \alpha \end{pmatrix},$$

where  $\bar{A} = (a_{ij})$  for  $i, j = 1, 2$ ,  $a$  is vector  $(a_{13}, a_{23})$  and  $\alpha = a_{33}$ . This means that the conic section is defined by the equation

$$u^T \bar{A} u + 2a^T u + \alpha = 0$$

for a vector  $u = (x, y)$ . Now we show that

**4.C.15.** The axes of a conic section are the polars of the points at infinity determined by the eigenvectors of the matrix  $\bar{A}$ .

**Solution.** Because of the symmetry of  $\bar{A}$  in the basis of its eigenvectors, it has a diagonal shape  $D = \begin{pmatrix} \lambda & 0 \\ 0 & \mu \end{pmatrix}$ , where  $\lambda, \mu \in \mathbb{R}$  and this basis is orthogonal. Denote by  $U$  the matrix changing basis to a basis of eigenvectors (columns), then the conic section matrix is

$$\begin{pmatrix} U^T & 0 \\ 0 & 1 \end{pmatrix} \begin{pmatrix} \bar{A} & a \\ a^T & \alpha \end{pmatrix} \begin{pmatrix} U & 0 \\ 0 & 1 \end{pmatrix} = \begin{pmatrix} D & U^T a \\ a^T U & \alpha \end{pmatrix}$$

Since the matrices of a collineation on the former and the dual space differ only by the transposition, their eigenvalues coincide (the eigenvectors are column vectors, respectively row vectors corresponding to the same eigenvalues). For example in the projective plane (and for the same reason in each real projective space of even dimension) each collineation has at least one fixed point, since the characteristic polynomials of corresponding linear maps are of odd degree. Hence they have at least one real root.

Instead of discussing a general theory, we illustrate its usefulness in several results for projective planes.

**Proposition.** A projective transformation other than the identity has either exactly one center and exactly one axis, or it has neither a center nor an axis.

**PROOF.** Consider a collineation  $f$  on  $\mathcal{P}\mathbb{R}^3$  and assume that it has two distinct centers  $A$  and  $B$ . Denote by  $\ell$  the line given by these two centers, and choose a point  $X$  in the projective plane outside of  $\ell$ . If  $p$  and  $q$  are the lines passing through pairs of points  $(A, X)$  respectively  $(B, X)$ , then  $f(p) = p$  and  $f(q) = q$ . In particular,  $X$  is fixed. But then all points of the plane outside of  $\ell$  are fixed. Hence each line different from  $\ell$  has all points out of  $\ell$  fixed and thus also its intersection with  $\ell$  is fixed. It follows that  $f$  is the identity mapping. So it is proved that every projective transformation other than the identity has at most one center. The same argument for the dual projective plane proves that there is at most one axis.

If  $f$  has a center  $A$ , then all lines passing through  $A$  are fixed. They correspond therefore to a two-dimensional subspace of a row eigenvectors of the matrix corresponding to the transformation  $f$ . Therefore, there exists a two-dimensional subspace of column eigenvectors for the same eigenvalue. This represents exactly the line of fixed points, hence it represents the axis. The same consideration in the reversed order proves the opposite statement – if a projective transformation of plane has an axis, then it has also a center. □

picture missing!

For practical problems it is useful to work with complex projective extensions also in the case of a real plane. Then

So in this basis there is the canonical form defined by vector  $U^T a$  (up to a translation). Specifically, denote the eigenvectors by  $v_\lambda, v_\mu$ , and then

$$\lambda\left(x + \frac{a^T v_\lambda}{\lambda}\right)^2 + \mu\left(y + \frac{a^T v_\mu}{\mu}\right)^2 = \frac{(a^T v_\lambda)^2}{\lambda} + \frac{(a^T v_\mu)^2}{\mu} - \alpha.$$

This means that the eigenvectors are the direction vectors of the conic section axes (main directions). The axes equations in this basis are  $x = -\frac{a^T v_\lambda}{\lambda}$  and  $y = -\frac{a^T v_\mu}{\mu}$ . The axes coordinates  $u_\lambda$  and  $u_\mu$  in the standard basis satisfy  $v_\lambda^T u_\lambda = -\frac{a^T v_\lambda}{\lambda}$  and  $v_\mu^T u_\mu = -\frac{a^T v_\mu}{\mu}$ , because  $v_\lambda^T(\lambda u_\lambda + a) = 0$  and  $v_\mu^T(\mu u_\mu + a) = 0$ . These equations are equivalent to the equations  $v_\lambda^T(\bar{A}u_\lambda + a) = 0$  and  $v_\mu^T(\bar{A}u_\mu + a) = 0$  which are the polar equations of the points defined by the vectors  $v_\lambda$  and  $v_\mu$ .

□

**4.C.16. Remark.** A corollary of the previous claim is that the centre of the conic section is polar conjugated with all points at infinity. The coordinates of the centre  $s$  then satisfy the equation  $\bar{A}s + a = 0$ .

If  $\det(A) \neq 0$ , then the equation  $\bar{A}s + a = 0$  for centre coordinates has exactly one solution if  $\delta = \det(\bar{A}) \neq 0$ , and no solutions if  $\delta = 0$ . That means that, regarding non-degenerate conic sections, the ellipse and the hyperbola have exactly one centre. The parabola has no centre. (its centre is point at infinity).

**4.C.17.** Prove that the angle between the tangent to the parabola (with arbitrary touch point) and the parabola axis is the same as the angle between the tangent and the line connecting the focus and the point of tangency

**Solution.** The polar (i.e. tangent) of a point  $X=[x_0, y_0]$  to a parabola defined by the canonical equation in the polar basis is a line satisfying

$$(x_0, y_0, 1) \begin{pmatrix} 1 & 0 & 0 \\ 0 & 0 & -p \\ 0 & -p & 0 \end{pmatrix} \begin{pmatrix} x \\ y \\ 1 \end{pmatrix} = x_0x - py - py_0 = 0$$

The cosine of the angle between the tangent and the axis of the parabola ( $x = 0$ ) is given by the dot product of the corresponding unit direction vectors. The unit direction vector of the tangent is  $\frac{1}{\sqrt{p^2+x_0^2}}(p, x_0)$  and therefore

$$\frac{1}{\sqrt{p^2+x_0^2}}(p, x_0) \cdot (0, 1) = \frac{x_0}{\sqrt{p^2+x_0^2}}$$

Now we show that this is the same as the cosine of the angle between the tangent and line connecting the focus  $F=[0, \frac{p}{2}]$ ,

the geometric behaviour can be easily read off the potential existence of real or imaginary centers and axes.

**4.3.10. Pappus Theorem.** The following result known as Pappus theorem is a classic result of projective geometry.

**Proposition.** Let two triples of distinct consecutive collinear points  $\{A, B, C\}$  and  $\{A', B', C'\}$  lie on two lines that meet at the point  $T$ , which is closest to  $A$  and  $A'$ , respectively. Define points  $Q, R$  and  $S$  as

$$Q = [AB'] \cap [BA'], \quad R = [AC'] \cap [CA'], \quad S = [BC'] \cap [CB'].$$

Then  $\{Q, R, S\}$  are also collinear.

picture missing!

**PROOF.** Without loss of generality, consider the plane, passing through  $\{T, A, B, C, A', B', C'\}$  as a 2-dimensional plane in  $\mathcal{P}^2$  defined by  $z = 1$  in the homogeneous coordinates  $(x : y : z)$ .

The points  $\{T, A, B, C, A', B', C'\}$  may be considered as objects in  $\mathcal{P}^2$ , representing lines through the origin in  $\mathbb{R}^3$  with directional vectors  $\{t, a, b, c, a', b', c'\}$ , respectively. These can be chosen up to a real non-zero factor. The condition  $\{z = 1\}$  uniquely identifies those points in  $\mathbb{R}^3$  regardless of the choice of  $\{t, a, b, c, a', b', c'\}$ . Since  $\{T, A, B, C\}$  are collinear points, (they lie in the same 2-dimensional linear subspace of  $\mathbb{R}^3$ ), we may assume that this plane is generated by  $t$  and  $a$ . Choose

$$b = t + a, \quad c = \lambda t + a,$$

and analogously, for  $\{T, A', B', C'\}$

$$b' = t + a', \quad c' = \lambda' t + a'$$

for some real constants  $\lambda$  and  $\lambda'$ . It is only necessary to show that the vectors  $q, r, s$ , representing  $Q, R, S$  in  $\mathcal{P}^2$  generate a 2-dimensional subspace in  $\mathbb{R}^3$ .

Since

$$(t + a) + a' = a + (t + a'),$$

$q = t + a + a'$  represents  $Q$ . Since

$$\lambda\lambda' t + \lambda' a + \lambda a' = \lambda(\lambda' t + a') + \lambda' a = \lambda'(\lambda t + a) + \lambda a',$$

and the touch point X. The unit direction vector of the connecting line is

$$\frac{1}{\sqrt{x_0^2 + (y_0 - \frac{p}{2})^2}}(x_0, y_0 - \frac{p}{2}).$$

For the cosine of the angle,

$$\frac{1}{\sqrt{p^2 + x_0^2}} \frac{1}{\sqrt{x_0^2 + (y_0 - \frac{p}{2})^2}}(x_0 y_0 + \frac{p x_0}{2})$$

Substitute  $y_0 = \frac{x_0^2}{2p}$  to obtain  $\frac{x_0}{\sqrt{p^2 + x_0^2}}$ .

This example shows that light rays striking parallel with axis of parabolic mirror are reflecting to the focus and, vice versa, light rays going through focus reflect in direction parallel with axis of parabola. This is the principle of many devices such as parabolic reflectors.  $\square$

**Solution.** (Alternative) At the point  $P = (at^2, 2at)$  on the parabola, the tangent line has slope  $(1/t)$  and the focus is at  $(a, 0)$ . So the line joining  $P$  to the focus  $F$  has slope  $\frac{2at-0}{at^2-a} = \frac{2t}{t^2-1}$ . If  $\theta$  is the angle between the tangent line and the  $x$ -axis, then  $\tan \theta = 1/t$ , so

$$\tan 2\theta = \frac{2 \tan \theta}{1 - \tan^2 \theta} = \frac{2/t}{(1 - 1/t^2)} = \frac{2t}{t^2 - 1}$$

By subtraction, the angle between the tangent line and the line joining  $P$  to the focus is  $\theta$ .

Note that the tangent line meets the  $x$ -axis at  $Q$  where  $Q = (-at^2, 0)$ . The result follows from showing that  $|FP| = |FQ|$ , and hence the triangle  $QFP$  is isosceles.  $\square$

You can find many more examples on quadrics on [D](#)

$r = \lambda \lambda' t + \lambda' a + \lambda a'$  represents  $R$ . Finally,

$$\begin{aligned} s &= q - r = t + a + a' - \lambda \lambda' t - \lambda' a - \lambda a' \\ &= (1 - \lambda')(t + a) + (1 - \lambda)(\lambda' t + a') \\ &= (1 - \lambda)(t + a') + (1 - \lambda')(\lambda t + a) \end{aligned}$$

represents the point  $S$ . Thus, the points  $\{Q, R, S\}$  lie in the 2-dimensional subspace generated by vectors  $q$  and  $r$ . Since  $Q, R, S$  also belong to the plane  $\{z = 1\}$ , these points are collinear.  $\square$

### 4.3.11. Projective classification of quadrics.

To end this section, we return to conics and quadrics. A quadric  $Q$  in  $n$ -dimensional affine space  $\mathbb{R}^n$  is defined by a general quadratic equation (1) on the page 252. By viewing the affine space  $\mathbb{R}^n$  as affine coordinates in projective space  $\mathcal{P}\mathbb{R}^{n+1}$  we may wish to describe the set  $Q$  by homogeneous coordinates in projective space. The formula in these coordinates should contain only the terms of second order since only a homogeneous formula is independent of the choice of the multiple of homogeneous coordinates  $(x_0, x_1, \dots, x_n)$  of a point. Hence we search for a homogeneous formula whose restriction to affine coordinates, (that is, substitution  $x_0 = 1$ ), gives the original formula (1).

But this is especially easy. Simply add the right number of  $x_0$  to all terms – nothing to the quadratic terms, one to the linear terms and  $x_0^2$  to the constant term in the original affine equation for  $Q$ . We obtain a well defined quadratic form  $f = \sum_{i,j=0}^n a_{ij} x_i x_j$  on the vector space  $\mathbb{R}^{n+1}$  whose zero set defines correctly the *projective quadric*  $\bar{Q}$ .

The intersection of a “cone”  $\bar{Q} \subset \mathbb{R}^{n+1}$  of the zero set of this form with the affine plane  $x_0 = 1$  is the original quadric  $Q$  whose points are called the proper points of the quadric. The other points  $\bar{Q} \setminus Q$  in the projective extension are the infinite points.

The classification of real or complex projective quadrics, up to projective transformations, is a problem already considered. It is all about finding the canonical polar basis, see paragraph 4.2.6. From this classification, given by the signature of the form in the real case and by the rank only in the complex case, we can deduce also the classification of the affine quadrics. We show the essential part of the procedure in the case of conics in the affine and the projective plane.

The projective classification gives the following possibilities, described by homogeneous coordinates  $(x : y : z)$  in the projective plane  $\mathcal{P}\mathbb{R}^3$ :

- imaginary regular conic given by  $x^2 + y^2 + z^2 = 0$
- real regular conic given by  $x^2 + y^2 - z^2 = 0$
- pair of imaginary lines given by  $x^2 + y^2 = 0$
- pair of real lines given by  $x^2 - y^2 = 0$
- one double line  $x^2 = 0$ .

We consider this classification as real, that is, the classification of quadratic forms is given not only by its rank but also by

its signature. Nevertheless, the points of a quadric are considered also in the complex extension. In this way we should understand the stated names. For example the imaginary conic does not have any real points.

**4.3.12. Affine classification of quadrics.** For an affine classification we must restrict the projective transformations to those which preserve the line of infinite points. This can be seen also by the converse procedure — for a fixed projective type of conic  $Q$ , that is, its cone  $\tilde{Q} \subset \mathbb{R}^3$ , we choose different affine planes  $\alpha \subset \mathbb{R}^3$  which do not pass through the origin. We observe the changes to the set of points  $\tilde{Q} \cap \alpha$ , which are proper points of  $Q$  in affine coordinates, as realized by the plane  $\alpha$ .

Hence in the case of a regular conic there is a real cone  $\tilde{Q}$  given by the equation  $z^2 = x^2 + y^2$ . As planes  $\alpha$  we may for instance choose the tangent planes to the unit sphere. If we begin with the plane  $z = 1$ , the intersection consists only of finite points forming a unit circle  $Q$ . By a gradual change of the slope of  $\alpha$  we obtain a more and more stretched ellipse until we get such a slope that  $\alpha$  is parallel with one of lines of the cone. At that moment there appears one (double) infinite point of the conic whose finite points still form one connected component, and so we have a parabola. Continuing to change the slope gives rise to two infinite points. The set of finite points is no longer connected, and so we obtain the last regular quadric in the affine classification, a hyperbola.

We can take advice from the introduced method which enables us to continue the classification in higher dimensions. In particular, we notice that the intersection of the conic with the projective line of infinite points is always a quadric in dimension one less. It is either the empty set or a double point or two points as types of quadrics on a projective line. Next we found an affine transformation transforming one of possible realizations of a fixed projective type to another one, only if the corresponding quadrics in the infinite line were projectively equivalent. In this way, it is possible to continue the classification of quadrics in dimension three and above.

**D. Further exercise on this chapter**

**4.D.1.** Find a parametric equation for the intersection of the following planes in  $\mathbb{R}^3$ :

$$\sigma : 2x + 3y - z + 1 = 0 \quad \text{a} \quad \rho : x - 2y + 5 = 0.$$

**4.D.2.** Find a common perpendicular for the skew lines

$$p : [1, 1, 1] + t(2, 1, 0), \quad q : [2, 2, 0] + t(1, 1, 1).$$

**4.D.3.** Jarda is standing in  $[-1, 1, 0]$  and has a stick of length 4. Can he simultaneously touch the lines  $p$  and  $q$ , where

$$p : [0, -1, 0] + t(1, 2, 1),$$

$$q : [3, 4, 8] + s(2, 1, 3)?$$

(The stick must pass through  $[-1, 1, 0]$ .)

**4.D.4.** A cube  $ABCDEFGH$  is given. The point  $T$  lies on the edge  $BF$ , with  $|BT| = \frac{1}{4}|BF|$ . Compute the cosine of the angle between  $ATC$  and  $BDE$ .

**4.D.5.** A cube  $ABCDEFGH$  is given. The point  $T$  lies on the edge  $AE$ , with  $|AT| = \frac{1}{4}|AE|$ .  $S$  is the midpoint of  $AD$ . Compute the cosine of the angle between  $BDT$  and  $SCH$ .

**4.D.6.** A cube  $ABCDEFGH$  is given. The point  $T$  lies on the edge  $BF$ ,  $|BT| = \frac{1}{3}|BF|$ . Compute the cosine of the angle between  $ATC$  and  $BDE$ .

**4.D.7.** What are the lengths of semi-axes, when the sum of their lengths equals the distance between foci both equal 1.

**Solution.** It is given that  $a + b = 1$  and  $2ae = 1$ . Also  $b^2 = a^2(1 - e^2)$ . Eliminating  $e$  gives  $b^2 = a^2 - (1/4)$ . So  $1/4 = a^2 - b^2 = (a - b)(a + b) = a - b$ . So  $a = 5/8$  and  $b = 3/8$ . □

**Solution.** (Alternative.) Solve the system

$$\begin{aligned} a + b &= 1 \\ 2e &= 2\sqrt{a^2 - b^2} = 1 \end{aligned}$$

and find solution  $a = \frac{5}{8}$ ,  $b = \frac{3}{8}$ . □

**4.D.8.** For what slopes  $k$  are the lines passing through  $[-4, 2]$  secant and tangent lines of the ellipse defined by

$$\frac{x^2}{9} + \frac{y^2}{4} = 1$$

**Solution.** The direction vector of the line is  $(1, k)$  and its parametric equations then are  $x = -4 + t$ ,  $y = 2 + kt$ . The intersection with the ellipse satisfies

$$\frac{(-4 + t)^2}{9} + \frac{(2 + kt)^2}{4} = 1$$

This quadratic equation has discriminant equal to

$$D = -\frac{k}{9}(7k + 16).$$

This implies that for  $k \in (-\frac{16}{7}, 0)$  there are two solutions, and the line is a secant. For  $k = -\frac{16}{7}$  and  $k = 0$  there is only one solution and the line is a tangent to the ellipse. □

**4.D.9.** Find all lines tangent to the ellipse  $3x^2 + 7y^2 = 30$ , so that the distance from the centre of the ellipse to the tangent is 3.

**Solution.** All lines at distance 3 from the origin are tangents to the circle centre at  $[0, 0]$  and radius 3. They all have an equation  $x \cos \theta + y \sin \theta = 3$  for some  $\theta$ . This line meets the standard ellipse  $x^2/a^2 + y^2/b^2 = 1$  where

$$\frac{x^2}{a^2} + \frac{(3 - x \cos \theta)^2}{b^2 \sin^2 \theta} = 1$$

or

$$x^2(a^2 \cos^2 \theta + b^2 \sin^2 \theta) - 6a^2 x \cos \theta - a^2(b^2 \sin^2 \theta - 9) = 0$$

It is a tangent line if the above equation has a double root for  $x$ . Thus it is required that

$$36a^4 \cos^2 \theta = 4(a^2 \cos^2 \theta + b^2 \sin^2 \theta)(9 - b^2 \sin^2 \theta).$$

This simplifies to requiring that

$$a^2 \cos^2 \theta + b^2 \sin^2 \theta = 9.$$

This implies

$$\begin{aligned} \cos^2 \theta &= \frac{(9 - b^2)}{(a^2 - b^2)} \\ \sin^2 \theta &= \frac{(a^2 - 9)}{(a^2 - b^2)} \end{aligned}$$

For the given problem  $a^2 = 10$  and  $b^2 = 30/7$ . The solution is  $x\sqrt{33} + y\sqrt{7} = 3\sqrt{40}$ . □

**Solution.** (Alternative.) The tangent line is  $(y - b \sin \theta) = -\frac{b \cos \theta}{a \sin \theta}(x - a \cos \theta)$  with  $a^2 = 10$  and  $b^2 = 30/7$ . The distance to the origin, 3, implies  $3 = (a/\cos \theta) \sin \varphi$  where

$$\tan \varphi = \frac{b \cos \theta}{a \sin \theta} \quad 3 \cos \theta = a \sin \varphi \quad \text{where } a \sin \theta \tan \varphi = b \cos \theta \quad 3 \sin \theta = b \cos \varphi$$

$$9/a^2 \cos^2 \theta + 9/b^2 \sin^2 \theta = 1. \quad 9 \cos^2 \theta + 21 \sin^2 \theta = 10. \quad 12 \sin^2 \theta = 1$$

$$(y - \sqrt{35/2}) = -(x - \sqrt{55}/\sqrt{6})[\sqrt{33/7}]$$
□

**Solution.** (Alternative.) The centre of the ellipse is at the origin. The distance  $d$  between the line  $ax + by + c = 0$  and the origin is  $d = \frac{|c|}{\sqrt{a^2 + b^2}}$ . The tangent then satisfies  $a^2 + b^2 = \frac{c^2}{9}$ . The equation of the tangent passing through the point  $[x_T, y_T]$  is  $3xx_T + 7yy_T - 30 = 0$ . For coordinates of the point of tangency,

$$\begin{aligned} (3x_T)^2 + (7y_T)^2 &= 100 \\ 3x_T^2 + 7y_T^2 &= 30 \end{aligned}$$

Its solution is  $x_T = \pm\sqrt{\frac{55}{6}}$ ,  $y_T = \pm\sqrt{\frac{5}{14}}$ . Considering the symmetry of ellipse, there are four solutions

$$\pm 3\sqrt{\frac{55}{6}}x \pm 7\sqrt{\frac{5}{14}}y - 30 = 0.$$
□

**4.D.10.** A hyperbola  $x^2 - y^2 = 2$  is given. Find an equation of a hyperbola having the same foci and passing through point  $[-2, 3]$ .

**Solution.** The given hyperbola has  $a^2 = b^2 = 2$ , so  $a^2 e^2 = a^2 + b^2 = 4$ , and the foci are at  $(\pm ae, 0) = (\pm 2, 0)$ . So the desired hyperbola has equation

$$\sqrt{(x-2)^2 + y^2} - \sqrt{(x+2)^2 + y^2} = k,$$

for some constant  $k$ . Since the hyperbola passes through  $[-2, 3]$ ,  $k = 2$ . Squaring gives

$$\sqrt{(x-2)^2 + y^2} = [\sqrt{(x+2)^2 + y^2} + 2],$$

$$(x-2)^2 + y^2 = (x+2)^2 + y^2 + 4\sqrt{(x+2)^2 + y^2} + 4$$

$(-2x-1)^2 = (x+2)^2 + y^2$  or  $3x^2 = y^2 + 3$  which is the required hyperbola. □

**Solution.** (Alternative.) The equation of the desired hyperbola is  $\frac{x^2}{a^2} - \frac{y^2}{b^2} = 1$ , with its eccentricity  $e$  satisfying  $a^2e^2 = a^2 + b^2 = 4$ , since the foci are at  $[\pm ae, 0] = [\pm 2, 0]$ . The point  $[-2, 3]$  lies on the hyperbola, so  $\frac{4}{a^2} - \frac{9}{b^2} = 1$ . It follows that  $a^2 = 1, b^2 = 3$ . The desired hyperbola is  $x^2 - \frac{y^2}{3} = 1$ .  $\square$

**4.D.11.** Determine the equations of the tangent lines to the hyperbola  $4x^2 - 9y^2 = 1$ , which are perpendicular to line  $x - 2y + 7 = 0$ .

**Solution.** All lines perpendicular to the given line have an equation  $2x + y + c = 0$  for some  $c$ . So the line has an intersection with a double root with the given hyperbola. So the equation  $4x^2 - 9(-2x - c)^2 = 1$  has a double root. Hence  $(36c)^2 - 4 \cdot 32 \cdot (9c^2 + 1) = 0$ , and  $c = \pm \frac{2\sqrt{2}}{3}$ .  $\square$

**4.D.12.** Determine the tangent to the ellipse  $\frac{x^2}{16} + \frac{y^2}{9} = 1$  which is parallel with line  $x + y - 7 = 0$ .

**Solution.** The lines parallel with the given line intersect this line in a point at infinity  $(1 : -1 : 0)$ . Construct tangents to given ellipse passing through this point. The point of tangency  $T = (t_1 : t_2 : t_3)$  lies on its polar and therefore satisfies  $\frac{t_1}{16} - \frac{t_2}{9} = 0$ , so  $t_2 = \frac{9}{16}t_1$ . Substituting into the ellipse equation, we get  $t_1 = \pm \frac{16}{5}$ . The touching points of the desired tangents are  $[\frac{16}{5}, \frac{9}{5}]$  and  $[-\frac{16}{5}, -\frac{9}{5}]$ . The tangents are polars of those points. They have equations  $x + y = 5$  and  $x + y = -5$ .  $\square$

**Solution.** (Alternative). The given line has slope  $-1$ . The tangent line at  $(4 \cos \theta, 3 \sin \theta)$  has slope  $-\frac{3 \cos \theta}{4 \sin \theta}$ , so it is required that  $\tan \theta = \frac{3}{4}$ . The tangent line has equation  $(y - 3 \sin \theta) = (-1)(x - 4 \cos \theta)$  where either  $\sin \theta = 3/5$  and  $\cos \theta = 4/5$  or  $\sin \theta = -3/5$  and  $\cos \theta = -4/5$ . The two solutions are  $x + y = \pm 5$ .  $\square$

**4.D.13.** Determine the points at infinity and the asymptotes of the conic section

$$2x^2 + 4xy + 2y^2 - y + 1 = 0$$

**Solution.** The equation for the points at infinity of  $2x^2 + 4xy + 2y^2 = 0$  or rather  $2(x + y)^2 = 0$  has a solution  $x = -y$ . The only point at infinity therefore is  $(1 : -1 : 0)$ , so the conic section is a parabola. The asymptote is a polar of this point, specifically the line at infinity  $z = 0$ .  $\square$

**4.D.14.** Prove that the product of the distances between an arbitrary point on a hyperbola and both of its asymptotes is constant. Find its value.

**Solution.** Denote the point lying on the hyperbola by  $P$ . The asymptote equation of the hyperbola in canonical form is  $bx \pm ay = 0$ . Their normals are  $(b, \pm a)$  and from here we determine the projections  $P_1, P_2$  of point  $P$  to asymptotes. For the distance between point  $P$  and asymptotes we get  $|PP_{1,2}| = \frac{|aq \pm bp|}{\sqrt{a^2 + b^2}}$ . The product is therefore equal to  $\frac{a^2q^2 - b^2p^2}{a^2 + b^2} = \frac{a^2b^2}{a^2 + b^2}$ , because  $P$  lies on hyperbola.  $\square$

**4.D.15.** Compute the angle between the asymptotes of the hyperbola  $3x^2 - y^2 = 3$ .

**Solution.** For the cosine of the angle between the asymptotes of the hyperbola in canonical form,  $\cos \alpha = \frac{b^2 - a^2}{b^2 + a^2}$ . In this case the angle is 60 degrees.  $\square$

**4.D.16.** Locate the centers of the conic sections

- (a)  $9x^2 + 6xy - 2y - 2 = 0$
- (b)  $x^2 + 2xy + y^2 + 2x + y + 2 = 0$
- (c)  $x^2 - 4xy + 4y^2 + 2x - 4y - 3 = 0$
- (d)  $\frac{(x-\alpha)^2}{a^2} + \frac{(y-\beta)^2}{b^2} = 1$

**Solution.** (a) The system  $\bar{A}s + a = 0$  for computing centers is

$$\begin{aligned} 9s_1 + 3s_2 &= 0 \\ 3s_1 - 2 &= 0 \end{aligned}$$

Solve it to obtain the center at  $[\frac{2}{3}, -2]$ .

(b) In this case,

$$\begin{aligned} s_1 + s_2 + 1 &= 0 \\ s_1 + s_2 + \frac{1}{2} &= 0. \end{aligned}$$

Therefore there is no proper center (the conic section is a parabola). Moving to homogeneous coordinates we can obtain the center at infinity  $(1 : -1 : 0)$ .

(c) The coordinates of the center in this case satisfy

$$\begin{aligned} s_1 - 2s_2 + 1 &= 0 \\ -2s_1 + 4s_2 - 2 &= 0. \end{aligned}$$

The solution is the line of centers. This is so because the conic section is degenerate: it is a pair of parallel lines.

(d) The center is at  $(\alpha, \beta)$ . The coordinates of the center therefore give the translation of the coordinate system to the frame in which the ellipse has its basic form.

□

**4.D.17.** Find the equations of the axes of the conic section  $6xy + 8y^2 + 4y + 2x - 13 = 0$ .

**Solution.** The major and minor axes of the conic section are in the direction of the eigenvectors of matrix  $\begin{pmatrix} 0 & 3 \\ 3 & 8 \end{pmatrix}$ . The characteristic equation has the form  $\lambda^2 - 8\lambda - 9 = 0$ . The eigenvalues are therefore  $\lambda_1 = -1, \lambda_2 = 9$ . The corresponding eigenvectors are then  $(3, -1)$  and  $(1, -3)$ . The axes are the polars of points at infinity defined by those directions. For  $(3, -1)$ , the axis equation is  $-3x + y + 1 = 0$ . For  $(1, -3)$  it is  $-9x - 21y - 5 = 0$ .

□

**4.D.18.** Determine the equations of the axes of the conic section  $4x^2 + 4xy + y^2 + 2x + 6y + 5 = 0$ .

**Solution.** The eigenvalues of the matrix  $\begin{pmatrix} 4 & 2 \\ 2 & 1 \end{pmatrix}$  are  $\lambda_1 = 0, \lambda_2 = 5$  and the corresponding eigenvectors are  $(-1, 2)$  and  $(2, 1)$ . There is one axis  $2x + y + 1 = 0$ , and the conic section is a parabola.

□

4.D.19. The equation

$$x^2 + 3xy - y^2 + x + y + 1 = 0.$$

defines a conic section. Determine its center, axes, asymptotes and foci.

**4.D.20.** Find the equation of the tangent at  $P=[1, 1]$  to the conic section

$$4x^2 + 5y^2 - 8xy + 2y - 3 = 0$$

**Solution.** By projecting, this is a conic section defined by the quadratic form  $(x, y, z)A(x, y, z)^T$  with matrix

$$A = \begin{pmatrix} 4 & -4 & 0 \\ -4 & 5 & 1 \\ 0 & 1 & -3 \end{pmatrix}$$

Using the previous theorem, the tangent is a polar of P, which has homogenous coordinates  $(1 : 1 : 1)$ . It is given by equation  $(1, 1, 1)A(x, y, z)^T = 0$ , which in this case gives

$$2y - 2z = 0$$

Moving back to inhomogeneous coordinates, the tangent line equation is  $y = 1$ .

□

**4.D.21.** Find the coordinates of the intersection of the  $y$  axis and the conic section defined by

$$5x^2 + 2xy + y^2 - 8x = 0$$

**Solution.** The  $y$  axis, is the line  $x = 0$ . It is the polar of the point P with homogeneous coordinates  $\langle p \rangle = (p_1 : p_2 : p_3)$ . That means that the equation  $x = 0$  is equivalent to the polar equation  $F(p, v) = p^T A v = 0$ , where  $v = (x, y, z)^T$ . This is satisfied when  $A p = (\alpha, 0, 0)^T$  for some  $\alpha \in \mathbb{R}$ . This condition gives the conic section matrix

$$A = \begin{pmatrix} 5 & 1 & -4 \\ 1 & 1 & 0 \\ -4 & 0 & 0 \end{pmatrix}$$

equation system

$$\begin{aligned} 5p_1 + p_2 - 4p_3 &= \alpha \\ p_1 + p_2 &= 0 \\ -4p_1 &= 0 \end{aligned}$$

We can find the coordinates of P by the inverse matrix,  $p = A^{-1}(\alpha, 0, 0)^T$ , or solve the system directly by backward substitution. In this case we can easily obtain solution  $p = (0, 0, -\frac{1}{4}\alpha)$ . So the  $y$  axis touches the conic section at the origin.

□

**4.D.22.** Find a touch point of the line  $x = 2$  with the conic section from the previous exercise.

**Solution.** The line has equation  $x - 2z = 0$  in its projective extension and therefore we get the condition  $A p = (\alpha, 0, -2\alpha)$  for the touch point P, which gives

$$\begin{aligned} 5p_1 + p_2 - 4p_3 &= \alpha \\ p_1 + p_2 &= 0 \\ -4p_1 &= -2\alpha \end{aligned}$$

Its solution is  $p = (\frac{1}{2}\alpha, -\frac{1}{2}\alpha, \frac{1}{4}\alpha)$ . These homogeneous coordinates are equivalent to  $(2, -2, 1)$  and hence the touch point has coordinates  $[2, -2]$ . □

**4.D.23.** Find equations of the tangents passing through  $P = [3, 4]$  to the conic defined by

$$2x^2 - 4xy + y^2 - 2x + 6y - 3 = 0.$$

**Solution.** Suppose that the point of tangency  $T$  has homogeneous coordinates given by a multiple of the vector  $t = (t_1, t_2, t_3)$ . The condition that  $T$  lies on the conic section is  $t^T A t = 0$ , which gives

$$2t_1^2 - 4t_1 t_2 + t_2^2 - 2t_1 t_3 + 6t_2 t_3 - 3t_3^2 = 0$$

The condition that P lies on the polar of T is  $p^T A t = 0$ , where  $p = (3, 4, 1)$  are the homogeneous coordinates of point P. In this case, the equation gives

$$(3, 4, 1) \begin{pmatrix} 2 & -2 & -1 \\ -2 & 1 & 3 \\ -1 & 3 & -3 \end{pmatrix} \begin{pmatrix} t_1 \\ t_2 \\ t_3 \end{pmatrix} = -3t_1 + t_2 + 6t_3 = 0$$

Now we can substitute  $t_2 = 3t_1 - 6t_3$  to the previous quadratic equation. Then

$$-t_1^2 + 4t_1 t_3 - 3t_3^2 = 0$$

Because the equation is not satisfied for  $t_3 = 0$ , we move to inhomogeneous coordinates  $(\frac{t_1}{t_3}, \frac{t_2}{t_3}, 1)$ , for which we get

$$-\left(\frac{t_1}{t_3}\right)^2 + 4\left(\frac{t_1}{t_3}\right) - 3 = 0 \quad \text{a} \quad \frac{t_2}{t_3} = 3\left(\frac{t_1}{t_3}\right) - 6,$$

tj.  $\frac{t_1}{t_3} = 1$  a  $\frac{t_2}{t_3} = -3$ , nebo  $\frac{t_1}{t_3} = 3$  a  $\frac{t_2}{t_3} = 3$ . So the touch points have homogeneous coordinates  $(1 : -3 : 1)$  and  $(3 : 3 : 1)$ . The tangent equations are the polars of those points  $7x - 2y - 13 = 0$  and  $x = -3$ . □

**4.D.24.** Find an equation of the tangent passing through the origin to the circle

$$x^2 + y^2 - 10x - 4y + 25 = 0$$

**Solution.** The touch point  $(t_1 : t_2 : t_3)$  satisfies

$$(0, 0, 1) \begin{pmatrix} 1 & 0 & -5 \\ 0 & 1 & -2 \\ -5 & -2 & 25 \end{pmatrix} \begin{pmatrix} t_1 \\ t_2 \\ t_3 \end{pmatrix} = -5t_1 - 2t_2 + 25 = 0$$

From here we eliminate  $t_2$  and substitute into circle equation, which  $(t_1 : t_2 : t_3)$  has to be satisfied as well. We obtain the quadratic equation  $29t_1^2 - 250t_1 + 525 = 0$ , with solutions  $t_1 = 5$  and  $t_1 = \frac{105}{29}$ . We compute the coordinate  $t_2$  and get touch points  $[5, 0]$  and  $[\frac{105}{29}, \frac{100}{29}]$ . The tangents are polars of those points with equations  $y = 0$  and  $20x - 21y = 0$ .  $\square$

**4.D.25.** Find tangents equations to circle  $x^2 + y^2 = 5$  which are parallel with  $2x + y + 2 = 0$ .

**Solution.** In the projective extension, these tangents intersect at the point at infinity satisfying  $2x + y + z = 0$ , so in point with homogeneous coordinates  $(1 : -2 : 0)$ . They are tangents from this point to the circle. We can use the same method as in previous exercise. The conic section matrix is diagonal with the diagonal  $(1, 1, -5)$  and therefore the touch point  $(t_1 : t_2 : t_3)$  of the tangents satisfies  $t_1 - 2t_2 = 0$ . Substitute into the circle equation to get  $5t_2^2 = 5$ . Since  $t_2 = \pm 1$ , the touch points are  $[2, 1]$  and  $[-2, -1]$ .  $\square$

**Solution.** Alternative. The point  $P = \sqrt{5}(\cos \theta, \sin \theta)$  lies on the circle for all  $\theta$ . The tangent line at  $P$  is  $x \cos \theta + y \sin \theta = \sqrt{5}$ . This has slope  $-(\cos \theta)/(\sin \theta)$  which is  $-2$  provided  $\tan \theta = 1/2$ . It follows that  $P$  is at either  $[2, 1]$  or  $[-2, -1]$ .  $\square$

A tangent line touching the conic section at infinity is called an *asymptote*. The number of asymptotes of a conic section equals the number of intersections between the conic section and the line at infinity. So the ellipse has no real asymptotes, the parabola has one (which is however a line at infinity) and the hyperbola has two.

**4.D.26.** Find the points at infinity and the asymptotes of the conic section defined by

$$4x^2 - 8xy + 3y^2 - 2y - 5 = 0$$

**Solution.** First, rewrite the conic section in homogeneous coordinates.

$$4x^2 - 8xy + 3y^2 - 2yz - 5z^2 = 0$$

the homogeneous coordinates  $(x : y : 0)$  satisfying this equation, which means

$$4x^2 - 8xy + 3y^2 = 0.$$

It follows that either:  $\frac{x}{y} = -\frac{1}{2}$  or  $\frac{x}{y} = -\frac{3}{2}$ . The conic section is therefore a hyperbola with points at infinity  $P = (-1 : 2 : 0)$  and  $Q = (-3 : 2 : 0)$ .

$$(-1, 2, 0) \begin{pmatrix} 4 & -4 & 0 \\ -4 & 3 & -1 \\ 0 & -1 & -5 \end{pmatrix} \begin{pmatrix} x \\ y \\ 1 \end{pmatrix} = -12x + 10y - 2 = 0$$

and

$$(-3, 2, 0) \begin{pmatrix} 4 & -4 & 0 \\ -4 & 3 & -1 \\ 0 & -1 & -5 \end{pmatrix} \begin{pmatrix} x \\ y \\ 1 \end{pmatrix} = -20x + 18y - 2 = 0$$

$\square$

There are further exercises on conic sections on the page [270](#).

**4.D.27. Harmonic cross-ratio.** If the cross-ratio of four points lying on the line equals  $-1$ , we talk about a *harmonic quadruple*. Let  $ABCD$  be a quadrilateral. Denote by  $K$  the intersection of the lines  $AB$  and  $CD$ , by  $M$  the intersection of

the lines  $AD$  and  $BC$ . Further let  $L, N$  be the intersection of  $KM$  and  $AC, BD$  respectively. Show that the points  $K, L, M, N$  are a harmonic quadruple. ○

**Exercise solution**

**4.A.9.** 2, 3, 4, 6, 7, 8. Find planes the positions of which correspond to each of those numbers.

**4.B.12.** For the normal vector  $(a, b, c)$  of such planes  $ax + by + cz = d$ ,  $a + b = 0$  since  $(a, b, c)$  must be orthogonal to the direction of  $p$ .  $a = d$  since the plane contains  $(1, 0, 0)$ . So the plane is  $ax - ay + cz = a$ . If  $a = 0$ , then the plane is  $z = 0$ . The angle condition requires  $\cos 60^\circ = \frac{1}{2} = \frac{a+b+c}{\sqrt{a^2+b^2+c^2}\sqrt{3}}$

and by choosing  $a = -b = 1$  (vector  $(0, 0, 1)$  does not satisfy the conditions, so by certain multiplication we can get  $a = -b = 1$ ) we then get, using the angle condition,  $\left| \frac{c}{\sqrt{3}\sqrt{2+c^2}} \right| = \frac{1}{2}$ , altogether, the sought equations are  $x - y \pm \sqrt{6} - 1 = 0$ .

**4.B.17.**  $(-1, 3, 2)$ .

**4.D.1.** Line  $(2t, t, 7t) + [-5, 0, -9]$ .

**4.D.2.**  $[3, 2, 1][8/3, 8/3, 2/3]$ .

**4.D.3.** The transversal  $[1, 1, 1][-3, 1, -1]$  is of length  $\sqrt{20}$ , so the stick is not long enough.

**4.D.4.**  $\frac{2\sqrt{6}}{9}$

**4.D.5.**  $\frac{\sqrt{3}}{6}$ .

**4.D.6.**  $\frac{\sqrt{3}}{\sqrt{11}}$

## Establishing the ZOO

which functions do we need for our models?  
– a thorough menagerie

### A. Polynomial interpolation

Let us start with some examples which will hopefully make us more comfortable with polynomials.

**5.A.1.** Determine the sum of coefficients of the polynomial  $(1 - 2x + 3x^2 - x^3)^r$ , where  $r$  is your age in years.

**Solution.** The sum of coefficients of a polynomial is equal to its value in 1. Therefore the sum is  $(1 - 2 + 3 - 1)^r = 1^r = 1$ .  $\square$

**5.A.2.** Determine the coefficient by  $x^{120}$  of the polynomial  $P(x) = (1 - x + x^2 - x^3 + \dots - x^{49})(1 + x + x^2 + \dots + x^{101})$ .

**Solution.**

$$\begin{aligned} P(x) &= \frac{1 - x^{50}}{1 + x} \frac{1 - x^{102}}{1 - x} = (1 - x^{50}) \frac{1 - x^{102}}{1 - x^2} \\ &= (1 - x^{50})(1 + x^2 + x^4 + \dots + x^{100}) \\ &= 1 + x^2 + \dots + x^{48} - x^{102} - \dots - x^{150}. \end{aligned}$$

The coefficient by  $x^{120}$  is  $-1$ .  $\square$

In this chapter, we start using tools allowing us to model dependencies which are neither linear, nor discrete. Such models are often needed when dealing with time dependent systems. We try to describe them not only at discrete moments of time, but “continuously”. Sometimes this is advantageous, for instance in physical models of classical mechanics and engineering. It might also be appropriate and computationally effective to employ an approximation of discrete models in economics, chemistry, or biology. In particular such ideas may be appropriate in relation to stochastic models, as we shall see in Chapter 10.

The key concept is that of a function, also called a “signal” in practical applications. The larger the class of functions used, the more difficult is the development of effective tools. On the other hand, if there are only a few simple types of functions available, it may be that some real situations cannot be modelled at all.

The objective of the following two chapters is thus to introduce explicitly the most elementary functions of real variables. It is also to describe implicitly many more functions, and to build the standard tools to use them. This is the differential and integral calculus of one variable. While the focus has been mainly on the part of mathematics called *algebra*, the emphasis will now be on *mathematical analysis*. The link between the two is provided by a “geometric approach”. If possible, this means building concepts and intuition independently of any choice of coordinates. Often this leads to a discrete (finite) description of the objects of interest. This is immediate when working with polynomials now.

### 1. Polynomial interpolation

In the previous chapters, we often worked with sequences of real or complex numbers, i.e. with scalar functions  $\mathbb{N} \rightarrow \mathbb{K}$  or  $\mathbb{Z} \rightarrow \mathbb{K}$ , where  $\mathbb{K}$  is a given set of numbers. We also worked with sequences of vectors over real or complex numbers.

Recall the discussion from paragraph 1.1.6, about dealing with scalar functions. This discussion is adequate to work with functions  $\mathbb{R} \rightarrow \mathbb{R}$  (*real-valued functions of one real variable*), or  $\mathbb{R} \rightarrow \mathbb{C}$  (*complex-valued functions of one real variable*), or sometimes more generally the *vector-valued functions of one real variable*  $\mathbb{R} \rightarrow V$ . The results can usually be

**5.A.3.** Prove that any real solution  $x_0$  of the equation  $x^3 + px + q = 0$  ( $p, q \in \mathbb{R}$ ) satisfies the inequality  $4qx_0 \leq p$ .

**Solution.** Note that  $x_0$  is the solution of the quadratic equation  $x_0x^2 + px + q = 0$ , therefore its discriminant  $p^2 - 4x_0p$  is non-negative.  $\square$

**5.A.4.** Let  $P(x)$  be a polynomial of degree at most  $n, n \geq 1$ , such that

$$P(k) = \frac{n+1-k}{k+1}$$

for  $k = 0, 1, \dots, n$ . Find  $P(n+1)$ .

**Solution.** Let  $Q(x) = (x+1)P(x) - (n+1-x)$ . Note that  $Q(x)$  has degree  $n+1$  and the condition from the problem statement now says that  $(n+1)$  numbers  $0, 1, \dots, n$  are roots of the polynomial, that is  $Q(x) = K \cdot x \cdot (x-1) \cdots (x-n)$ . Now we use the two expressions of  $Q(x)$  to determine  $K$ . On one hand  $Q(-1) = -(n+2)$ , but  $Q(-1) = K \cdot (-1)^{n+1} \cdot (n+1)!$  as well. Thus

$$K = \frac{(-1)^n(n+2)}{(n+1)!}$$

that is  $Q(n+1) = (-1)^n(n+2)$ . On the other hand from our definition of  $Q(x)$  we get  $Q(n+1) = (n+2)P(n+1)$ . All together  $P(n+1) = (-1)^n$ .  $\square$

**5.A.5.** Let  $P(x)$  be a polynomial with real non-negative coefficients. Prove, that if  $P(\frac{1}{x})P(x) \geq 1$  for  $x = 1$  than the same inequality holds for every positive  $x$ .

**Solution.** Let  $P(x) = a_nx^n + a_{n-1}x^{n-1} + \dots + a_1x + a_0$ . From the problem statement we have  $P(1)^2 \geq 1$ . Further

$$\begin{aligned} P(x)P\left(\frac{1}{x}\right) &= (a_nx^n + a_{n-1}x^{n-1} + \dots + a_1x + a_0) \\ &\quad \cdot (a_nx^{-n} + a_{n-1}x^{-(n-1)} + \dots + a_1x^{-1} + a_0) \\ &= \sum_{i=0}^n a_i^2 + \sum_{i < j} a_i a_j (x^{j-i} + x^{i-j}) \\ &\geq \sum_{i=0}^n a_i^2 + 2 \sum_{i < j} a_i a_j = P(1)^2 \geq 1 \end{aligned}$$

where we have used the well known inequality  $x + \frac{1}{x} \geq 2$  which holds for any positive real number  $x$  (equivalent to  $(\sqrt{x} - \frac{1}{\sqrt{x}})^2 \geq 0$ ).  $\square$

Now we will try to approximate functions by polynomials. Suppose we have incomplete information about an unknown function, namely the values it takes at several points, or the values of its first or second derivatives at those points

extended to cases concerning vector values over the considered scalars, rather than just real and complex numbers.

We begin with some easily computable functions.

**5.1.1. Polynomials.** We can add and multiply scalars.

These operations satisfy a number of properties which we listed in the paragraphs 1.1.1 and 1.1.5. If we admit any finite number of these operations, leaving one of the variables as an unknown and fixing the other scalars, we obtain the polynomial functions. We consider the scalars  $\mathbb{K} = \mathbb{R}, \mathbb{C}$ , or  $\mathbb{Q}$ .

### POLYNOMIALS

A *polynomial* over a ring of scalars  $\mathbb{K}$  is a mapping  $f : \mathbb{K} \rightarrow \mathbb{K}$  given by the expression

$$f(x) = a_nx^n + a_{n-1}x^{n-1} + \dots + a_1x + a_0,$$

where  $a_i, i = 0, \dots, n$ , are fixed scalars. Multiplication is indicated by juxtaposition of symbols, and “+” denotes addition. If  $a_n \neq 0$ , the polynomial  $f$  is said to have *degree*  $n$ . The degree of the zero polynomial is undefined. The scalars  $a_i$  are called the *coefficients of the polynomial*  $f$ .

The polynomials of degree zero are exactly the non-zero constant mappings. In algebra, polynomials are more often defined as formal expressions of the aforementioned form of  $f(x)$ , i. e. a polynomial is defined to be a sequence  $a_0, a_1, \dots$  of coefficients such that only finitely many of them are non-zero. However, we will show shortly that these approaches are equivalent for our choices of scalars.

It is easy to verify that the polynomials over a given ring of scalars form a ring. Multiplication and addition of polynomials are given by the operations in the original ring  $\mathbb{K}$  by the values of the polynomials. Hence,

$$(f \cdot g)(x) = f(x) \cdot g(x), \quad (f + g)(x) = f(x) + g(x),$$

where the operations on the left-hand side are interpreted in the ring of polynomials whereas the operations on the right-hand side are of the ring of scalars (see the second part of Chapter 12 for detailed algebraic treatment).

**5.1.2. Division of polynomials.** As already mentioned, the scalar fields used are  $\mathbb{Q}, \mathbb{R}$ , or  $\mathbb{C}$ . In all of these fields, the following holds:

### EUCLIDEAN DIVISION OF POLYNOMIALS

**Proposition.** For any two polynomials  $f$  of degree  $n$  and  $g$  of degree  $m$ , there is exactly one pair of polynomials  $q, r$  such that  $f = q \cdot g + r$ , where either  $r = 0$ , or the degree of  $r$  is less than  $m$ .

**PROOF.** This is a special simple case of the much more general algebraic result in 12.2.6. Write  $f(x) = a_nx^n + a_{n-1}x^{n-1} + \dots + a_1x + a_0$  for the polynomial of degree  $n$ , and  $g(x) = b_mx^m + b_{m-1}x^{m-1} + \dots + b_1x + b_0$ , with  $a_n \neq 0$  and  $b_m \neq 0$ .

as well. We will try to find a polynomial (of the least degree possible) satisfying these dependencies.

**5.A.6.** Find a polynomial  $P$  satisfying the following conditions:

$$\begin{aligned} P(2) &= 1, P(3) = 0, \\ P(4) &= -1, P(5) = 6. \end{aligned}$$

**Solution.** First, let us solve this task by creating a system of four linear equations in four variables. Suppose the polynomial is of the form  $a_3x^3 + a_2x^2 + a_1x + a_0$ . We know there is exactly one polynomial of degree less than four and satisfying the given conditions.

$$\begin{aligned} a_0 + 2a_1 + 4a_2 + 8a_3 &= 1 \\ a_0 + 3a_1 + 9a_2 + 27a_3 &= 0 \\ a_0 + 4a_1 + 16a_2 + 64a_3 &= -1 \\ a_0 + 5a_1 + 25a_2 + 125a_3 &= 6. \end{aligned}$$

Each equation arose from one of the given conditions.

Another option is to construct the required polynomial from the fundamental Lagrange polynomials.

(see 5.1.4):

$$\begin{aligned} P(x) &= 1 \cdot \frac{(x-3)(x-4)(x-5)}{(2-3)(2-4)(2-5)} + 0 \cdot (\dots) \\ &\quad + (-1) \cdot \frac{(x-2)(x-3)(x-5)}{(4-2)(4-3)(4-5)} \\ &\quad + 6 \cdot \frac{(x-2)(x-3)(x-4)}{(5-2)(5-3)(5-4)} \\ &= \frac{4}{3}z^3 - 12z^2 + \frac{101}{3}z - 29. \end{aligned}$$

The coefficients of the polynomial form, of course, the solution of the aforementioned system of linear equations.  $\square$

The methods from the previous example can be applied to complex valued polynomials as well:

**5.A.7.** Find a polynomial  $P$  satisfying the following conditions:

$$P(1+i) = i, P(2) = 1, P(3) = -i.$$

**5.A.8.** For pairwise distinct points  $x_0, \dots, x_n \in \mathbb{R}$ , consider the elementary Lagrange polynomials (5.1.4):

$$l_i(x) = \frac{(x-x_0) \cdots (x-x_{i-1})(x-x_{i+1}) \cdots (x-x_n)}{(x_i-x_0) \cdots (x_i-x_{i-1})(x_i-x_{i+1}) \cdots (x_i-x_n)},$$

$x \in \mathbb{R}, i = 0, \dots, n.$

Prove that

$$\sum_{i=0}^n l_i(x) = 1 \quad \text{for all } x \in \mathbb{R}.$$

Consider uniqueness. Suppose there are polynomials  $q, q', r,$  and  $r'$ , such that

$$f = q \cdot g + r = q' \cdot g + r'.$$

Then subtraction gives  $0 = (q - q') \cdot g + (r - r')$ .

If  $q = q'$ , then also  $r = r'$ . If  $q \neq q'$ , then the term of highest degree in  $(q - q') \cdot g$  cannot be replicated in  $r - r'$ . This leads to a contradiction. This proves uniqueness.

It remains to prove that  $f$  can always be expressed in the desired form. If  $m > n$ , then  $f = 0 \cdot g + f$  satisfies the requirements. So suppose that  $n \geq m$ . The result is proved by induction on the degree of  $f$ .

If  $f$  is of degree zero, then the statement is trivial. Suppose the statement holds for all polynomials  $f$  of degree less than  $n > 0$ . Put

$$h(x) = f(x) - \frac{a_n}{b_m} x^{n-m} g(x)$$

If  $h(x)$  is the zero polynomial, then  $f$  is of the desired form. Otherwise  $h(x)$  is a polynomial of degree less than that of  $f$  and so  $h$  can be written in the desired form as  $h(x) = q \cdot g + r$ . But then

$$f(x) = h(x) + \frac{a_n}{b_m} x^{n-m} g(x) = (q + \frac{a_n}{b_m} x^{n-m})g(x) + r$$

and the proof is complete.  $\square$

If  $f(b)$  equals zero for some element  $b \in \mathbb{K}$ , then  $0 = f(b) = q(b) \cdot 0 + r$ , so  $r = 0$ . Consequently  $f(x) = (x-b)q(x)$ .  $b$  is called a *root of the polynomial*  $f$ . The degree of  $q$  is then  $n - 1$ . If  $q$  also has a root, we can continue and in no more than  $n$  steps we arrive at a constant polynomial. It follows that the number of roots of any non-zero polynomial over the field  $\mathbb{K}$  is at most the degree of the polynomial. Hence the following observation:

**Corollary.** *If the field of scalars  $\mathbb{K}$  is infinite, then the polynomials  $f$  and  $g$  are equal as mappings if and only if they are equal as sequences of coefficients.*

**PROOF.** Suppose that  $f = g$ , i.e.  $f - g = 0$ , as a mapping. Then the polynomial  $(f - g)(x)$  has infinitely many roots, which is possible only if it is the zero polynomial.  $\square$

Notice that of course, this statement does not hold for finite fields. A simple counter-example is the polynomial  $x^2 + x$  over  $\mathbb{Z}_2$  which represents a constant zero mapping.

**5.1.3. Interpolation polynomial.** It is often desirable to use an easily computable expression for a function which is given by its values at some given points  $x_0, \dots, x_n$ . Mostly this would be an approximation of an unknown function represented by the finite values only. We look for such polynomials.

If the values were all zeros, we can immediately find a polynomial of degree  $n + 1$ , namely

$$f(x) = (x - x_0)(x - x_1) \cdots (x - x_n).$$

This is zero at these points and only at them. However, there are other polynomials which are zero at the given points. For

**Solution.** Apparently,

$$\begin{aligned} \sum_{i=0}^n l_i(x_0) &= 1 + 0 + \cdots + 0 = 1, \\ \sum_{i=0}^n l_i(x_1) &= 0 + 1 + \cdots + 0 = 1, \\ &\vdots \\ \sum_{i=0}^n l_i(x_n) &= 0 + 0 + \cdots + 1 = 1. \end{aligned}$$

This means that the polynomial  $\sum_{i=0}^n l_i(x)$  of degree not greater than  $n$  takes the value 1 at the  $n+1$  points  $x_0, \dots, x_n$ . However, there is exactly one such polynomial, namely the constant polynomial  $y \equiv 1$ .  $\square$

**5.A.9.** Find a polynomial  $P$  satisfying the following conditions:

$$P(1) = 0, P'(1) = 1, P(2) = 3, P'(2) = 3.$$

**Solution.** Once again, we will provide two methods of finding the polynomial.

The given conditions give rise to four linear equations for the coefficients of the wanted polynomial. So if we look for a polynomial of degree less than four, we get the same number of equations and unknown coefficients (let us say  $P(x) = a_3x^3 + a_2x^2 + a_1x + a_0$ ):

$$\begin{aligned} P(1) &= a_3 + a_2 + a_1 + a_0 = 0, \\ P'(1) &= 3a_3 + 2a_2 + a_1 = 1, \\ P(2) &= 8a_3 + 4a_2 + 2a_1 + a_0 = 3, \\ P'(2) &= 12a_3 + 4a_2 + a_1 = 3. \end{aligned}$$

By solving this system, we obtain the polynomial  $P(x) = -2x^3 + 10x^2 - 13x + 5$ .

**Another solution.** We will use fundamental Hermite polynomials:

$$\begin{aligned} h_1^1(x) &= \left(1 - \frac{2}{0 + (-1)}(x - 1)\right) (2 - x)^2 \\ &= (2x - 1)(x - 2)^2, \\ h_2^1(x) &= (5 - 2x)(x - 1)^2, \\ h_1^2(x) &= (x - 1)(x - 2)^2, \\ h_2^2(x) &= (x - 2)(x - 1)^2. \end{aligned}$$

Altogether,

$$\begin{aligned} P(x) &= 0 \cdot h_1^1(x) + 3 \cdot h_2^1(x) + 1 \cdot h_1^2(x) + 3 \cdot h_2^2(x) \\ &= -2x^3 + 10x^2 - 13x + 5. \end{aligned}$$

$\square$

instance the zero polynomial, which is the only such polynomial in the vector space of polynomials of degree at most  $n$ . The general situation is analogous:

INTERPOLATION POLYNOMIALS

Let  $\mathbb{K}$  be an infinite field of scalars. An *interpolation polynomial*  $f$  for the set of (pairwise distinct) points  $x_0, \dots, x_n \in \mathbb{K}$  and given values  $y_0, \dots, y_n \in \mathbb{K}$  is either the zero polynomial, or a polynomial of degree at most  $n$  such that  $f(x_i) = y_i$  for all  $i = 0, 1, \dots, n$ .

**Theorem.** For every set of  $n + 1$  (pairwise distinct) points  $x_0, \dots, x_n \in \mathbb{K}$  and given values  $y_0, \dots, y_n \in \mathbb{K}$ , there is exactly one interpolation polynomial  $f$ .

**PROOF.** If  $f$  and  $g$  are interpolation polynomials with the same defining values, then their difference is a polynomial of degree  $n$  which has at least  $n + 1$  roots, and thus  $f - g = 0$ . This proves uniqueness.

It remains to prove the existence. Label the coefficients of the polynomial  $f$  of degree  $n$ :

$$f = a_n x^n + \cdots + a_1 x + a_0.$$

Substituting the desired values leads to a system of  $n+1$  equations for the same number of unknown coefficients  $a_i$

$$\begin{aligned} a_0 + x_0 a_1 + \cdots + (x_0)^n a_n &= y_0 \\ &\vdots \\ a_0 + x_n a_1 + \cdots + (x_n)^n a_n &= y_n. \end{aligned}$$

The existence of a solution of this system is easily shown by constructing the polynomial by using the Lagrange polynomials for the given points  $x_0, \dots, x_n$ . (See below).

However, the proof can be concluded by using only basic knowledge from linear algebra. This system of linear equations has a unique solution if the determinant of its matrix is a non-zero scalar (see 2.3.5 and 2.2.11). The determinant is the *Vandermonde determinant*, which was discussed in the exercise 2.B.7 on page 89.

Since it is verified that for zero right-hand sides, there is exactly one solution, we know that this determinant must be non-zero.

Since polynomials are equal as mappings if and only if they are equal as sequences of coefficients, the theorem is proved.  $\square$

**5.A.10.** Using Lagrange interpolation, approximate  $\cos^2 1$ . Use the values the function takes at the points  $\frac{\pi}{4}$ ,  $\frac{\pi}{3}$ , and  $\frac{\pi}{2}$ .

**Solution.** First, we determine the mentioned values:  $\cos^2(\frac{\pi}{4}) = 1/2$ ,  $\cos^2(\frac{\pi}{3}) = 1/4$ ,  $\cos^2(\frac{\pi}{2}) = 0$ . Then, we determine the elementary Lagrange polynomials, calculating their values at the given point.

$$l_0(1) = \frac{(1 - \frac{\pi}{3})(1 - \frac{\pi}{2})}{(\frac{\pi}{4} - \frac{\pi}{3})(\frac{\pi}{4} - \frac{\pi}{2})} = 8 \frac{(\pi - 3)(\pi - 2)}{\pi^2},$$

$$l_1(1) = \frac{(1 - \frac{\pi}{4})(1 - \frac{\pi}{2})}{(\frac{\pi}{3} - \frac{\pi}{4})(\frac{\pi}{3} - \frac{\pi}{2})} = -9 \frac{(\pi - 4)(\pi - 2)}{\pi^2},$$

$$l_2(1) = \frac{(1 - \frac{\pi}{4})(1 - \frac{\pi}{3})}{(\frac{\pi}{2} - \frac{\pi}{4})(\frac{\pi}{2} - \frac{\pi}{3})} = 2 \frac{(\pi - 4)(\pi - 3)}{\pi^2}.$$

Altogether,

$$\begin{aligned} P(1) &= \frac{1}{2} \cdot 8 \frac{(\pi - 3)(\pi - 2)}{\pi^2} - \frac{1}{4} \cdot 9 \frac{(\pi - 4)(\pi - 2)}{\pi^2} + 0 = \\ &= \frac{(7\pi - 12)(\pi - 2)}{4\pi^2} \doteq 0.288913. \end{aligned}$$

We may notice we did not need to calculate the third elementary polynomial. The actual value is  $\cos^2 1 \doteq 0.291927$ .

□

**5.A.11.** Joe needs to calculate values of the sine function with a calculator capable of basic arithmetic operations only. As he remembers the sine's values at the points  $0$ ,  $\frac{\pi}{6}$ ,  $\frac{\pi}{4}$ ,  $\frac{\pi}{3}$ ,  $\frac{\pi}{2}$  and knows that  $\pi$ ,  $\sqrt{2}$ , and  $\sqrt{3}$  are approximately 3.1416, 1.4142, and 1.7321, respectively, he decided to use interpolation. Help him build an approximate formula, using all of the given values.

**Solution.** We will construct the elementary Lagrange polynomials:

$$\begin{aligned} l_0(x) &= \frac{(x - \frac{\pi}{6})(x - \frac{\pi}{4})(x - \frac{\pi}{3})(x - \frac{\pi}{2})}{(0 - \frac{\pi}{6})(0 - \frac{\pi}{4})(0 - \frac{\pi}{3})(0 - \frac{\pi}{2})} \\ &\doteq 1.4783x^4 - 5.8052x^3 + 8.1057x^2 - 4.7746x + 1, \end{aligned}$$

$$\begin{aligned} l_1(x) &= \frac{(x - 0)(x - \frac{\pi}{4})(x - \frac{\pi}{3})(x - \frac{\pi}{2})}{(\frac{\pi}{6} - 0)(\frac{\pi}{6} - \frac{\pi}{4})(\frac{\pi}{6} - \frac{\pi}{3})(\frac{\pi}{6} - \frac{\pi}{2})} \\ &\doteq -13.3046x^4 + 45.2808x^3 - 49.2419x^2 + 17.1887x, \end{aligned}$$

$$\begin{aligned} l_2(x) &= \frac{(x - 0)(x - \frac{\pi}{6})(x - \frac{\pi}{3})(x - \frac{\pi}{2})}{(\frac{\pi}{4} - 0)(\frac{\pi}{4} - \frac{\pi}{6})(\frac{\pi}{4} - \frac{\pi}{3})(\frac{\pi}{4} - \frac{\pi}{2})} \\ &\doteq 23.6526x^4 - 74.3070x^3 + 71.3298x^2 - 20.3718x, \end{aligned}$$

$$\begin{aligned} l_3(x) &= \frac{(x - 0)(x - \frac{\pi}{6})(x - \frac{\pi}{4})(x - \frac{\pi}{2})}{(\frac{\pi}{3} - 0)(\frac{\pi}{3} - \frac{\pi}{6})(\frac{\pi}{3} - \frac{\pi}{4})(\frac{\pi}{3} - \frac{\pi}{2})} \\ &\doteq -13.3046x^4 + 38.3146x^3 - 32.8279x^2 + 8.5943x, \end{aligned}$$

$$\begin{aligned} l_4(x) &= \frac{(x - 0)(x - \frac{\pi}{6})(x - \frac{\pi}{4})(x - \frac{\pi}{3})}{(\frac{\pi}{2} - 0)(\frac{\pi}{2} - \frac{\pi}{6})(\frac{\pi}{2} - \frac{\pi}{4})(\frac{\pi}{2} - \frac{\pi}{3})} \\ &\doteq 1.4783x^4 - 3.4831x^3 + 2.6343x^2 - 0.6366x. \end{aligned}$$

**5.1.4. Applications of interpolations.** At first sight, it may seem that real or rational polynomials, that is, polynomial functions  $\mathbb{R} \rightarrow \mathbb{R}$  or  $\mathbb{Q} \rightarrow \mathbb{Q}$ , form a very useful class of functions of one variable. We can arrange for them to attain any set of given values. Moreover, they are easily expressible, so their value at any point can be calculated without difficulties.

However, there are a number of problems when trying to use them in practice.

The first of the problems is to find quickly the polynomial which will interpolate the given data. Solving the aforementioned system of linear equations generally requires time proportional to the cube of the number of given points  $x_i$ . This is unacceptable for large data. We will demonstrate how to overcome this on one popular type of polynomial related to fixed points  $x_0, \dots, x_n$ :

#### LAGRANGE<sup>1</sup> INTERPOLATION POLYNOMIALS

The *Lagrange interpolation polynomial* is expressed in terms of the *elementary Lagrange polynomials*  $l_i$  of degree  $n$  with the properties

$$l_i(x_j) = \begin{cases} 1 & i = j \\ 0 & i \neq j \end{cases}.$$

These polynomials must (up to a constant factor) equal the expressions  $(x - x_0) \dots (x - x_{i-1})(x - x_{i+1}) \dots (x - x_n)$ . So

$$l_i(x) = \frac{\prod_{j \neq i} (x - x_j)}{\prod_{j \neq i} (x_i - x_j)}.$$

The desired Lagrange interpolation polynomial is then given by

$$f(x) = y_0 l_0(x) + y_1 l_1(x) + \dots + y_n l_n(x).$$

dat nekam poznamku o pocitani pres vzorecek s derivaci

The usage of Lagrange polynomials is especially efficient when working with different values  $y_i$  for the same set of values  $x_i$ . For in this case, the elementary polynomials  $l_i$  are already prepared.

One of the disadvantages of this expression is a large sensitivity to inaccuracies in a computation when the differences of the given values  $x_i$  are small. This is because division by these differences is required.

Another disadvantage (common to all ways of expressing the unique interpolation polynomial) is poor stability of the values of real or rational polynomials outside of the interval containing all its roots.

Soon we will develop tools for an exact description of the functions' behaviour. But even without such tools, it is clear that, according to the sign of the coefficient of the term with highest degree, the value of the polynomial will rapidly approach plus or minus infinity as  $x$  increases (or decreases).

<sup>1</sup>Joseph-Louis Lagrange (1736-1813) was a famous Italian mathematician and astronomer, who contributed in particular to celestial mechanics. His famous *Mécanique analytique* appeared in 1788. His name appears often even in this elementary textbook.

Then, the value of the interpolation polynomial  $P(x)$  is

$$0 \cdot l_0(x) + \frac{1}{2}l_1(x) + \frac{\sqrt{2}}{2}l_2(x) + \frac{\sqrt{3}}{2}l_3(x) + l_4(x) \\ \doteq 0.0288x^4 - 0.2043x^3 + 0.0214x^2 + 0.9956x.$$

□

**Additional questions:** Can Joe use this formula to calculate the sine's values at the interval  $[\frac{\pi}{2}, \pi]$ ? If not, what should he do?

What would the approximate formulae look like if he used not all five knots, but only the three nearest ones for each point?

**5.A.12.** The day after, Joe needed to calculate the binary logarithm of 25. (Actually, he needed the natural logarithm of 25, but since he knows that  $\ln 2$  is approximately 0.6931, the binary one will do.) So he took the points 16 and 32 (with values 4 and 5, respectively) and constructed the interpolation polynomial (line).

$P(x) = \frac{1}{16}x + 3$ , hence  $P(25) = \frac{73}{16} = 4.5625$ . Then, he added the point 8 (with value 3) in order to arrive at a more accurate result. In this case, the interpolation polynomial equals  $P(x) = -\frac{1}{384}x^2 + \frac{3}{16}x + \frac{5}{3}$ , which gives  $P(25) \doteq 4.7266$ . Joe wanted to obtain an even more accurate number, so he added two more points, namely 2 and 4 (with values 1 and 2, respectively). How shocked he was when he got the result  $P(25) \doteq 5.892$ , which is apparently wrong as the binary logarithm is an increasing function. Can you explain the origin of this error?

**Solution.** Joe asked Google and learned that the interpolation error can be expressed as

$$f(x) - P_n(x) = \frac{(x - x_0)(x - x_1) \dots (x - x_n)}{(n + 1)!} f^{(n+1)}(\xi),$$

where the point  $\xi$  is not known, but lies in the interval given by the least and greatest knots. The term in the fraction's numerator causes the accuracy to deteriorate by adding farther knots. □

**5.A.13.** A week later, Joe needed to approximate  $\sqrt{7}$ . He got the idea of reversing the problem and using the inverse interpolation, i.e. to interchange the roles of arguments (function inputs) and values (function outputs) and to approximate the value of an appropriate function at the point 0. Describe his procedure.

**Solution.** The function  $x^2 - 7$  takes 0 at  $\sqrt{7}$ . Joe took the points  $x_0 = 2$ ,  $x_1 = 2.5$ , and  $x_2 = 3$ , with the function values  $-3$ ,  $-0.75$ , and 2, respectively. Then he interchanged

However, the above mentioned sign is even not stable under small changes of the defining values  $y_i$ . This is illustrated by the following two diagrams, displaying eleven values of the function  $\sin(x)$  with two different small changes of values. The interpolated function  $\sin(x)$  is the dotted line, the circles are the gently moved values  $y_i$  and the uniquely determined interpolation polynomial is the solid line. While the approximation is quite good inside the interval covering the eleven points, it is very poor at the margins.

There is a rich theory about the interpolation polynomials. If interested, consult the special literature.

**5.1.5. Remark.** Numerical instability caused by the closeness of (some of) the points  $x_i$  is clearly seen in the system of equations from the proof of the Theorem 5.1.3. When solving a system of linear equations, instability is closely related to the size of the determinant of the corresponding matrix. This is the Vandermonde determinant  $V$  in our case.

**Lemma.** For any sequence of pairwise distinct scalars  $x_0, \dots, x_n \in \mathbb{K}$ ,

$$V(x_0, \dots, x_n) = \prod_{i>k=0}^n (x_i - x_k).$$

**PROOF.** The proof is by induction on the number of the points  $x_i$ . The result is true for  $n = 1$ . (The problem is completely uninteresting for  $n = 0$ ). Suppose that the result is true for  $n - 1$ , i.e.

$$V(x_0, \dots, x_{n-1}) = \prod_{i>k=0}^{n-1} (x_i - x_k).$$

Consider the values  $x_0, \dots, x_{n-1}$  to be fixed, and vary the value of  $x_n$ . Expand the determinant by the last row (see 2.2.9). This exhibits the desired determinant as the polynomial

$$(1) \quad V(x_0, \dots, x_n) = (x_n)^n V(x_0, \dots, x_{n-1}) - (x_n)^{n-1} V(x_0, \dots, x_{n-2}, x_n) + \dots$$

their roles, thus obtaining the elementary Lagrange polynomials

$$l_0(x) = \frac{(x + 0.75)(x - 2)}{(-3 + 0.75)(-3 - 2)} = \frac{4}{45}x^2 - \frac{1}{9}x - \frac{2}{15},$$

$$l_1(x) = -\frac{16}{99}x^2 - \frac{16}{99}x + \frac{32}{33},$$

$$l_2(x) = \frac{6}{55}x^2 + \frac{3}{11}x + \frac{9}{55}.$$

For  $\sqrt{7}$ , he got the approximate value  $2 \cdot l_0(0) + 2.5 \cdot l_1(0) + 3 \cdot l_2(0) = \frac{437}{165} \doteq 2.6485$ .

**Additional questions:** Joe made a mistake while constructing one of the elementary polynomials, try to find it. Does this mistake affect the resulting value?

How could we make use of the value of the derivative at the point 2.5? □

Finding a spline through given data is a tedious task for the hand computation (if we are given  $n$  ( $n \geq 2$ ) points and values in them, then we need to solve  $4n - 4$  linear equations. The matrix of this system is special though (see 5.1.9) and there are algorithms to transform the task to solve actually only  $n$  linear equations with  $n$  unknowns.

We show some "ad hoc" approach which can even more simplify the problem in a special situation.

**5.A.14.** Find a natural spline  $S$  which satisfies

$$S(-1) = 0, S(0) = 1, S(1) = 0.$$

**Solution.** The wanted spline consists of two cubic polynomials, let us denote them  $S_1$  for the interval  $[-1, 0]$  and  $S_2$  for the interval  $[0, 1]$ . The word "natural" requires that the second derivatives of  $S_1 = ax^3 + bx^2 + cx + d$  and  $S_2 = ex^3 + fx^2 + gx + h$  be zero at the points  $-1$  and  $1$ , respectively. Applying the definition of spline only, we get eight linear equations. We can reduce the system in the following way: Thanks to the given value at 0, we know that the absolute coefficients of both the polynomials are 1. The resulting spline has to be symmetric along the  $y$  axis, otherwise we would get two splines satisfying the condition by the reflection along the axis. But the spline is unique. Thus the only possibility for the common values for the first derivatives of  $S_1$  and  $S_2$  at zero is zero, further the second derivatives in zero have to agree, that is  $b = d$ , and the symmetry gives also  $a = -c$ .

So we have  $S_1(x) = ax^3 + bx^2 + 1$  and  $S_2(x) = -ax^3 + bx^2 + 1$ , Confronting these forms with the conditions

This is a polynomial of degree  $n$  since its coefficient at  $(x_n)^n$  is non-zero, by the induction hypothesis. Evidently, it vanishes at any point  $x_n = x_i$  for  $i < n$  because in that case, the original determinant contains two identical rows. The polynomial is thus divisible by the expression

$$(x_n - x_0)(x_n - x_1) \cdots (x_n - x_{n-1}),$$

which itself is of degree  $n$ . It follows that the Vandermonde determinant (as a polynomial in the variable  $x_n$ ) must, up to a multiplicative constant, be given by

$$V(x_0, \dots, x_n) = c \cdot (x_n - x_0)(x_n - x_1) \cdots (x_n - x_{n-1}).$$

Comparing the coefficients at the highest power in (1) with this expression yields

$$c = V(x_0, \dots, x_{n-1}),$$

which completes the proof. □

Notice that the value of the determinant is small if the points  $x_i$  are close together.

**5.1.6. Derivatives of polynomials.** The values of polynomials

rapidly tend to infinite values as the input variable grows. Hence polynomials are unable to describe periodic events, such as the values of the trigonometric functions. One could say that we will achieve much better results, at least between the points  $x_i$ , if we look not only at the function values, but also at the rate of increase of the function at those points.

For this purpose, we introduce (only intuitively, for the time being) the concept of a *derivative* for polynomials. Again, we can work with real, complex or rational polynomials. The rate of increase of a real-valued polynomial  $f(x)$  at a point  $x \in \mathbb{R}$  should be related to the values

$$(1) \quad \frac{f(x + \delta x) - f(x)}{\delta x},$$

where  $\delta x$  is a small value in  $\mathbb{K}$  expressing the increment of the argument  $x$ . Since we can calculate (over an arbitrary ring)

$$(x + \delta x)^k = x^k + \cdots + \binom{k}{l}x^l(\delta x)^{k-l} + \cdots + (\delta x)^k,$$

we get for the polynomial  $f(x) = a_n x^n + \cdots + a_0$ , the above quotient (1) in the form

$$\frac{f(x+\delta x)-f(x)}{\delta x} = a_n \frac{nx^{n-1}\delta x + \cdots + (\delta x)^k}{\delta x} + \cdots + a_1 \frac{\delta x}{\delta x} = na_n x^{n-1} + (n-1)a_{n-1}x^{n-2} + \cdots + a_1 + \delta x(\dots)$$

where the expression in parentheses in the end of the expression is polynomially dependent on  $\delta x$ . Clearly, for values  $\delta x$  very close to zero, there is a value arbitrarily close to the following expression:

DERIVATIVES OF POLYNOMIALS

The derivative of the polynomial  $f(x) = a_n x^n + \cdots + a_0$  with respect to the variable  $x$  is the polynomial

$$f'(x) = na_n x^{n-1} + (n-1)a_{n-1}x^{n-2} + \cdots + a_1.$$

obrazek, treba uplne explicitne pro kvadraticky pripad

$S_1(-1) = 0$  and  $S_1''(-1) = 0$  yields the following system of only two linear equations in  $a$  and  $b$ .

$$\begin{aligned} -a + b + 1 &= 0, \\ -6a + 2b &= 0. \end{aligned}$$

Having solved that, we get  $S_1(x) = -\frac{1}{2}x^3 - \frac{3}{2}x^2 + 1$ ,  $S_2(x) = \frac{1}{2}x^3 - \frac{3}{2}x^2 + 1$ . Altogether,

$$S(x) = \begin{cases} -\frac{1}{2}x^3 - \frac{3}{2}x^2 + 1 & \text{pro } x \in [-1, 0], \\ \frac{1}{2}x^3 - \frac{3}{2}x^2 + 1 & \text{pro } x \in [0, 1]. \end{cases}$$

□

You can use the same trick to solve the following problem.

**5.A.15.** Find a (cubic) spline  $S$  which satisfies

$$S(-1) = 0, S(0) = 1, S(1) = 0, S'(-1) = -1, S'(1) = 1.$$

○

**5.A.16.** Find a polynomial of degree two or less such that its values at the points

$$x_0 = -1, \quad x_1 = 1, \quad x_2 = 2$$

are

$$y_0 = 1, \quad y_1 = -3, \quad y_2 = 4,$$

respectively.

○

**5.A.17.** Construct the Lagrange interpolation polynomial for

$x_i$	-2	-1	1	2
$y_i$	1	-1	-1	1

Then find any polynomial of degree greater than three which satisfies the conditions in the table.

○

**5.A.18.** Find a polynomial  $p(x) = ax^3 + bx^2 + cx + d$  which satisfies  $p(0) = 1$ ,  $p(1) = 0$ ,  $p(2) = 1$ ,  $p(3) = 10$ .

○

**5.A.19.** Construct a polynomial  $p$  of degree three or less which satisfies  $p(0) = 2$ ,  $p(1) = 3$ ,  $p(2) = 12$ ,  $p(5) = 147$ .

○

**5.A.20.** Let the values  $y_0, \dots, y_n \in \mathbb{R}$  at pairwise distinct points  $x_0, \dots, x_n \in \mathbb{R}$ , respectively, be given. How many polynomials of degree exactly  $n + 1$  and taking the given values at the given points are there?

○

**5.A.21.** Determine the Hermite interpolation polynomials  $P$ ,  $Q$  satisfying

$$P(-1) = -11, P(1) = 1, P'(-1) = 12, P'(1) = 4;$$

$$Q(-1) = -9, Q(1) = -1, Q'(-1) = 10, Q'(1) = 2.$$

○

From the definition, it is clear that it is just the value  $f'(x_0)$  of the derivative which gives a good approximation of the polynomial's behaviour near the point  $x_0$ . More precisely, the lines

$$y = \frac{f(x_0 + \delta x) - f(x_0)}{\delta x}(x - x_0) + f(x_0),$$

that is, the secant lines of the graph of the polynomial going through the points  $[x_0, f(x_0)]$  and  $[x_0 + \delta x, f(x_0 + \delta x)]$  approach, as  $\delta x$  decreases, to the line

$$y = f'(x_0)(x - x_0) + f(x_0),$$

which is the “tangent” to the graph of the polynomial  $f$ . This is *linear approximation* to the polynomial  $f$  by its *tangent line*. Exact meaning to all these concepts is given later.

The derivative of polynomials is a linear mapping which, to polynomials of degree at most  $n$ , assigns polynomials of degree at most  $n - 1$ .

Iterating this procedure, there are the second derivative  $f''$ , the third derivative  $f^{(3)}$ , and generally after  $k$ -tuple iteration, the polynomial  $f^{(k)}$  of degree  $n - k$ . Thus the  $(n + 1)$ -st derivative is the zero polynomial. This linear mapping is an example of cyclic nilpotent mappings, which are more thoroughly examined in paragraph 3.4.10.

The derivative behaves well also with respect to the multiplication of polynomials. A straightforward combinatorial check reveals the *derivation property* or *Leibniz rule* for this linear operator :

$$(f(x) \cdot g(x))' = f'(x) \cdot g(x) + f(x) \cdot g'(x).$$

Actually this is a purely algebraic result (which holds over any ring of scalars!) and you may either check it yourself or consult the formal proof in 12.2.7.

**5.1.7. Hermite's interpolation problem.** Consider  $m + 1$

pairwise distinct real numbers  $x_0, \dots, x_m$ , i.e.  $x_i \neq x_j$  for all  $i \neq j$ . It is desired to place polynomials through given values at these points, but to determine also the first derivatives of the interpolating polynomial in these points. Set  $y_i$  and  $y'_i$  for all  $i$ . A polynomial  $f$  is wanted which will satisfy these conditions on the values and derivatives.

picture missing!

As in the case of interpolating the values only, we obtain the following system of  $2(m + 1)$  equations for the coefficients of the polynomial  $f(x) = a_n x^n + \dots + a_0$ :

$$\begin{aligned} a_0 + x_0 a_1 + \dots + (x_0)^n a_n &= y_0 \\ &\vdots \\ a_0 + x_m a_1 + \dots + (x_m)^n a_n &= y_m \\ a_1 + 2x_0 a_2 + \dots + n(x_0)^{n-1} a_n &= y'_0 \\ &\vdots \\ a_1 + 2x_m a_2 + \dots + n(x_m)^{n-1} a_n &= y'_m. \end{aligned}$$

5.A.22. Replace the function  $f$  with a Hermite polynomial, knowing following values of  $f$ :

$x_i$	-1	1	2
$f(x_i)$	4	-4	-8
$f'(x_i)$	8	-8	11

In the following exercises let  $y_i := f(x_i)$ .

5.A.23. Without calculation, determine the Hermite interpolation polynomial if the following is given:

$$x_0 = 0, x_1 = 2, x_2 = 1,$$

$$y_0 = 0, y_1 = 4, y_2 = 1,$$

$$y'_0 = 0, y'_1 = 4, y'_2 = 2.$$

5.A.24. Find a polynomial of degree three or less taking the value  $y = 4$  at the point  $x = 1$  and  $y = 9$  at  $x = 2$ , having its derivative equal to  $-2$  at  $x = 0$  and to  $1$  at  $x = 1$ . Then find a polynomial of degree three or less taking the value  $y = 6$  at both the points  $x = 1$  and  $x = -1$  and having its derivative equal to  $2$  at both these points.

5.A.25. How many polynomials satisfying the following conditions are there? The degree is four or less, the values at  $x_0 = 5$  and  $x_1 = 55$  are  $y_0 = 55$  and  $y_1 = 5$ , respectively, and both the first and second derivatives at the point  $x_0$  are zero.

5.A.26. Find any polynomial  $P$  satisfying

$$P(0) = 6, \quad P(1) = 4, \quad P(2) = 4, \quad P'(2) = 1.$$

5.A.27. Construct the natural cubic interpolation spline for the values  $y_0 = 1, y_1 = 0, y_2 = 1$  at the points  $x_0 = -1, x_1 = 0, x_2 = 1$ , respectively.

5.A.28. Construct the natural cubic interpolation spline for the function

$$f(x) = |x|, \quad x \in [-1, 1],$$

selecting the points  $x_0 = -1, x_1 = 0, x_2 = 1$ .

5.A.29. Construct the natural cubic interpolation spline for the points  $x_0 = -3, x_1 = 0, x_2 = 3$  and the values  $y_0 = -3, y_1 = 0, y_2 = 3$ .

5.A.30. Without calculation, construct the natural cubic interpolation spline for the points  $x_0 = -1, x_1 = 0$  at  $x_2 = 2$  and the value  $y_0 = y_1 = y_2 = 1$  at these points.

We could verify that with the choice  $n = 2m + 1$ , the determinant of this system is non-zero, and thus there is exactly one solution.

The polynomial  $f$  can be constructed immediately. Simply create a set of polynomials with values  $0$  or  $1$  respectively for the derivatives and the values, in order to express the desired values as the linear combination. We sketch briefly, how to construct them now, leaving the details to the reader.

The elementary Lagrange polynomials serve well for this purpose. The derivative of  $f(x) = (\ell_i(x))^2$  is  $2\ell'_i(x)\ell_i(x)$  and thus all  $x_j$  are roots of this polynomial, except for  $j = i$ . Similarly for the derivative  $f'(x)$ . But a polynomial of degree  $2m + 1$  is wanted. So we consider rather  $g(x) = (x - x_i)f(x)$ . Now the values will be all zero, while the derivative  $g'(x) = f(x) + (x - x_i)f'(x)$  has the required properties too. Thus we take  $h_i^{(2)}(x) = (x - x_i)(\ell_i(x))^2$ . This is called the *fundamental Hermitian polynomial*<sup>2</sup> of the second type.

Finally we look for a polynomial which has zero derivatives at all points  $x_i$  with the same values as  $\ell_i$  at the given points  $x_i$ . We can apply a very similar trick. Look for polynomials of the form  $h_i^{(1)}(x) = (1 - a(x - x_i))(\ell_i(x))^2$ . All  $x_j$  will be roots of this polynomial, except for  $j = i$  where the value is  $1$ . The derivative is

$$(h_i^{(1)}(x))' = -a(\ell_i(x))^2 + (1 - a(x - x_i))2\ell_i(x)\ell'_i(x).$$

All  $x_j, j \neq i$ , are roots of  $\ell_i(x)$ , thus they are also roots of this polynomial. Finally, at the point  $x_i$  we want  $0 = -a + 2\ell'_i(x_i)$ . Thus we choose  $a = 2\ell'_i(x_i)$ .

The combinatorial check that  $2\ell'_i(x_i) = \frac{\ell''(x_i)}{\ell'(x_i)}$  is left to the reader. We summarize:

<sup>2</sup>Charles Hermite (1822-1901) was a Frenchman active in many areas of Mathematics. His name is mostly linked to the Hermitian operators and matrices, cf. 3.4.6.

**5.A.31.** Construct the complete (i. e., the derivatives at the marginal points are given) cubic interpolation spline for the points  $x_0 = -3$ ,  $x_1 = -2$ ,  $x_2 = -1$  and the values  $y_0 = 0$ ,  $y_1 = 1$ ,  $y_2 = 2$ ,  $y'_0 = 1$ ,  $y'_2 = 1$ . ○

**5.A.32.** Construct the natural cubic interpolation spline for the function

$$y = \frac{1}{1+x^2},$$

selecting the points  $x_0 = 0$ ,  $x_1 = 1$ ,  $x_2 = 3$ . ○

More problems concerning polynomial interpolation can be found at 346.

**B. Topology of real numbers and their subsets**

**5.B.1.** Find limit, isolated, boundary, and interior points of the sets  $\mathbb{N}$ ,  $\mathbb{Q}$ ,  $X = \{x \in \mathbb{R}; 0 \leq x < 1\}$  as subsets of  $\mathbb{R}$ .

**Solution.** The set  $\mathbb{N}$ . For any  $n \in \mathbb{N}$ , we have that

$$\mathcal{O}_1(n) \cap \mathbb{N} = (n-1, n+1) \cap \mathbb{N} = \{n\}.$$

Hence, there is a neighborhood of  $n \in \mathbb{N}$  in  $\mathbb{R}$  which contains only one natural number (the number  $n$ ), therefore every point  $n \in \mathbb{N}$  is isolated. There are thus no interior points (an isolated point cannot be interior). A point  $a \in \mathbb{R}$  is a limit point of  $A$  if and only if every neighborhood of  $a$  contains infinitely many points of  $A$ . However, the set

$$\mathcal{O}_1(a) \cap \mathbb{N} = (a-1, a+1) \cap \mathbb{N}, \quad \text{where } a \in \mathbb{R},$$

is finite, hence  $\mathbb{N}$  has no limit points. By finiteness of this set, we have that

$$\delta_b := \inf_{n \in \mathbb{N}} |b-n| = \inf_{n \in \mathcal{O}_1(b) \cap \mathbb{N}} |b-n| > 0 \quad \text{for } b \in \mathbb{R} \setminus \mathbb{N}.$$

Therefore,  $\mathcal{O}_{\delta_b}(b) \cap \mathbb{N} = \emptyset$ , so no  $b \in \mathbb{R} \setminus \mathbb{N}$  is a boundary point of  $\mathbb{N}$ . We also know that every point which is not an interior point of a given set is necessarily its boundary point. The set of  $\mathbb{N}$ 's boundary points thus contains  $\mathbb{R}$ , and so it equals  $\mathbb{R}$ .

The set  $\mathbb{Q}$ . The rational numbers are a dense subset of the real numbers. This means that for every real number, there is a sequence of rational numbers converging to it. (We can, for instance, imagine the decimal representation of a real number and the corresponding sequence whose  $i$ -th term will be the representation truncated to the first  $i$  decimal digits. Furthermore, we can suppose that the terms of this sequence are pairwise distinct, for example by deliberately changing the

HERMITE'S 1ST ORDER INTERPOLATION POLYNOMIAL

The *fundamental Hermite polynomials* are defined as follows:

$$h_i^{(1)}(x) = \left[ 1 - \frac{\ell''(x_i)}{\ell'(x_i)}(x-x_i) \right] (\ell_i(x))^2$$

$$h_i^{(2)}(x) = (x-x_i) (\ell_i(x))^2,$$

where  $\ell(x) = \prod_{i=0}^m (x-x_i)$ ,  $\ell_i(x)$  is the elementary Lagrange polynomial. These polynomials satisfy:

$$h_i^{(1)}(x_j) = \delta_i^j = \begin{cases} 1 & \text{for } i=j \\ 0 & \text{for } i \neq j \end{cases}$$

$$(h_i^{(1)})'(x_j) = 0$$

$$h_i^{(2)}(x_j) = 0$$

$$(h_i^{(2)})'(x_j) = \delta_i^j.$$

The *Hermite's interpolation polynomial* is given by the expression

$$f(x) = \sum_{i=0}^m (y_i h_i^{(1)}(x) + y'_i h_i^{(2)}(x)).$$

**5.1.8. Examples of Hermite's polynomials.** The simplest example is the one of prescribing the value and the derivative at one point. This determines a polynomial of degree one

$$f(x) = f(x_0) + f'(x_0)(x-x_0).$$

This is exactly the equation of the straight line given by the value and slope at the point  $x_0$ . When we set the values and the derivatives at two points, i.e.  $y_0 = f(x_0)$ ,  $y'_0 = f'(x_0)$ ,  $y_1 = f(x_1)$ ,  $y'_1 = f'(x_1)$  for two distinct points  $x_i$ , we still obtain an easily computable problem.

Consider the simple case when  $x_0 = 0$ ,  $x_1 = 1$ . Then the matrix of the system and its inverse is

$$A = \begin{pmatrix} 0 & 0 & 0 & 1 \\ 1 & 1 & 1 & 1 \\ 0 & 0 & 1 & 0 \\ 3 & 2 & 1 & 0 \end{pmatrix}, \quad A^{-1} = \begin{pmatrix} 2 & -2 & 1 & 1 \\ -3 & 3 & -2 & -1 \\ 0 & 0 & 1 & 0 \\ 1 & 0 & 0 & 0 \end{pmatrix}.$$

The multiplication  $A \cdot (y_0, y_1, y'_0, y'_1)^T$  gives the vector  $(a_3, a_2, a_1, a_0)^T$  of coefficients of the polynomial  $f$ , i.e.

$$f(x) = (2y_0 - 2y_1 + y'_0 + y'_1)x^3 + (-3y_0 + 3y_1 - 2y'_0 - y'_1)x^2 + y'_0x + y_0.$$

**5.1.9. Spline interpolation.** We can prescribe any finite number of derivatives at the particular points and a convenient choice for the upper bound on the degree of the desired polynomial, leading to a unique interpolation. We will not consider the details here. Unfortunately, these interpolations do not solve the problems mentioned already – complexity of the computations and instability. However, a smarter usage of derivatives allows an improvement.

last digit, or by taking the representation with recurring nines rather than zeros, ie.  $0.999\dots$  for the integer 1 and so on). The set of  $\mathbb{Q}$ 's limit points is thus the whole  $\mathbb{R}$  and every point  $x \in \mathbb{R} \setminus \mathbb{Q}$  is a boundary point. Especially, we get that any  $\delta$ -neighborhood

$$\mathcal{O}_\delta\left(\frac{p}{q}\right) = \left(\frac{p}{q} - \delta, \frac{p}{q} + \delta\right), \quad \text{where } p, q \in \mathbb{Z}, q \neq 0,$$

of a rational number  $p/q$  contains infinitely many rational numbers, hence there are no isolated points. The number  $\sqrt{2}/10^n$  is rational for no  $n \in \mathbb{N}$ . Supposing the contrary (again,  $p, q \in \mathbb{Z}, q \neq 0$ )

$$\frac{\sqrt{2}}{10^n} = \frac{p}{q}, \quad \text{ie. } \sqrt{2} = \frac{10^n p}{q},$$

we arrive at an immediate contradiction as we know that the number  $\sqrt{2}$  is not rational. Every neighborhood of a rational number  $p/q$  thus contains infinitely many real numbers  $p/q + \sqrt{2}/10^n$  ( $n \in \mathbb{N}$ ) which are not rational ( $\mathbb{Q}$ , as a field, is closed under subtraction). Therefore, every point  $p/q \in \mathbb{Q}$  is boundary as well, and there are no interior points of the set  $\mathbb{Q}$ .

The set  $X = [0, 1]$ . Let  $a \in [0, 1]$  be an arbitrary number. Apparently, the sequences  $\{a + \frac{1}{n}\}_{n=1}^\infty, \{1 - \frac{1}{n}\}_{n=1}^\infty$  converge to  $a$  and 1, respectively. So we have easily shown that the set of  $X$ 's limit points contains the interval  $[0, 1]$ . There are no other limit points: for any  $b \notin [0, 1]$  there is  $\delta > 0$  such that  $\mathcal{O}_\delta(b) \cap [0, 1] = \emptyset$  (for  $b < 0$  it suffices to take  $\delta = -b$ , and for  $b > 1$  we can choose  $\delta = b - 1$ ). Since every point of the interval  $[0, 1]$  is a limit point, there are no isolated points. For  $a \in (0, 1)$ , let  $\delta_a$  be the less one of the two positive numbers  $a, 1 - a$ . Considering

$$\mathcal{O}_{\delta_a}(a) = (a - \delta_a, a + \delta_a) \subseteq (0, 1), \quad a \in (0, 1),$$

we see that every point of the interval  $(0, 1)$  is an interior point of  $X$ . For every  $\delta \in (0, 1)$ , we have that

$$\mathcal{O}_\delta(0) \cap [0, 1] = (-\delta, \delta) \cap [0, 1] = [0, \delta),$$

$$\mathcal{O}_\delta(1) \cap [0, 1] = (1 - \delta, 1 + \delta) \cap [0, 1] = (1 - \delta, 1],$$

so every  $\delta$ -neighborhood of the point 0 contains some points of the interval  $[0, 1]$  and some points of the interval  $(-\delta, 0)$ , and every  $\delta$ -neighborhood of 1 has a non-empty intersection with the intervals  $[0, 1], [1, 1 + \delta)$ . Therefore, 0 and 1 are boundary points. Altogether, we have found that the set of  $X$ 's interior points is the interval  $(0, 1)$  and the set of  $X$ 's boundary points is the two-element set  $\{0, 1\}$ , as we know that no point can be both interior and boundary and that a boundary point must be an interior or limit point.  $\square$

As seen in the diagrams demonstrating the instability of interpolation by a single polynomial of sufficiently large degree, small local changes of the values may dramatically affect the overall changes of the behaviour of the resulting polynomial. In particular, this may happen outside of the interval covered by the points  $x_i$ . We try gluing together polynomial pieces of low degree.

The simplest possibility is to interpolate each pair of adjacent points by a polynomial of degree at most one. This corresponds either to the interpolation by values with two points, or by guessing the slope and employing Hermite's first order interpolation at a single point. This is a common way of displaying data. This means that derivatives will be constant on each of the segments, with a discontinuous 'jump' at the given points. There is no freedom for improvements.

A more sophisticated method is to prescribe the value and the derivative at each point. We have then four values for each pair of neighbouring points. As seen earlier, this uniquely determines Hermite's polynomial of degree three. This polynomial can then be used for all the values of the input variable between the distinguished points  $x_0 < x_1$ . Such a piece-wise polynomial approximation has the property that the first derivatives will be compatible (equal) at the meeting points  $x_i$  in the interval  $[x_0, x_1]$ .

In practice, mere compatibility of the first derivatives is often insufficient. Consider for instance railway tracks, where the second derivative corresponds to acceleration. Discontinuous jumps would be very undesirable for the second derivative. Furthermore, the values of the first derivatives are usually predetermined. So instead of requiring fixed values of the first derivatives, we insist on equality of both first and second derivatives at adjacent pieces of the cubic polynomials, as well as fixing the values at the given points. This requirement yields the same number of equations and unknowns, and so the problem is solvable similarly to the 1st order Hermite interpolation problem:

#### CUBIC SPLINES

Let  $x_0 < x_1 < \dots < x_n$  be real values at which the required values  $y_0, \dots, y_n$  are given. A *cubic interpolation spline* for this assignment is a function  $S : \mathbb{R} \rightarrow \mathbb{R}$  which satisfies the following conditions:

- the restrictions of  $S$  on the intervals  $[x_{i-1}, x_i]$  are polynomials  $S_i$  of degree at most three, for all  $i = 1, \dots, n$ ,
- $S_i(x_{i-1}) = y_{i-1}$  and  $S_i(x_i) = y_i$  for all  $i = 1, \dots, n$ ,
- $S'_i(x_i) = S'_{i+1}(x_i)$  for all  $i = 1, \dots, n - 1$ ,
- $S''_i(x_i) = S''_{i+1}(x_i)$  for all  $i = 1, \dots, n - 1$ .

The cubic spline<sup>3</sup> for  $n + 1$  points consists of  $n$  cubic polynomials. There are  $4n$  free parameters (the first condition from the definition). The other conditions then yield  $2n +$

<sup>3</sup>The name comes from the name of an elastic ruler used by engineers to draw smooth curve interpolation points. In fact, the requirement on the equality of the first and second derivatives is a good model for natural elasticity behaviour.

**5.B.2.** Determine the suprema and infima of the following sets in  $\mathbb{R}$ :

$$A = (-3, 0] \cup (1, \pi) \cup \{6\}; \quad B = \left\{ \frac{(-1)^n}{n^2} \mid n \in \mathbb{N} \right\};$$

$$C = (-9, 9) \cap \mathbb{Q}.$$

**5.B.3.** Find  $\sup A$  and  $\inf A$  for

$$A = \left\{ \frac{n + (-1)^n}{n} \mid n \in \mathbb{N} \right\} \subset \mathbb{R}.$$

**5.B.4.** The following sets are given:

$$\mathbb{N} = \{1, 2, \dots, n, \dots\}, \quad \mathcal{M} = \left\{ -\frac{1}{n} \mid n \in \mathbb{N} \right\},$$

$$\mathcal{J} = (0, 2] \cup [3, 5] \setminus \{4\}.$$

Determine  $\inf \mathbb{N}$ ,  $\sup \mathcal{M}$ ,  $\inf \mathcal{J}$  and  $\sup \mathcal{J}$  in  $\mathbb{R}$ .

**5.B.5.** Find a set  $M \subset \mathbb{R}$  which does not have an infimum in  $\mathbb{R}$  but has a supremum there. Similarly, find a set  $N \subset \mathbb{R}$  which does not have a supremum in  $\mathbb{R}$  but has an infimum there.

**5.B.6.** Find a subset  $X$  of the set  $\mathbb{R}$  such that  $\sup X \leq \inf X$ .

**5.B.7.** Find sets  $A, B, C \subseteq \mathbb{R}$  such that  $A \cap B = \emptyset$ ,  $A \cap C = \emptyset$ ,  $B \cap C = \emptyset$ ,  $\sup A = \inf B = \inf C = \sup C$ .

### C. Limits

In the subsequent exercises, we will deal with calculating limits of sequences, that is what the sequences “look like at infinity”. Then, if we were to determine the  $n$ -th term of a given sequence for a very large  $n$ , the limit of the sequence (supposing it exists) can approximate it very well. We devote much space to computation of limits of sequences (and limits of functions) in this exercise column, that is why they begin earlier (and end later) than in the part concerning theory.

Let us begin with limits of sequences. The needful definitions can be found at page. 292.

$(n - 1) + (n - 1)$  more equalities. Two parameters remain free. The values of the derivatives at the marginal points may be prescribed explicitly (the *complete spline*), or the second derivatives can be set to zero (the *natural spline*).

Unfortunately, the computation of the whole spline is not as easy as with the independent computations of Hermite’s cubic polynomials because the data mingles between adjacent intervals. However, ordering the variables and equations properly, gives a matrix of the system such that all of its non-zero elements appear only on three diagonals. These matrices are nice enough to be solved in a time proportional to the number of points, using a suitable numerical method. The results are stunning.

For comparison, look at the interpolation of the same data as in the case of the Lagrange polynomial, now using splines. The spline is the solid line, the interpolated function is again the dotted line.

Although the diagrams look nearly identical, the data is different.

### 2. Real numbers and limit processes

Polynomials and splines do not supply a sufficiently large stock of functions to express many dependencies.

Actually, the first problem to solve is how to define the values of more general functions at all. In principle, all we can get with a finite number of multiplications and additions is polynomial functions. Perhaps division by polynomial quantities, and some efficient manipulation with rational numbers can be done. However, we cannot restrict ourselves to rational numbers. For instance,  $\sqrt{2}$  is not a rational number.

Thus the first step is a thorough introduction to limit processes. We define precisely what it means for a sequence of numbers to approach another number.

An important property of polynomials is the “continuous” dependency of their values on the input variable. We expect intuitively that if  $x$  is changed by a little, then the value of  $f(x)$  also changes only a little. This behaviour is not possessed by piece-wise constant functions  $f : \mathbb{R} \rightarrow \mathbb{R}$  near the

**5.C.1.** Calculate the following limits of sequences: “jump discontinuities”. For instance, the *Heaviside function*<sup>4</sup>

- i)  $\lim_{n \rightarrow \infty} \frac{2n^2+3n+1}{n+1},$
- ii)  $\lim_{n \rightarrow \infty} \frac{2n^2+3n+1}{3n^2+n+1},$
- iii)  $\lim_{n \rightarrow \infty} \frac{n+1}{2n^2+3n+1},$
- iv)  $\lim_{n \rightarrow -\infty} \frac{2^n - 2^{-n}}{2^n + 2^{-n}},$
- v)  $\lim_{n \rightarrow \infty} \frac{\sqrt{4n^2+n}}{n},$
- vi)  $\lim_{n \rightarrow \infty} \sqrt{4n^2+n} - 2n.$

**Solution.**

- i)  $\lim_{n \rightarrow \infty} \frac{2n^2+3n+1}{n+1} = \lim_{n \rightarrow \infty} \frac{2n+3+\frac{1}{n}}{1+\frac{1}{n}} = \infty.$
- ii)  $\lim_{n \rightarrow \infty} \frac{2n^2+3n+1}{3n^2+n+1} = \lim_{n \rightarrow \infty} \frac{2+\frac{3}{n}+\frac{1}{n^2}}{3+\frac{1}{n}+\frac{1}{n^2}} = \frac{2}{3}.$
- iii)  $\lim_{n \rightarrow \infty} \frac{n+1}{2n^2+3n+1} = \lim_{n \rightarrow \infty} \frac{1+\frac{1}{n}}{2n+3+\frac{1}{n}} = \frac{1}{\infty} = 0.$

iv)

$$\lim_{n \rightarrow -\infty} \frac{2^n - 2^{-n}}{2^n + 2^{-n}} = \lim_{n \rightarrow -\infty} \frac{\frac{2^n}{2^{-n}} - 1}{\frac{2^n}{2^{-n}} + 1} = -1$$

v) By the squeeze theorem (5.2.12):

$$\forall n \in \mathbb{N} : \frac{\sqrt{4n^2}}{n} < \frac{\sqrt{4n^2+n}}{n} < \frac{\sqrt{4n^2+n+\frac{1}{16}}}{n}.$$

$$\text{Then } \lim_{n \rightarrow \infty} \frac{\sqrt{4n^2}}{n} = \lim_{n \rightarrow \infty} \frac{2n}{n} = 2,$$

$$\lim_{n \rightarrow \infty} \frac{\sqrt{4n^2+n+\frac{1}{16}}}{n} = \lim_{n \rightarrow \infty} \frac{2n+\frac{1}{4}}{n} = 2.$$

$$\text{So } \lim_{n \rightarrow \infty} \frac{\sqrt{4n^2+n}}{n} = 2 \text{ as well.}$$

vi)  $\lim_{n \rightarrow \infty} \sqrt{4n^2+n} - 2n =$

$$\lim_{n \rightarrow \infty} \frac{(\sqrt{4n^2+n} - 2n)(\sqrt{4n^2+n} + 2n)}{\sqrt{4n^2+n} + 2n} =$$

$$\lim_{n \rightarrow \infty} \frac{n}{\sqrt{4n^2+n} + 2n} =$$

$$\lim_{n \rightarrow \infty} \frac{1}{\frac{\sqrt{4n^2+n}}{n} + 2} = \frac{1}{4}.$$

□

**5.C.2.** Let  $c \in \mathbb{R}^+$  (a positive real number). We will show that  $\lim_{n \rightarrow \infty} \sqrt[n]{c} = 1.$

**Solution.** First, let us consider  $c > 1.$  The function  $\sqrt[n]{c}$  is decreasing (in  $n$ ), yet all its values are greater than 1, hence the sequence  $\sqrt[n]{c}$  has a limit, and this limit is equal to the infimum of the sequence’s terms. Let us suppose, for a while, that this limit is greater than 1, that is  $1 + \varepsilon$  for some  $\varepsilon > 0.$  Then by the definition of a limit, all the sequence’s terms will eventually (from some index  $m$  on) be less than  $1 + \varepsilon + \frac{\varepsilon^2}{4},$

$$f(x) = \begin{cases} 0 & \text{for all } x < 0, \\ 1/2 & \text{for } x = 0, \\ 1 & \text{for all } x > 0 \end{cases}$$

has this type of “discontinuity” for  $x = 0.$

We formalize these intuitive statements.

**5.2.1. Real numbers.** We have dealt with algebraic properties of real numbers, summarized by the claim that  $\mathbb{R}$  is a field. However, we have also used the relation of the standard (total) ordering of the real numbers, denoted by “ $\leq$ ”. See the paragraph 1.6.3 on the page 43.

The properties (axioms) of the real numbers, including the connections between the relations and other operations, are enumerated in the following table. The bars indicate how the axioms guarantee that the real numbers form an abelian (commutative) group with respect to addition, that  $\mathbb{R} \setminus \{0\}$  is an abelian group with respect to multiplication, that  $\mathbb{R}$  is a field, that the set  $\mathbb{R}$  together with the operations  $+, \cdot$  and the order relation is an *ordered field*. The last axiom can be considered as claiming that  $\mathbb{R}$  is “sufficiently dense”.

AXIOMS OF THE REAL NUMBERS

- (R1)  $(a + b) + c = a + (b + c),$  for all  $a, b, c \in \mathbb{R}$
- (R2)  $a + b = b + a,$  for all  $a, b \in \mathbb{R}$
- (R3) there is an element  $0 \in \mathbb{R}$  such that for all  $a \in \mathbb{R},$   $a + 0 = a$
- (R4) for all  $a \in \mathbb{R},$  there is an additive inverse  $(-a) \in \mathbb{R}$  such that  $a + (-a) = 0$

---

- (R5)  $(a \cdot b) \cdot c = a \cdot (b \cdot c),$  for all  $a, b, c \in \mathbb{R}$
- (R6)  $a \cdot b = b \cdot a$  for all  $a, b \in \mathbb{R}$
- (R7) there is an element  $1 \in \mathbb{R}, 1 \neq 0,$  such that for all  $a \in \mathbb{R}, 1 \cdot a = a$
- (R8) for all  $a \in \mathbb{R}, a \neq 0,$  there is a multiplicative inverse  $a^{-1} \in \mathbb{R}$  such that  $a \cdot a^{-1} = 1$

---

- (R9)  $a \cdot (b + c) = a \cdot b + a \cdot c,$  for all  $a, b, c \in \mathbb{R}$

---

- (R10) the relation  $\leq$  is a total order, i.e. reflexive, anti-symmetric, transitive, and total on  $\mathbb{R}$
- (R11) for all  $a, b, c \in \mathbb{R}, a \leq b$  implies  $a + c \leq b + c$
- (R12) for all  $a, b \in \mathbb{R}, a > 0$  and  $b > 0$  implies  $a \cdot b > 0$

---

- (R13) every non-empty set  $A \subset \mathbb{R}$  which has an upper bound has a least upper bound.

The concept of a least upper bound from axiom (R13), also called the *supremum*, is very important. It makes sense

<sup>4</sup>Oliver Heaviside was an unconventional English electrical engineer (1850-1925) with an innovative and very original approach to practical mathematical modelling. His famous sayings include “*Mathematics is an experimental science, and definitions do not come first, but later on*”. Or, defending his incomplete argumentation, “*I do not refuse my dinner simply because I do not understand the process of digestion*”. Is this suggestive of the methodology of this textbook?

especially  $\sqrt[m]{c} < 1 + \varepsilon + \frac{\varepsilon^2}{4}$ . But then we have that

$$\sqrt[m]{c} = \sqrt{\sqrt[m]{c}} < \sqrt{1 + \varepsilon + \frac{\varepsilon^2}{4}} = 1 + \frac{\varepsilon}{2} < 1 + \varepsilon,$$

which contradicts our assumption that  $1 + \varepsilon$  is the infimum of the considered sequence.

The theorem is trivial for  $c = 1$ , and for a number  $c \in (0, 1)$  it follows from the above, if we invoke the theorem for the number  $1/c$ .  $\square$

**5.C.3.** Determine

$$\lim_{n \rightarrow \infty} \sqrt[n]{n}.$$

**Solution.** Apparently, we have  $\sqrt[n]{n} \geq 1, n \in \mathbb{N}$ . So we can set

$$\sqrt[n]{n} = 1 + a_n \quad \text{for certain numbers } a_n \geq 0, n \in \mathbb{N}.$$

By the binomial theorem we get that

$$n = (1 + a_n)^n = 1 + \binom{n}{1} a_n + \binom{n}{2} a_n^2 + \dots + a_n^n, \\ n \geq 2 (n \in \mathbb{N}).$$

Hence we have the bound (all the numbers  $a_n$  are non-negative)

$$n \geq \binom{n}{2} a_n^2 = \frac{n(n-1)}{2} a_n^2, \quad n \geq 2 (n \in \mathbb{N}),$$

which leads to

$$0 \leq a_n \leq \sqrt{\frac{2}{n-1}}, \quad n \geq 2 (n \in \mathbb{N}).$$

By the squeeze theorem,

$$0 = \lim_{n \rightarrow \infty} 0 \leq \lim_{n \rightarrow \infty} a_n \leq \lim_{n \rightarrow \infty} \sqrt{\frac{2}{n-1}} = 0.$$

Thus we have obtained the result

$$\lim_{n \rightarrow \infty} \sqrt[n]{n} = \lim_{n \rightarrow \infty} (1 + a_n) = 1 + 0 = 1.$$

We can notice that by further application of the squeeze theorem, we get

$$1 = \lim_{n \rightarrow \infty} 1 \leq \lim_{n \rightarrow \infty} \sqrt[n]{c} \leq \lim_{n \rightarrow \infty} \sqrt[n]{n} = 1, \\ \text{for every real number } c \geq 1. \quad \square$$

for any partially ordered set. This is a set with a (not necessarily total) ordering relation. Recall that an ordering relation is a binary relation on a set which is reflexive, antisymmetric, and transitive; see the paragraph 1.6.3.

SUPREMUM AND INFIMUM

Consider a subset  $A \subset B$  in a partially ordered set  $B$ . An *upper bound* of the set  $A$  is any element  $b \in B$  such that  $b \geq a$  for all  $a \in A$ .

Similarly, a *lower bound* of the set  $A$  is an element  $b \in B$  such that  $b \leq a$  for all  $a \in A$ .

The least upper bound of the set  $A$ , if it exists, is called its *supremum* and it is denoted by  $\sup A$ . Similarly, the greatest lower bound, if it exists, is called the *infimum* and it is denoted by  $\inf A$ .

Thus, the last axiom (R13) from the table of properties of the real numbers can be reformulated as follows: *Every non-empty bounded set  $A$  of real numbers has a supremum. This means that if there is a number  $a$  which is larger than or equal to all numbers  $x \in A$ , then there is a smallest number with this property.*

For instance, the choice  $A = \{x \in \mathbb{Q}, x^2 < 2\}$  gives the supremum  $\sup A$  which is called  $\sqrt{2}$ ; the square root of two.

An immediate consequence of this axiom is the existence of the infima for any non-empty set of real numbers bounded from below. Observe that changing the sign of all the numbers in a set interchanges suprema and infima.

For the formal construction, it is necessary to know whether or not there is such a set  $\mathbb{R}$  with the operations and ordering relation which satisfies the thirteen axioms. So far, only the rational numbers have been constructed formally. These form an ordered field. This means that  $\mathbb{Q}$  satisfies the axioms (R1) – (R12), and this can easily be verified.

We do not go into details here of the consistent construction of the real numbers now. We will be satisfied with an intuitive idea of the real line, and we will work with the axioms (R1) through R(13). But we shall come back to this issue in a more general framework in chapter 7, see the paragraph 5.2.4 and the discussion started in 7.3.6. Actually, we shall see, that if the real numbers can be constructed, then the construction is unique up to isomorphism. This is a bijection preserving all algebraic structures of two different realizations of the field  $\mathbb{R}$ .

**5.2.2. The complex plane.** Recall that the complex numbers are given as pairs of real numbers. We usually write them as  $z = \operatorname{Re} z + i \operatorname{Im} z$ . Therefore, the plane  $\mathbb{C} = \mathbb{R}^2$  is an appropriate image of the complex numbers.

With addition and multiplication, the complex numbers satisfy the axioms (R1)-(R9) and thus form a field. There is, however, no natural ordering defined on them which would satisfy the axioms (R10)-R(13). Nevertheless, we work with them, since extending real scalars to the complex numbers is highly advantageous or sometimes even necessary.  $\square$

5.C.4. Calculate the limit

$$\lim_{n \rightarrow \infty} (\sqrt{2} \cdot \sqrt[4]{2} \cdot \sqrt[8]{2} \cdots \sqrt[2^n]{2}).$$

**Solution.** To determine the limit, it is sufficient to express the terms in the form

$$2^{\frac{1}{2}} \cdot 2^{\frac{1}{4}} \cdot 2^{\frac{1}{8}} \cdots 2^{\frac{1}{2^n}} = 2^{\frac{1}{2} + \frac{1}{4} + \frac{1}{8} + \cdots + \frac{1}{2^n}}.$$

Thus we get

$$\begin{aligned} \lim_{n \rightarrow \infty} (\sqrt{2} \cdot \sqrt[4]{2} \cdot \sqrt[8]{2} \cdots \sqrt[2^n]{2}) &= \\ \lim_{n \rightarrow \infty} 2^{\frac{1}{2} + \frac{1}{4} + \frac{1}{8} + \cdots + \frac{1}{2^n}} &= \\ 2^{\lim_{n \rightarrow \infty} (\frac{1}{2} + \frac{1}{4} + \frac{1}{8} + \cdots + \frac{1}{2^n})} &= 2^{\sum_{n=1}^{\infty} \frac{1}{2^n}}. \end{aligned}$$

By the well-known formula for the sum of geometric series,

$$\sum_{n=1}^{\infty} \left(\frac{1}{2}\right)^n = \frac{\frac{1}{2}}{1 - \frac{1}{2}} = 1,$$

whence it follows that

$$\lim_{n \rightarrow \infty} (\sqrt{2} \cdot \sqrt[4]{2} \cdot \sqrt[8]{2} \cdots \sqrt[2^n]{2}) = 2^1 = 2.$$

5.C.5. Determine

$$\lim_{n \rightarrow \infty} \left( \frac{1}{n^2} + \frac{2}{n^2} + \cdots + \frac{n-2}{n^2} + \frac{n-1}{n^2} \right).$$

5.C.6. Calculate

$$\lim_{n \rightarrow \infty} \frac{\sqrt{n^3 - 11n^2 + 2} + \sqrt[5]{n^7 - 2n^5 - n^3} - n + \sin^2 n}{2 - \sqrt[3]{5n^4 + 2n^3 + 5}}.$$

5.C.7. Determine the limit

$$\lim_{n \rightarrow \infty} \frac{n! + (n-2)! - (n-4)!}{n^{50} + n! - (n-1)!}.$$

5.C.8. Find two sequences (let us denote their terms by  $x_n$  and  $y_n$  ( $n \in \mathbb{N}$ ), respectively) having infinite limits and such that

$$\lim_{n \rightarrow \infty} (x_n + y_n) = 1, \quad \lim_{n \rightarrow \infty} (x_n y_n^2) = +\infty.$$

5.C.9. Determine the limit points of the sequence given by

$$a_n = \frac{(-1)^n 2n}{\sqrt{4n^2 + 5n + 3}}, \quad n \in \mathbb{N}.$$

5.C.10. Calculate

$$\limsup_{n \rightarrow \infty} a_n \quad \text{and} \quad \liminf_{n \rightarrow \infty} a_n$$

There is an important operation on the complex numbers called *complex conjugation*. It is the reflection symmetry with respect to the line of real numbers. We denote it by a bar over the number  $z \in \mathbb{C}$ :

$$\bar{z} = \operatorname{Re} z - i \operatorname{Im} z.$$

It changes the sign of the imaginary part. Since for  $z = x + iy$ ,

$$z \cdot \bar{z} = (x + iy)(x - iy) = x^2 + y^2,$$

this value expresses the squared distance of the complex numbers from the origin. The square root of this non-negative real number is called the absolute value of the complex number  $z$ ; written

$$(1) \quad |z|^2 = z \cdot \bar{z}.$$

The absolute value can be defined on any ordered field of scalars  $\mathbb{K}$ . Define the *absolute value*  $|a|$  as follows:

$$|a| = \begin{cases} a & \text{if } a \geq 0 \\ -a & \text{if } a < 0. \end{cases}$$

For any numbers  $a, b \in \mathbb{K}$ ,

$$(2) \quad |a + b| \leq |a| + |b|.$$

□ This property is called the *triangle inequality*. It holds also for the absolute value of the complex numbers.

○ For the fields of rational numbers or real numbers, both of which are subfields of the complex numbers, both definitions of the absolute value coincide. The absolute value must be understood in the context of which ever field  $\mathbb{K}$  of rational, real, or complex numbers is involved. The triangle inequality holds in all these cases.

5.2.3. **Convergence of a sequence.** We wish to formalize

the notion of a sequence of numbers approaching a limit. The key object of interest is a sequence of numbers  $a_i$ , where the index  $i$  usually goes through all the natural numbers. Denote the sequences loosely either as  $a_0, a_1, \dots$ , or as infinite vectors  $(a_0, a_1, \dots)$ , or as  $(a_i)_{i=1}^{\infty}$ .

CAUCHY<sup>5</sup> SEQUENCES

Consider a sequence  $(a_0, a_1, \dots)$  of elements of  $\mathbb{K}$  such that for any fixed positive number  $\varepsilon > 0$ ,

$$|a_i - a_j| < \varepsilon.$$

for all but finitely many terms  $a_i, a_j$  of the sequence.

○ In other words, for any fixed  $\varepsilon > 0$ , there is an index  $N$  such that the above inequality holds for all  $i, j > N$ . Loosely put, the elements of the sequence are eventually arbitrarily close to each other. Such a sequence is called a *Cauchy sequence*.

<sup>5</sup>Augustin-Louis Cauchy (1789-1857) was a French mathematician pioneering a rigorous approach to infinitesimal analysis. He was very productive, wrote about 800 research articles. There are dozens of concepts and theorems named after him.

if

$$a_n = \frac{n^2 + 4n - 5}{n^2 + 9} \sin^2 \frac{n\pi}{4}, \quad n \in \mathbb{N}.$$

5.C.II. Determine

$$\liminf_{n \rightarrow \infty} \left( (-1)^n \left( 1 + \frac{1}{n} \right)^n + \sin \frac{n\pi}{4} \right).$$

5.C.12. Now let us proceed with limits of functions. The definition can be found at page 300.

Determine

(a)

$$\lim_{x \rightarrow \pi/3} \sin x;$$

(b)

$$\lim_{x \rightarrow 2} \frac{x^2 + x - 6}{x^2 - 3x + 2};$$

(c)

$$\lim_{x \rightarrow +\infty} \left( \arccos \frac{1}{x+1} \right)^3;$$

(d)

$$\lim_{x \rightarrow -\infty} \operatorname{arctg} \frac{1}{x}, \quad \lim_{x \rightarrow -\infty} \operatorname{arctg} x^4, \quad \lim_{x \rightarrow -\infty} \operatorname{arctg} (\sin x).$$

**Solution.** (a) Let us remind that a function  $f$  is, by definition, continuous at a given point  $x$  iff the limit of  $f$  at  $x$  is equal to the function value  $f(x)$ . However, we know that the function  $y = \sin x$  is continuous at every real number. Thus we get that

$$\lim_{x \rightarrow \pi/3} \sin x = \sin \frac{\pi}{3} = \frac{\sqrt{3}}{2}.$$

(b) The immediate substitution  $x = 2$  leads to both zero numerator and zero denominator. Despite that, the problem can be solved very easily. The reduction

$$\begin{aligned} \lim_{x \rightarrow 2} \frac{x^2 + x - 6}{x^2 - 3x + 2} &= \lim_{x \rightarrow 2} \frac{(x-2)(x+3)}{(x-2)(x-1)} = \lim_{x \rightarrow 2} \frac{x+3}{x-1} \\ &= \frac{2+3}{2-1} = 5 \end{aligned}$$

leads to the correct result (thanks to continuity of the obtained at function at the point  $x_0 = 2$ ). Let us realize that the limit of a function can be calculated from the function values in an arbitrarily small deleted neighborhood of a given point  $x_0$  and that the limit does not depend on the function value at the point. We can thus make use of multiplying or reducing by factors which do not change the function values in an arbitrarily selected deleted neighborhood of the point  $x_0$ .

Intuitively, either all but finitely many of the sequence's terms are equal, (then  $|a_i - a_j| = 0$  from some index  $N$  on), or they "approach" some particular value. This is easily imaginable in the complex plane. Choose an arbitrarily small disc (with radius equal to  $\varepsilon$ ). Suppose a Cauchy sequence is given. It must be possible to put the disc into the complex plane in such a way that it covers all but a finitely many of the elements of the infinite sequence  $a_i$ . Imagine that the disc has very small radius, and contains a number  $a$ ; see the diagram. If such a value  $a \in \mathbb{K}$  exists for a Cauchy sequence, we would expect the sequence to have the property of *convergence*:

#### CONVERGENT SEQUENCES

A sequence  $(a_i)_{i=0}^{\infty}$  converges to a value  $a$  iff for any positive real number  $\varepsilon$ ,

$$|a_i - a| < \varepsilon$$

for all but finitely many indices  $i$ . Notice that the set of those  $i$  for which the inequality does not hold may depend on  $\varepsilon$ . The number  $a$  is called the *limit* of the sequence  $(a_i)_{i=0}^{\infty}$ .

If a sequence  $a_i \in \mathbb{K}$ ,  $i = 0, 1, \dots$ , converges to  $a \in \mathbb{K}$ , then for any fixed positive  $\varepsilon$ ,  $|a_i - a| < \varepsilon$  for all  $i$  greater than a certain  $N \in \mathbb{N}$ . By the triangle inequality,

$$|a_i - a_j| = |a_i - a_N + a_N - a_j| < |a_i - a_N| + |a_N - a_j| < 2\varepsilon.$$

for all pairs of indices  $i, j \geq N$ . Thus:

**Lemma.** Every convergent sequence is a Cauchy sequence.

However, in the field of rational numbers, it can happen that for a Cauchy sequence a corresponding value  $a$  does not exist. For instance, the number  $\sqrt{2}$  can be approached by a sequence of rational numbers  $a_i$ , thereby obtaining a sequence converging to  $\sqrt{2}$ , but the limit is not rational.

Ordered fields of scalars in which every Cauchy sequence converges are called *complete*. The following theorem states that the axiom (R13) guarantees that the real numbers are such a field:

**Theorem.** Every Cauchy sequence of real numbers  $a_i$  converges to a real number  $a \in \mathbb{R}$ .

**PROOF.** The terms of any Cauchy sequence form a bounded set since any choice of  $\varepsilon$  bounds all but finitely many of them. Let  $B$  be the set of those real numbers  $x$  for which  $x < a_j$  for all but finitely many terms  $a_j$  of the sequence.  $B$  has an upper bound, and thus  $B$  has a supremum as well, by (R13).

Define  $a = \sup B$ . Fix  $\varepsilon > 0$ , and choose  $N$  so that  $|a_i - a_j| < \varepsilon$  for all  $i, j \geq N$ . Then  $a_j > a_N - \varepsilon$  and  $a_j < a_N + \varepsilon$  for all indices  $j > N$ , and so  $a_N - \varepsilon$  belongs

(c) By moving the limit inwards twice, the original limit transforms to

$$\left( \arccos \left( \lim_{x \rightarrow +\infty} \frac{1}{x+1} \right) \right)^3.$$

It can easily be shown that

$$\lim_{x \rightarrow +\infty} \frac{1}{x+1} = 0.$$

As the function  $y = \arccos x$  is continuous at the point 0 and takes the value  $\pi/2$  there, and the function  $y = x^3$  is continuous at  $\pi/2$ , we get that

$$\begin{aligned} \lim_{x \rightarrow +\infty} \left( \arccos \frac{1}{x+1} \right)^3 &= \left( \arccos \left( \lim_{x \rightarrow +\infty} \frac{1}{x+1} \right) \right)^3 \\ &= \left( \frac{\pi}{2} \right)^3. \end{aligned}$$

(d) The function  $y = \arctg x$  has properties which are “useful when calculating limits” – it is continuous and injective (increasing) on the whole domain. These properties always (with no further conditions or limitations) allow to move the examined limit into the argument of such a function. Therefore, let us consider

$$\begin{aligned} \arctg \left( \lim_{x \rightarrow -\infty} \frac{1}{x} \right), \quad \arctg \left( \lim_{x \rightarrow -\infty} x^4 \right), \\ \arctg \left( \lim_{x \rightarrow -\infty} \sin x \right). \end{aligned}$$

Apparently,

$$\lim_{x \rightarrow -\infty} \frac{1}{x} = 0, \quad \lim_{x \rightarrow -\infty} x^4 = +\infty$$

and the limit  $\lim_{x \rightarrow -\infty} \sin x$  does not exist, which implies

$$\begin{aligned} \lim_{x \rightarrow -\infty} \arctg \frac{1}{x} &= \arctg 0 = 0, \\ \lim_{x \rightarrow -\infty} \arctg x^4 &= \lim_{y \rightarrow +\infty} \arctg y = \frac{\pi}{2} \end{aligned}$$

and the last limit does not exist, either.

**5.C.13.** Determine the limit

$$\lim_{x \rightarrow 0} \frac{1 - \cos x}{x^2 \sin(x^2)}.$$

**Solution.**

$$\begin{aligned} \lim_{x \rightarrow 0} \frac{1 - \cos x}{x^2 \sin(x^2)} &= \lim_{x \rightarrow 0} \frac{2 \sin^2 \left( \frac{x}{2} \right)}{x^2 \sin(x^2)} \\ &= \lim_{x \rightarrow 0} \frac{\frac{1}{2} \sin^2 \left( \frac{x}{2} \right)}{\left( \frac{x}{2} \right)^2 \sin(x^2)} \\ &= \frac{1}{2} \left( \lim_{x \rightarrow 0} \frac{\sin \left( \frac{x}{2} \right)}{\frac{x}{2}} \right)^2 \cdot \lim_{x \rightarrow 0} \frac{1}{\sin^2(x^2)} \\ &= \frac{1}{2} \cdot \infty = \infty. \end{aligned}$$

to  $B$ , while  $a_N + \varepsilon$  does not. Hence  $|a - a_N| \leq \varepsilon$ , and thus

$$|a - a_j| \leq |a - a_N| + |a_N - a_j| \leq 2\varepsilon$$

for all  $j > N$ . So  $a$  is the limit of the given sequence.  $\square$

**Corollary.** Every Cauchy sequence of complex numbers  $z_i$  converges to a complex number  $z$ .

**PROOF.** Write  $z_i = a_i + i b_i$ . Since  $|a_i - a_j|^2 \leq |z_i - z_j|^2$  and similarly for the values  $b_i$ , both sequences of real numbers  $a_i$  and  $b_i$  are Cauchy sequences. They converge to  $a$  and  $b$ , respectively. It is easily verified that  $z = a + i b$  which is the limit of the sequence  $z_i$ .  $\square$

**5.2.4. Remark.** The previous discussion proposes a construction method for the real numbers. Proceed similarly to building the integers from the natural numbers (adding in all additive inverses). Build the rational numbers from the integers (adding all multiplicative inverses of non-zero numbers). Then “complete” the rational numbers by adding in all limits of Cauchy sequences.

Cauchy sequences  $(a_i)_{i=0}^{\infty}$  and  $(b_i)_{i=0}^{\infty}$  of rational numbers are equivalent if and only if the distances  $|a_i - b_i|$  converge to zero. This is the same as the condition that merging these sequences into a single sequence also yields a Cauchy sequence. For example, a sequence can be formed by selecting alternately terms from the first sequence and the second sequence. Check the properties of the equivalence relations. Clearly the relation is reflexive, it is symmetric (since the distance of the rational numbers is symmetric in its arguments) and transitivity follows easily from the triangle inequality. Thus, we may define  $\mathbb{R}$  as the set of equivalence classes on the above set of sequences.

We introduce algebraic structures on this set  $\mathbb{R}$  and check their properties. Of course, the rational numbers can be represented by constant sequences, so that  $\mathbb{Q} \subset \mathbb{R}$ , as expected. Next, define the sum and product of equivalence classes by taking the sum and product of sequences representing them, respectively. It is easy to check that the results represent a class independent of the choices.

Ordering is dealt with similarly. Here it is required to prove that  $a \leq b$  if and only if there are representatives with  $a_i \leq b_i$ . Finally it is necessary to show that all Cauchy sequences in  $\mathbb{R}$  converge. We do not go into details here and advise the reader to return back now and check all the details when going through the full discussion of the completion of metric spaces in the paragraph 7.3.6. The arguments used there with the real scalars replaced by rational ones provide an adequate proof. The arguments proving that the axioms (R1)–(R13) define the real numbers uniquely up to isomorphism are also to be found there.

The previous calculation must be considered “from the back”. Since the limits on the right-hand side exist (no matter whether finite or infinite) and the expression  $\frac{1}{2} \cdot \infty$  is meaningful (see the note after theorem 5.2.13), the original limit exists as well. If we split the original limit into the product

$$\lim_{x \rightarrow 0} (1 - \cos x) \cdot \lim_{x \rightarrow 0} \frac{1}{x^2 \sin(x^2)},$$

we would get the  $0 \cdot \infty$  type, which is an indeterminate form, but this tells us nothing about existence of the original limit.

□

**5.C.14.** Determine the following limits:

$$\begin{aligned} \text{i)} \quad & \lim_{x \rightarrow 2} \frac{x-2}{\sqrt{x^2-4}}, & \text{ii)} \quad & \lim_{x \rightarrow 0} \frac{\sin(\sin x)}{x}, \\ \text{iii)} \quad & \lim_{x \rightarrow 0} \frac{\sin^2 x}{x}, & \text{iv)} \quad & \lim_{x \rightarrow 0} e^{\frac{1}{x}}. \end{aligned}$$

**Solution.**

i)

$$\begin{aligned} \lim_{x \rightarrow 2} \frac{x-2}{\sqrt{x^2-4}} &= \lim_{x \rightarrow 2} \frac{x-2}{\sqrt{(x-2)(x+2)}} = \\ \lim_{x \rightarrow 2} \frac{\sqrt{x-2}}{\sqrt{x+2}} &= \frac{0}{4} = 0. \end{aligned}$$

ii)

$$\lim_{x \rightarrow 0} \frac{\sin(\sin x)}{x} \stackrel{(5.2.20)}{=} \lim_{y \rightarrow 0} \frac{\sin y}{y} = 1,$$

where we made use of the fact that  $\lim_{x \rightarrow 0} \sin x = 0$ .

iii)

$$\lim_{x \rightarrow 0} \frac{\sin^2 x}{x} = \lim_{x \rightarrow 0} \sin x \cdot \lim_{x \rightarrow 0} \frac{\sin x}{x} = 0 \cdot 1 = 0,$$

again, the original limit exists because both the right-hand side limits exist and their product is well-defined.

iv) One must be cautious when calculating this limit. Both one-sided limits exist, but are different, which implies that the examined limit does not exist:

$$\lim_{x \rightarrow 0^+} e^{\frac{1}{x}} = e^{\lim_{x \rightarrow 0^+} \frac{1}{x}} = e^\infty = \infty,$$

$$\lim_{x \rightarrow 0^-} e^{\frac{1}{x}} = e^{\lim_{x \rightarrow 0^-} \frac{1}{x}} = e^{-\infty} = 0.$$

□

In the following exercise, we will be concerned with so-called indeterminate forms. We recommend perceiving indeterminate forms as a helping concept which is only to facilitate the first approach to limit calculations because the obtained indeterminate form only means that one “has found out nothing”. We know the limit of a sum is the sum of the limits, the limit of a product is the product of the limits, and the limit of a quotient is the quotient of the

**5.2.5. Closed sets.** For further work with real or complex numbers, we need to understand the notions of closeness, boundedness, convergence, and so on. These concepts belong to the topic “topology”<sup>6</sup>. As before, we work with  $\mathbb{K} = \mathbb{R}$  or  $\mathbb{K} = \mathbb{C}$ . We advise the reader to draw many diagrams for all the concepts and their properties for both the real line and the complex plane.

For any subset  $A$  of points in  $\mathbb{K}$ , we are interested not only in the points belonging to  $a \in A$ , but also in the ones which can be approached by limits of sequences in  $A$ .

#### LIMIT POINTS OF A SET

Let  $A$  be a subset of  $\mathbb{K}$ . A point  $x \in \mathbb{K}$  is called a *limit point* of  $A$  if and only if there is a sequence  $a_0, a_1, \dots$  of elements in  $A$  such that all its terms differ from  $x$ , yet its limit is  $x$ .

Notice that a limit point of a set may or may not belong to the set.

For every non-empty set  $A \subset \mathbb{K}$  and a fixed point  $x \in \mathbb{K}$ , the set of all distances  $|x - a|$ ,  $a \in A$ , is a set of real numbers bounded from below, and so it has an infimum  $d(x, A)$ , which is called the *distance of the point  $x$  from the set  $A$* . Notice that  $d(x, A) = 0$  if and only if either  $x \in A$  or if  $x$  is a limit point of  $A$ . (We suggest the reader proves this in detail directly from the definitions.)

#### CLOSED SETS

The *closure*  $\bar{A}$  of a set  $A \subset \mathbb{K}$  is the set of those points which have zero distance from  $A$  (note that the distance from the empty set of points is undefined, therefore  $\bar{\emptyset} = \emptyset$ ).

A *closed subset* in  $\mathbb{K}$  is a set which coincides with its closure. A set is closed if it contains all of its limit points. On the real line, a *closed interval*

$$[a, b] = \{x \in \mathbb{R}, a \leq x \leq b\}$$

of real numbers, where  $a$  and  $b$  are fixed real numbers is a closed set.

The sets  $(-\infty, b]$ ,  $[a, \infty)$ , and  $(-\infty, \infty)$  are also closed sets.

A closed set may also be formed by a sequence of real numbers without a limit point, or a sequence with a finite number of limit points together with these points.

The unit disc (including its boundary circle) in the complex plane is another example of a closed set.

An arbitrary intersection of closed sets is again a closed set. A finite union of closed sets is again a closed set. Indeed, if all of the points of some sequence belong to the considered intersection of closed sets, then they belong to each of the sets, and so do all the limit points. However, if we wanted to say the same about an arbitrary union, we would get in trouble: singleton sets are closed, but a sequence of points created

<sup>6</sup>The name of this mathematical discipline comes from the Greek “studying the shape” (topos + logos). The main concepts are built on the formalism of open and closed sets, compactness etc. We use the same names here but only in the realm of real and complex numbers. Later on, we go further in metric spaces in chapter 7.

limits, supposing the particular limits exist and do not lead to one of the following expressions  $\infty - \infty, 0 \cdot \infty, 0/0, \infty/\infty$ , which are called indeterminate forms. For completeness, let us add that these rules can be combined and that an expression containing an indeterminate form is itself considered an indeterminate form. For instance, the forms

$$-\infty + \infty = \infty - \infty, \quad \frac{-\infty}{3+\infty} = -\frac{\infty}{\infty},$$

$$\frac{0}{(-\infty)^3+\infty} = 0 \cdot (\infty - \infty)^{-1}$$

are all indeterminate, but the forms

$$-\infty - \infty, \quad \frac{0}{3+\infty}, \quad \frac{0}{(-\infty)^3 - \infty}$$

can be called “determinate” (one can immediately determine the limit – they correspond to the values  $-\infty, 0, 0$ , respectively).

**5.C.15.** Calculate

(a)  $\lim_{x \rightarrow 2} \frac{x+2}{(x-2)^6}$ ,      (b)  $\lim_{x \rightarrow 2} \frac{x+2}{(x-2)^5}$ ,  
 (c)  $\lim_{x \rightarrow +\infty} \left(2 + \frac{1}{x}\right)^{\frac{1}{x}}$ ,      (d)  $\lim_{x \rightarrow +\infty} x^{-x}$ .

**Solution.** In exercise (a), the quotient of the numerator and the denominator gives us  $4/0$ . Expressions containing division by zero are inappropriate (later, we should be able to avoid them). Yet it leads to the result, it is not an indeterminate form. We may notice that the denominator approaches zero from the right (for  $x \neq 2$  we have that  $(x - 2)^6 > 0$ ). We write this as  $4/ + 0$ . Thus the numerator and denominator are both positive in some deleted neighborhood of the point  $x_0 = 2$  and one can say that the denominator, at the limit point, is “infinitely times less” than the numerator, that is

$$\lim_{x \rightarrow 2} \frac{x+2}{(x-2)^6} = +\infty,$$

which corresponds to setting  $4/ + 0 = +\infty$  (similarly, we can set  $4/ - 0 = -\infty$ ).

When calculating the limit of (b), one can proceed analogously. Since the numbers have the same sign, we get that

$$\lim_{x \rightarrow 2^+} \frac{x+2}{(x-2)^5} = +\infty \neq -\infty = \lim_{x \rightarrow 2^-} \frac{x+2}{(x-2)^5},$$

so the examined limit does not exist. We can write  $4/\pm 0$  (or, more generally,  $a/\pm 0, a \neq 0, a \in \mathbb{R}^*$ ), which is a “determinate form”. When thoroughly distinguishing the symbols  $+0$  and  $-0$  from  $\pm 0, a/\pm 0$  for  $a \neq 0$  always means the limit in question does not exist.

Exercises (c), (d). If  $f(x) > 0$  for all considered  $x \in \mathbb{R}$ , then

$$f(x)^{g(x)} = e^{\ln(f(x)^{g(x)})} = e^{g(x) \cdot \ln f(x)}.$$

from them may not be. On the other hand, if we restrict our attention to finite unions and consider a limit point of some sequence lying in this union, then the limit point must also be the limit point of any subsequence, especially the one lying in only one of the united sets. As this set is assumed to be closed, the limit point lies in it, and thus it lies in the union.

**5.2.6. Open sets.** There is another useful type of subset of the real numbers: *open intervals*

$$(a, b) = \{x \in \mathbb{R}; a < x < b\},$$

where, again,  $a$  and  $b$  are fixed real numbers or infinite values  $\pm\infty$ . It is an open set, in the following sense:

OPEN SETS AND NEIGHBOURHOODS OF POINTS

An *open set* in  $\mathbb{K}$  is a set whose complement is a closed set.

A *neighbourhood of a point*  $a \in \mathbb{K}$  is an open set  $\mathcal{O}$  which contains  $a$ . If the neighbourhood is defined as

$$\mathcal{O}_\delta(a) = \{x \in \mathbb{K}, |x - a| < \delta\}$$

for some positive number  $\delta$ , then we call it the  $\delta$ -neighbourhood of the point  $a$ .

Clearly, for  $\mathbb{K} = \mathbb{R}$ ,  $\mathcal{O}_\delta(a)$  is an open interval of length  $2\delta$  centered at  $a$ , while in the complex plane it is the interior of the circle with radius  $\delta$  and center at  $a$ .

Notice that for any set  $A, a \in \mathbb{K}$  is a limit point of  $A$  if and only if every neighbourhood of  $a$  contains at least one point  $b \in A, b \neq a$ .

**Lemma.** A set  $A \subset \mathbb{K}$  of numbers is open if and only if every point  $a \in A$ , has a neighbourhood contained in  $A$ .

**PROOF.** Let  $A$  be an open set and let  $a \in A$ . If there is no neighbourhood of the point  $a$  inside  $A$ , then there is a sequence  $a_n \notin A, |a - a_n| \leq 1/n$ . But then the point  $a \in A$  is a limit point of the set  $\mathbb{K} \setminus A$ , which is impossible since the complement of  $A$  is closed.

Suppose every  $a \in A$  has a neighbourhood contained in  $A$ . This prevents a limit point  $b$  of the set  $\mathbb{K} \setminus A$  to lie in  $A$ . Thus the set  $\mathbb{K} \setminus A$  is closed, and so  $A$  is open.  $\square$

From this lemma, it follows immediately that any union of open sets is an open set. A finite intersection of open sets is also an open set.

For real numbers, the  $\delta$ -neighbourhood of a point  $a$  is the open interval of length  $2\delta$ , centered at  $a$ . In the complex plane, it is the disc of radius  $\delta$ , also centered at  $a$ .

**5.2.7. Bounded and compact sets.** The closed and open sets are basic concepts of *topology*. Without going into deeper connections, the above material describes the *topology of the real line* and the *topology of the complex plane*. The following concepts are extremely useful:

Making use of the fact that the exponential function is continuous and injective on the whole of its domain ( $\mathbb{R}$ ), we can replace the limit

$$\lim_{x \rightarrow x_0} f(x)^{g(x)}$$

with

$$e^{\lim_{x \rightarrow x_0} (g(x) \cdot \ln f(x))}.$$

Let us remind that either of these limits exists if and only if the other one exists. Further,

$$\begin{aligned} \lim_{x \rightarrow x_0} (g(x) \cdot \ln f(x)) = a \in \mathbb{R} &\implies \lim_{x \rightarrow x_0} f(x)^{g(x)} = e^a, \\ \lim_{x \rightarrow x_0} (g(x) \cdot \ln f(x)) = +\infty &\implies \lim_{x \rightarrow x_0} f(x)^{g(x)} = +\infty, \\ \lim_{x \rightarrow x_0} (g(x) \cdot \ln f(x)) = -\infty &\implies \lim_{x \rightarrow x_0} f(x)^{g(x)} = 0. \end{aligned}$$

Thus we can write

$$\lim_{x \rightarrow x_0} f(x)^{g(x)} = e^{\lim_{x \rightarrow x_0} g(x) \cdot \lim_{x \rightarrow x_0} \ln f(x)},$$

if both limits on the right-hand side exist and do not lead to the indeterminate form  $0 \cdot \infty$ . It is not difficult to realize that this indeterminate form can only be obtained in three cases, corresponding to the remaining indeterminate forms  $0^0$ ,  $\infty^0$ ,  $1^\infty$ , when we have, respectively, that

$$\begin{aligned} \lim_{x \rightarrow x_0} f(x) = 0 &\quad \text{and} \quad \lim_{x \rightarrow x_0} g(x) = 0, \\ \lim_{x \rightarrow x_0} f(x) = +\infty &\quad \text{and} \quad \lim_{x \rightarrow x_0} g(x) = 0, \\ \lim_{x \rightarrow x_0} f(x) = 1 &\quad \text{and} \quad \lim_{x \rightarrow x_0} g(x) = \pm\infty. \end{aligned}$$

In other cases, knowledge (and existence) of the limits

$$\lim_{x \rightarrow x_0} f(x), \quad \lim_{x \rightarrow x_0} g(x)$$

allows us to determine the result (having defined some more expressions)

$$\lim_{x \rightarrow x_0} f(x)^{g(x)} = \left( \lim_{x \rightarrow x_0} f(x) \right)^{\lim_{x \rightarrow x_0} g(x)}.$$

Since

$$\lim_{x \rightarrow +\infty} \left( 2 + \frac{1}{x} \right) = 2, \quad \lim_{x \rightarrow +\infty} \frac{1}{x} = 0, \quad \lim_{x \rightarrow +\infty} x = +\infty,$$

we have that

$$\begin{aligned} \lim_{x \rightarrow +\infty} \left( 2 + \frac{1}{x} \right)^{\frac{1}{x}} &= 2^0 = 1, \\ \lim_{x \rightarrow +\infty} x^{-x} &= \lim_{x \rightarrow +\infty} \left( \frac{1}{x} \right)^x = 0 \end{aligned}$$

or

$$\lim_{x \rightarrow +\infty} x^{-x} = \lim_{x \rightarrow +\infty} (x^x)^{-1} = 0.$$

The last result can be expressed as  $0^\infty = 0$  or  $\infty^\infty = \infty$ ,  $\infty^{-1} = 0$  (let us emphasize that these are not indeterminate forms).

BOUNDED AND COMPACT SETS

A set  $A$  of rational, real, or complex numbers is called *bounded* if and only if there is a positive real number  $r$  such that  $|z| \leq r$  for all numbers  $z \in A$ . Otherwise, the set is called *unbounded*.

A set which is both bounded and closed is called *compact*.

An *interior point* of a set  $A$  is a point such that one of its neighbourhoods is contained in  $A$ .

A *boundary point* of a set  $A$  is a point for which all its neighbourhoods have a non-trivial intersection with both  $A$  and its complement  $\mathbb{K} \setminus A$ . A boundary point of the set  $A$  may or may not belong to it.

An *open cover* of a set  $A$  is such a collection of open sets  $U_i, i \in I$ , that its union contains the whole of  $A$ .

An *isolated point* of a set  $A$  is a point  $a \in A$  such that there is a neighbourhood  $N$  of  $a$  satisfying  $N \cap A = \{a\}$ .

**5.2.8. Theorem.** All subsets  $A \subset \mathbb{K}$  of real or complex numbers satisfy:

- (1) a non-empty set  $A \subset \mathbb{R}$  is open if and only if it is a union of countably (or finitely) many open intervals; similarly  $A \subset \mathbb{C}$  is open if and only if it is a union of countably (finite) many open circles.
- (2) every point  $a \in A$  is either an interior or a boundary point,
- (3) every boundary point of  $A$  is either an isolated point or a limit point of  $A$ ,
- (4)  $A$  is compact if and only if every infinite sequence contained in it has a subsequence converging to a point in it.  $A$ ,<sup>7</sup>

<sup>7</sup>This result for real numbers is usually referred to as the Bolzano-Weierstrass theorem. Karl Weierstrass was a famous German mathematician (1815-1897) and his name is linked to many theorems in Mathematics. Bernard Bolzano (1781-1848) was a Bohemian mathematician, logician, philosopher, theologian and Catholic priest working in Prague at the beginning of the 19th century. He laid the basis of rigorous mathematical analysis a few decades before all the theory was worked out by Weierstrass and others. In particular he was skeptical about the effective use of Leibniz's infinitesimals without the necessary rigour.

Although we have laid great emphasis on the reader to prefer reasoning about the limit behavior of functions to mindless labeling of the forms as determinate and indeterminate, it is, we hope, clear now why we will focus on the indeterminate ones.  $\square$

**5.C.16.** Calculate

$$\begin{aligned} & \lim_{x \rightarrow +\infty} \frac{\sin x + \pi x^2}{2 \cos x - 1 - x^2}, \\ & \lim_{x \rightarrow +\infty} \frac{3^{x+1} + x^5 - 4x}{3^x + 2^x + x^2}, \\ & \lim_{x \rightarrow +\infty} \frac{4^x - 8x^6 - 2^x - 167}{3^x - 45x - \sqrt{11}\pi^{x+12}}, \\ & \lim_{x \rightarrow +\infty} \frac{\sqrt{x} - \sin^3 x + x \operatorname{arctg} x}{\sqrt{1 + 2x + x^2}}. \end{aligned}$$

**Solution.** Having reduced the first fraction by the polynomial  $x^2$ , we get

$$\lim_{x \rightarrow +\infty} \frac{\sin x + \pi x^2}{2 \cos x - 1 - x^2} = \lim_{x \rightarrow +\infty} \frac{\frac{\sin x}{x^2} + \pi}{\frac{2 \cos x - 1}{x^2} - 1}.$$

Boundedness of the expressions

$$|\sin x| \leq 1, \quad |2 \cos x - 1| \leq 3 \quad \text{pro } x \in \mathbb{R}$$

and  $x^2 \rightarrow +\infty$  for  $x \rightarrow +\infty$  give us the result

$$\lim_{x \rightarrow +\infty} \frac{\frac{\sin x}{x^2} + \pi}{\frac{2 \cos x - 1}{x^2} - 1} = \frac{0 + \pi}{0 - 1} = -\pi.$$

In the last argumentation, we actually used the squeeze theorem and the notation  $c/\infty = 0$  which is valid for any  $c \in \mathbb{R}$  (or bounded/ $\infty = 0$ , where “bounded” denotes a bounded function).

This procedure can be generalized. Any limit of the form

$$\lim_{x \rightarrow x_0} \frac{f_1(x) + f_2(x) + \dots + f_m(x)}{g_1(x) + g_2(x) + \dots + g_n(x)},$$

where

$$\lim_{x \rightarrow x_0} \frac{f_i(x)}{f_1(x)} = 0, \quad i \in \{2, \dots, m\},$$

$$\lim_{x \rightarrow x_0} \frac{g_i(x)}{g_1(x)} = 0, \quad i \in \{2, \dots, n\},$$

satisfies

$$\lim_{x \rightarrow x_0} \frac{f_1(x) + f_2(x) + \dots + f_m(x)}{g_1(x) + g_2(x) + \dots + g_n(x)} = \lim_{x \rightarrow x_0} \frac{f_1(x)}{g_1(x)},$$

supposing the limit on the right-hand side exists. It is advantageous to realize (the third limit can be determined, for example, by l’Hospital’s rule, with which we will make ourselves familiar later)

$$\lim_{x \rightarrow +\infty} \frac{c}{x^\alpha} = 0, \quad \lim_{x \rightarrow +\infty} \frac{x^\alpha}{x^\beta} = 0, \quad \lim_{x \rightarrow +\infty} \frac{x^\beta}{a^x} = 0,$$

(5)  $A$  is compact if and only if each of its open covers contains a finite subcover of  $A$ .

**PROOF.** (1) Every open set is a union of some neighbourhoods of its points, i.e., we may consider open intervals in reals, or open circles in  $\mathbb{C}$ . So the question that remains is whether it suffices to take countably many of them. Let us first prove the claim for the complex plane. For each  $z \in A$ , there is an open circle  $\mathcal{O}_\delta(z)$  contained in  $A$ , with some  $\delta > 0$ , and let  $\delta_z$  be the supremum of the values of such  $\delta$ . Clearly,  $A = \cup_{z \in A} \mathcal{O}_{\delta_z}(z)$ . Consider an arbitrary  $z \in A$  and pick up  $w$  with both real and imaginary parts rational, such that  $|w - z| < \delta_z/4$ . Thus,  $z \in \mathcal{O}_{\delta_w}(w)$  (draw a picture!) and we have checked that actually  $A$  is the union of the countably many open circles  $\mathcal{O}_{\delta_w}(w)$  for all  $w \in A$  with rational real and imaginary coordinates.

If  $A$  is an open subset in  $\mathbb{R}$ , then we may repeat the above argument with the circles  $\mathcal{O}_\delta(z)$  replaced by the intervals  $\mathcal{O}_\delta(x)$  and  $x \in A$ . Think about the details!

(2) It follows immediately from the definitions that no point can be both an interior and boundary point. Let  $a \in A$  be a point that is not interior. Then there is a sequence of points  $a_i \notin A$  with  $a$  as its limit point. At the same time,  $a$  belongs to each of its neighbourhoods. Thus  $a$  is a boundary point.

(3) Suppose that  $a \in A$  is a boundary point but not isolated. Then, similarly to the reasoning from the previous paragraph, there are points  $a_i$ , this time inside  $A$ , whose limit point is  $a$ .

(4) Suppose  $A \subset \mathbb{R}$  is a compact set, i.e., both closed and bounded. Consider an infinite sequence of points  $a_i \in A$ .  $A$  has both a supremum  $b$  and an infimum  $a$ . Divide the interval  $[a, b]$  into halves:  $[a, \frac{1}{2}(b - a)]$  and  $[\frac{1}{2}(b - a), b]$ . At least one of them contains infinitely many of the terms  $a_i$ . Select this half and one of the terms contained in it; then cut the selected interval into halves. Again, select such a half which contains infinitely many of the sequence’s terms and select one of those points. By this procedure, a Cauchy sequence is established. Cauchy sequences have limit points or are constant up to finitely many exceptions. Thus there is a subsequence with the desired limit. The fact that  $A$  is closed implies that the point obtained lies in  $A$ .

Now the other direction: if every infinite subset of  $A$  has a limit point in  $A$ , then all limit points are in  $A$ , and so  $A$  is closed. If  $A$  were not bounded, we would be able to find an increasing or decreasing sequence such that the differences of absolute values of adjacent numbers would be at least 1, for instance. However, such a sequence of points in  $A$  cannot have a limit point at all.

Finally, we have to deal with the general case  $A \subset \mathbb{C}$ . The arguments of the latter implication remain the same. Thus we have to show that any sequence  $z_n$  of complex numbers in  $A$  has got a limit point in  $A$ . Consider the sequences of real and imaginary parts,  $x_n$  and  $y_n$ . Since they both have to be in the bounded subsets  $A_{\mathbb{R}}$  and  $A_{i\mathbb{R}}$  of the

$$\lim_{x \rightarrow +\infty} \frac{a^x}{b^x} = 0, \quad c \in \mathbb{R}, \quad 0 < \alpha < \beta, \quad 1 < a < b.$$

Hence we immediately have that

$$\begin{aligned} \lim_{x \rightarrow +\infty} \frac{3^{x+1} + x^5 - 4x}{3^x + 2^x + x^2} &= \lim_{x \rightarrow +\infty} \frac{3 \cdot 3^x}{3^x} = 3, \\ \lim_{x \rightarrow +\infty} \frac{4^x - 8x^6 - 2^x - 167}{3^x - 45x - \sqrt{11}\pi^{x+12}} &= \lim_{x \rightarrow +\infty} \frac{4^x}{-\sqrt{11}\pi^{12} \cdot \pi^x} \\ &= -\infty. \end{aligned}$$

If we realize that

$$\lim_{x \rightarrow +\infty} \arctg x = \frac{\pi}{2} \geq 1,$$

we will also obtain that

$$\begin{aligned} \lim_{x \rightarrow +\infty} \frac{\sqrt{x} - \sin^3 x + x \arctg x}{\sqrt{1+2x+x^2}} &= \lim_{x \rightarrow +\infty} \frac{x \arctg x}{\sqrt{x^2}} \\ &= \lim_{x \rightarrow +\infty} \arctg x = \frac{\pi}{2}. \end{aligned}$$

**5.C.17.** Determine the limits

$$\begin{aligned} \lim_{n \rightarrow \infty} \left( \frac{1}{1 \cdot 2} + \frac{1}{2 \cdot 3} + \frac{1}{3 \cdot 4} + \cdots + \frac{1}{(n-1) \cdot n} \right); \\ \lim_{n \rightarrow \infty} \left( \frac{1}{\sqrt{n^2+1}} + \frac{1}{\sqrt{n^2+2}} + \cdots + \frac{1}{\sqrt{n^2+n}} \right). \end{aligned}$$

**Solution.** Since for every natural number  $k \geq 2$  it holds that (what we do here is called partial fraction decomposition – we will present it in detail in the chapter concerning integration of rational functions)

$$\frac{1}{(k-1)k} = \frac{1}{k-1} - \frac{1}{k},$$

we get that

$$\begin{aligned} \lim_{n \rightarrow \infty} \left( \frac{1}{1 \cdot 2} + \frac{1}{2 \cdot 3} + \frac{1}{3 \cdot 4} + \cdots + \frac{1}{(n-1) \cdot n} \right) \\ = \lim_{n \rightarrow \infty} \left( \frac{1}{1} - \frac{1}{2} + \frac{1}{2} - \frac{1}{3} + \frac{1}{3} - \frac{1}{4} + \cdots + \frac{1}{n-1} - \frac{1}{n} \right) \\ = \lim_{n \rightarrow \infty} \left( 1 - \frac{1}{n} \right) = 1. \end{aligned}$$

Let us remark that this limit is quite important: it determines the sum of one of the so-called telescoping series (with which Johann I Bernoulli (1667–1748) worked).

To determine the second limit, we invoke the squeeze theorem. The bounds

$$\begin{aligned} \frac{1}{\sqrt{n^2+1}} + \cdots + \frac{1}{\sqrt{n^2+n}} &\geq \frac{1}{\sqrt{n^2+n}} + \cdots + \frac{1}{\sqrt{n^2+n}} \\ &= \frac{n}{\sqrt{n^2+n}}, \\ \frac{1}{\sqrt{n^2+1}} + \cdots + \frac{1}{\sqrt{n^2+n}} &\leq \frac{1}{\sqrt{n^2+1}} + \cdots + \frac{1}{\sqrt{n^2+1}} \\ &= \frac{n}{\sqrt{n^2+1}} \end{aligned}$$

real and imaginary projections of  $A$ , there is a subsequence  $z_{n_k} = (x_{n_k}, y_{n_k})$  such that  $x_{n_k} \rightarrow x, y_{n_k} \rightarrow y$  with the limits sitting in the closures of  $A_{\mathbb{R}}$  and  $A_{i\mathbb{R}}$ , by virtue of the already proved real case. Obviously,  $z_{n_k} \rightarrow z = (x, y)$ , but the latter limit has to sit in  $A$  since  $A$  is closed.

(5) First, focus on the easier implication. That is, suppose that every open cover contains a finite subcover. It is required to prove that  $A$  is both closed and bounded.  $A \subset \mathbb{C}$  can be covered by a countable union of neighbourhoods  $\mathcal{O}_n(z)$ , with integers  $n$  and centers  $z$  with integral real and imaginary parts. Any choice of a finite subcover of them witnesses that  $A$  is bounded. If  $A \subset \mathbb{R}$ , then the same argument applies with intervals  $\mathcal{O}_n(x), n, x \in \mathbb{Z}$ .

Now suppose that  $a \in \mathbb{C} \setminus A$  is the limit point of a sequence  $a_i \in A$ . Further, assume that  $|a - a_n| < \frac{1}{n}$  (otherwise select a subsequence satisfying this property). The sets

$$J_n = \mathbb{C} \setminus \overline{\mathcal{O}_{1/n}(a)}$$

□ for all  $n \in \mathbb{N}, n > 0$ , are open and they also cover our set  $A$ . Since it is possible to choose a finite cover of  $A$ , the point  $a$  is inside the complement  $\mathbb{C} \setminus A$ , including one of its neighbourhoods, and thus it is not a limit point. Therefore, all of  $A$ 's limit points must again lie in  $A$ . Hence  $A$  is closed.

If  $A \subset \mathbb{R}$ , the same argument applies with closed circles replaced by closed intervals.

Finally, we have to prove the other implication. So assume  $A \subset \mathbb{C}$  is complete and bounded, but there is an open covering  $U_\alpha, \alpha \in I$ , of  $A$ , which does not contain any finite covering. Consider the sequence of positive real numbers  $\varepsilon_n = 1/n$  converging to 0 and sets

$$B_n = \{z = (\frac{k}{n}, \frac{m}{n}) \in A, k, m \in \mathbb{Z}\}$$

of complex numbers with real and imaginary parts in the “ $1/n$ -net of coordinates”. Clearly all sets  $B_n$  are finite. Further, for each  $k$ , consider the system  $\mathcal{A}_k$  of closed circles with centres in the points of  $B_k$  and diameters  $2\varepsilon_k$ . Clearly each such system  $\mathcal{A}_k$  covers the entire set  $A$ . Altogether, there must be at least one closed circle  $C$  in the system  $\mathcal{A}_1$  which is not covered by a finite number the sets  $U_\alpha$ . Call it  $C_1$  and notice that  $\text{diam } C_1 = 2\varepsilon_1$ .

Next, consider the sets  $C_1 \cap C$ , with circles  $C \in \mathcal{A}_2$  which cover the entire set  $C_1$ . Again, at least one of them cannot be covered by a finite number of  $U_\alpha$ , we call it  $C_2$ . This way, we inductively construct a sequence of sets  $C_k$  satisfying  $C_{k+1} \subset C_k, \text{diam } C_k \leq 2\varepsilon_k, \varepsilon_k \rightarrow 0$ , and none of them can be covered by a finite number of the open sets  $U_\alpha$ .

Finally we choose one point  $z_k \in C_k$  in each of these sets. By construction, this must be a Cauchy-sequence. Consequently, this sequence of complex numbers has a limit  $z$ . Thus there is  $U_{\alpha_0}$  containing  $z$  and containing also some  $\delta$ -neighbourhood  $\mathcal{O}_\delta(z)$ . But now, if  $\text{diam } C_k \leq 2\varepsilon_k < \delta$ , then  $C_k \subset \mathcal{O}_\delta(z) \subset U_{\alpha_0}$ , which is a contradiction. The proof is complete when considering  $A \subset \mathbb{C}$ .

Dealing with real subset  $A \subset \mathbb{R}$ , again the same line of arguments applies, just the 2-dimensional nets  $B_k$  become

for  $n \in \mathbb{N}$  give that

$$\begin{aligned} \lim_{n \rightarrow \infty} \frac{n}{\sqrt{n^2 + n}} &\leq \lim_{n \rightarrow \infty} \left( \frac{1}{\sqrt{n^2 + 1}} + \cdots + \frac{1}{\sqrt{n^2 + n}} \right) \\ &\leq \lim_{n \rightarrow \infty} \frac{n}{\sqrt{n^2 + 1}}. \end{aligned}$$

Since

$$\begin{aligned} \lim_{n \rightarrow \infty} \frac{n}{\sqrt{n^2 + n}} &= \lim_{n \rightarrow \infty} \frac{n}{\sqrt{n^2}} = 1, \\ \lim_{n \rightarrow \infty} \frac{n}{\sqrt{n^2 + 1}} &= \lim_{n \rightarrow \infty} \frac{n}{\sqrt{n^2}} = 1, \end{aligned}$$

we also have that

$$\lim_{n \rightarrow \infty} \left( \frac{1}{\sqrt{n^2 + 1}} + \frac{1}{\sqrt{n^2 + 2}} + \cdots + \frac{1}{\sqrt{n^2 + n}} \right) = 1. \quad \square$$

**5.C.18.** Calculate

(a)

$$\lim_{x \rightarrow 0} \frac{\sqrt{1+x} - \sqrt{1-x}}{x};$$

(b)

$$\lim_{x \rightarrow \pi/4} \frac{\cos x - \sin x}{\cos(2x)};$$

(c)

$$\lim_{x \rightarrow +\infty} \sqrt[3]{x^4} \left( \sqrt[3]{x^2 + 2x + 3} - \sqrt[3]{x^2 + 2x + 2} \right).$$

**Solution.** We will calculate the wanted limits using the method of multiplying both the numerator and the denominator by a suitable expression. The first fraction can be conveniently extended by

$$\sqrt{1+x} + \sqrt{1-x}$$

and making use of the well-known formula  $(a-b)(a+b) = a^2 - b^2$ . Thus we obtain

$$\begin{aligned} \lim_{x \rightarrow 0} \frac{\sqrt{1+x} - \sqrt{1-x}}{x} &= \lim_{x \rightarrow 0} \frac{(1+x) - (1-x)}{x(\sqrt{1+x} + \sqrt{1-x})} \\ &= \lim_{x \rightarrow 0} \frac{2}{\sqrt{1+x} + \sqrt{1-x}} = \frac{2}{\sqrt{1} + \sqrt{1}} = 1. \end{aligned}$$

Similarly we can calculate

$$\begin{aligned} \lim_{x \rightarrow \pi/4} \frac{\cos x - \sin x}{\cos(2x)} &= \lim_{x \rightarrow \pi/4} \frac{(\cos x + \sin x)(\cos x - \sin x)}{(\cos x + \sin x)\cos(2x)} \\ &= \lim_{x \rightarrow \pi/4} \frac{\cos^2 x - \sin^2 x}{(\cos x + \sin x)\cos(2x)} \\ &= \lim_{x \rightarrow \pi/4} \frac{1}{\cos x + \sin x} = \frac{1}{\frac{\sqrt{2}}{2} + \frac{\sqrt{2}}{2}} = \frac{\sqrt{2}}{2}. \end{aligned}$$

The reduction was made thanks to the identity

$$\cos(2x) = \cos^2 x - \sin^2 x, \quad x \in \mathbb{R}.$$

1-dimensional and the open circles are replaced by open intervals.  $\square$

**5.2.9. Limits of functions and sequences.** For the discussion of limits, it is advantageous to extend the set  $\mathbb{R}$  of real numbers by the two infinite values  $\pm\infty$  as we have done when defining intervals.

A neighbourhood of infinity is any interval  $(a, \infty)$ . Similarly, any interval  $(-\infty, a)$  is a neighbourhood of  $-\infty$ . Further, we will extend the concept of a limit point so that  $\infty$  is a limit point of a set  $A \subset \mathbb{R}$  if and only if every neighbourhood of  $\infty$  has a non-empty intersection with it, i.e. if the set  $A$  is unbounded from above. Similarly for  $-\infty$ . We talk about the infinite limit points, sometimes also called *improper limit points* of the set  $A$ .

“CALCULATIONS” WITH INFINITIES

We also introduce rules for calculation with the formally added values  $\pm\infty$  and arbitrary “finite” numbers  $a \in \mathbb{R}$ :

$$\begin{aligned} a + \infty &= \infty \\ a - \infty &= -\infty \\ a \cdot \infty &= \infty, \text{ if } a > 0 \\ a \cdot \infty &= -\infty, \text{ if } a < 0 \\ a \cdot (-\infty) &= -\infty, \text{ if } a > 0 \\ a \cdot (-\infty) &= \infty, \text{ if } a < 0 \\ \frac{a}{\pm\infty} &= 0, \text{ for all } a \neq 0. \end{aligned}$$

The following definition covers many cases of limit processes and needs to be thoroughly understood. Some particular cases are considered in great detail below.

REAL AND COMPLEX LIMITS

**Definition.** Consider a subset  $A \subset \mathbb{R}$  and a real-valued function  $f : A \rightarrow \mathbb{R}$  or a complex-valued function  $f : A \rightarrow \mathbb{C}$ , defined on  $A$ . Further, consider a limit point  $x_0$  of the set  $A$  (i.e. a real number or  $\pm\infty$ ).

We say that  $f$  has *limit*  $a \in \mathbb{R}$  (or a complex limit  $a \in \mathbb{C}$ ) at  $x_0$  and write

$$\lim_{x \rightarrow x_0} f(x) = a$$

if and only if for every neighbourhood  $\mathcal{O}(a)$  of the point  $a$ , there is a neighbourhood  $\mathcal{O}(x_0)$  of  $x_0$  such that for all  $x \in A \cap (\mathcal{O}(x_0) \setminus \{x_0\})$ ,  $f(x) \in \mathcal{O}(a)$ .

In the case of a real-valued function,  $a = \pm\infty$  can also be the limit. Such a limit is called infinite or *improper*. In the other case, i.e.  $a \in \mathbb{R}$ , we say the limit is finite or *proper*.

It is important to notice that the value of  $f$  at  $x_0$  does not occur in the definition, and that the function  $f$  may even not be defined at this limit point (and in the case of an improper limit point, it cannot be defined, of course)!

Do we want to talk about *deleted neighbourhood*  $\mathcal{O}(x) \setminus \{x\}$  of those points where we are interested in the function values?

As for the last limit, to make use of the formula

$$(a - b)(a^2 + ab + b^2) = a^3 - b^3,$$

we consider the expression

$$\begin{aligned} \sqrt[3]{(x^2 + 2x + 3)^2} + \sqrt[3]{x^2 + 2x + 3} \cdot \sqrt[3]{x^2 + 2x + 2} \\ + \sqrt[3]{(x^2 + 2x + 2)^2}, \end{aligned}$$

which corresponds to  $a^2 + ab + b^2$ , so we choose

$$a = \sqrt[3]{x^2 + 2x + 3}, \quad b = \sqrt[3]{x^2 + 2x + 2}.$$

By this extension, we transform the original limit to for some polynomials  $P, Q$ . Let us emphasize that this really holds for all  $n \in \mathbb{N}$ . For  $n = 1$ , we set  $\binom{1}{2} = 0$  and the polynomials  $P, Q$  may be constant zeros. So we get for all real  $x$ :

$$\begin{aligned} (1 + 2nx)^n &= 1 + 2n^2x + 2n^3(n-1)x^2 + P(x)x^3, \\ (1 + nx)^{2n} &= 1 + 2n^2x + n^3(2n-1)x^2 + Q(x)x^3. \end{aligned}$$

Mere substitution and simple rearrangements give us

$$\begin{aligned} \lim_{x \rightarrow 0} \frac{(1 + 2nx)^n - (1 + nx)^{2n}}{x^2} &= \\ \lim_{x \rightarrow 0} \frac{(2n^3(n-1) - n^3(2n-1))x^2 + (P(x) - Q(x))x^3}{x^2} &= \\ = \lim_{x \rightarrow 0} (-n^3 + (P(x) - Q(x))x) &= -n^3 + 0 = -n^3. \end{aligned}$$

### 5.C.19. Calculate

$$\lim_{x \rightarrow \pi/4} (\tan x)^{\tan(2x)}.$$

**Solution.** Limits of the type  $1^{\pm\infty}$  (like the examined one) can be calculated using the formula

$$\lim_{x \rightarrow x_0} f(x)^{g(x)} = e^{\lim_{x \rightarrow x_0} ((f(x)-1)g(x))},$$

supposing the limit on the right-hand side exists and  $f(x) \neq 1$  for all  $x$  of some deleted neighborhood of the point  $x_0 \in \mathbb{R}$ . Therefore, let us determine

$$\begin{aligned} \lim_{x \rightarrow \pi/4} (\tan x - 1) \tan(2x) &= \lim_{x \rightarrow \pi/4} \left( \frac{\sin x}{\cos x} - 1 \right) \frac{\sin(2x)}{\cos(2x)} \\ &= \lim_{x \rightarrow \pi/4} \frac{\sin x - \cos x}{\cos x} \cdot \frac{2 \sin x \cos x}{\cos^2 x - \sin^2 x} \\ &= \lim_{x \rightarrow \pi/4} \frac{-2 \sin x}{\cos x + \sin x} = \frac{-2 \frac{\sqrt{2}}{2}}{\frac{\sqrt{2}}{2} + \frac{\sqrt{2}}{2}} = -1. \end{aligned}$$

Hence we have that

$$\lim_{x \rightarrow \pi/4} (\tan x)^{\tan(2x)} = \frac{1}{e}.$$

We shall not deal with improper limits of complex functions now.

**5.2.10. The most important cases of domains.** Our definition of a limit covers several very dissimilar situations:

(1) **Limits of sequences.** If  $A = \mathbb{N}$ , i.e. the function  $f$  is defined for the natural numbers only, we talk about limits of sequences of real or complex numbers. In this case, the only limit point of the domain is  $\infty$ , and we mostly write the values (terms) of the sequence as  $f(n) = a_n$  and the limit in the form

$$\lim_{n \rightarrow \infty} a_n = a.$$

According to the definition, this means that for any neighbourhood  $\mathcal{O}(a)$  of the limit value  $a$ , there is an index  $N \in \mathbb{N}$  such that  $a_n \in \mathcal{O}(a)$  for all  $n \geq N$ . Actually, we have only reformulated the definition of convergence of a sequence (see 5.2.3). We have only added the possibility of infinite limits. As before, we also say that the *sequence  $a_n$  converges to  $a$* .

We can easily see from our definition for complex numbers that a sequence of complex values has limit  $a$  if and only if the real parts of  $a_i$  converge to  $\text{Re } a$  and the imaginary parts converge to  $\text{Im } a$ .

(2) **Limits of functions at interior points of intervals.** If  $f$  is defined on the interval  $A = (a, b)$  and  $x_0$  is an interior point of this interval, we talk about the limit of a function at an interior point of its domain. Usually, we write

$$\lim_{x \rightarrow x_0} f(x) = a.$$

□ Let us examine why it is important to require  $f(x) \in \mathcal{O}(a)$  only for the points  $x \neq x_0$  in this case as well. As an example, let us consider the function  $f: \mathbb{R} \rightarrow \mathbb{R}$

$$f(x) = \begin{cases} 0 & \text{if } x \neq 0 \\ 1 & \text{if } x = 0. \end{cases}$$

Apparently, the limit at zero is well-defined, and in accordance with our expectations,  $\lim_{x \rightarrow 0} f(x) = 0$  even though the value  $f(0) = 1$  does not belong into small neighbourhoods of the limit point 0.

An equivalent definition using  $\varepsilon$ -neighbourhoods of the limits  $a$  and  $\delta$ -neighbourhoods of the limit points  $x_0$  is the following:  $\lim_{x \rightarrow x_0} f(x) = a$  if for each  $\varepsilon > 0$  there is a  $\delta > 0$  such, that for all  $x \neq x_0$  satisfying  $|x - x_0| < \delta$ ,  $|f(x) - a| < \varepsilon$ .

(3) **One-sided limits.** If  $A = [a, b]$  is a bounded interval and  $x_0 = a$  or  $x_0 = b$ , we talk about a one-sided limit of the function  $f$  at the point  $x_0$ , from the right and from the left respectively.

If the point  $x_0$  is an interior point of the domain of  $f$ , we can, in order to determine the limit, consider the domain restricted to  $[x_0, b]$  or  $[a, x_0]$ . The resulting limits are also called a *right-sided limit* and *left-sided limit*, respectively, of the function  $f$  at the point  $x_0$ . We denote them by  $\lim_{x \rightarrow x_0^+} f(x)$  and  $\lim_{x \rightarrow x_0^-} f(x)$ , respectively. As an example, we can consider the one-sided limits at  $x_0 = 0$  for Heaviside's function

Let us remark that the used formula holds more generally for “the type 1<sup>whatever</sup>”, that is with no further conditions on the limit  $\lim_{x \rightarrow x_0} g(x)$  which even need not exist.  $\square$

**5.C.20.** Show that

$$\lim_{x \rightarrow 0} \frac{\sin x}{x} = 1.$$

**Solution.** Let us consider the unit circle (especially its quarter lying in the first quadrant) and its point  $[\cos x, \sin x]$ ,  $x \in (0, \pi/2)$ . The length of the arc between the points  $[\cos x, \sin x]$  and  $[1, 0]$  is equal to  $x$ . So we apparently have

$$\sin x < x, \quad x \in \left(0, \frac{\pi}{2}\right).$$

The value  $\tan x$  is then the distance between the points  $[1, \sin x / \cos x]$  and  $[1, 0]$ . We can see that (feel free to draw a picture)

$$x < \tan x, \quad x \in \left(0, \frac{\pi}{2}\right).$$

This inequality also follows from the fact that the area of the triangle with vertices  $[0, 0]$ ,  $[1, 0]$ ,  $[1, \tan x]$  is greater than the area of the considered circular sector. Altogether, we have obtained that

$$\sin x < x < \frac{\sin x}{\cos x}, \quad x \in \left(0, \frac{\pi}{2}\right),$$

that is

$$\begin{aligned} 1 &< \frac{x}{\sin x} < \frac{1}{\cos x}, & x \in \left(0, \frac{\pi}{2}\right), \\ 1 &> \frac{\sin x}{x} > \cos x, & x \in \left(0, \frac{\pi}{2}\right). \end{aligned}$$

Invoking the squeeze theorem, we get the inequalities

$$1 = \lim_{x \rightarrow 0^+} 1 \geq \lim_{x \rightarrow 0^+} \frac{\sin x}{x} \geq \lim_{x \rightarrow 0^+} \cos x = \cos 0 = 1.$$

Thus we have proved that

$$\lim_{x \rightarrow 0^+} \frac{\sin x}{x} = 1.$$

The function  $y = (\sin x)/x$  defined for  $x \neq 0$  is even, whence it follows that

$$\lim_{x \rightarrow 0^-} \frac{\sin x}{x} = \lim_{x \rightarrow 0^+} \frac{\sin x}{x} = 1.$$

Since both one-sided limits exist and have the same value, the examined limit exists as well and satisfies

$$\lim_{x \rightarrow 0} \frac{\sin x}{x} = \lim_{x \rightarrow 0^\pm} \frac{\sin x}{x} = 1.$$

Let us remark that at first sight, one could say the limit can be calculated using l’Hospital’s rule. However, then one would have to know the sine’s derivative at zero which, actually, is the limit in question. Thus we may not invoke l’Hospital’s rule in this case.  $\square$

$h$  from the beginning of this part. Apparently,

$$\lim_{x \rightarrow 0^+} h(x) = 1, \quad \lim_{x \rightarrow 0^-} h(x) = 0.$$

However, the limit  $\lim_{x \rightarrow 0} f(x)$  does not exist.

It follows from the definitions that *the limit at an interior point of the domain of an arbitrary function  $f$  exists if and only if both one-sided limits exist and are equal.*

**5.2.11. Further examples of limits.** (1) The limit of a complex function  $f : A \rightarrow \mathbb{C}$  in a limit point  $x_0$  of its domain exists if and only if the limits of both the real part and the imaginary part exist. In this case, we have

$$\lim_{x \rightarrow x_0} f(x) = \lim_{x \rightarrow x_0} (\operatorname{Re} f(x)) + i \lim_{x \rightarrow x_0} (\operatorname{Im} f(x)).$$

The proof is straightforward and makes direct use of the definitions of distances and neighbourhoods of the points in the complex plane. Indeed, the membership into a  $\delta$ -neighbourhood of a complex value  $z$  is guaranteed by the real  $(1/\sqrt{2})\delta$ -neighbourhoods of the real and the imaginary parts of  $z$ . Hence the proposition follows immediately.

(2) Let  $f$  be a real or complex polynomial. Then for every point  $x \in \mathbb{R}$ ,

$$\lim_{x \rightarrow x_0} f(x) = f(x_0).$$

Really, if  $f(x) = a_n x^n + \dots + a_0$ , then the identity  $(x_0 + \delta)^k = x_0^k + k\delta x_0^{k-1} + \dots + \delta^k$ , substituted for  $k = 0, \dots, n$ , gives that choosing a sufficiently small  $\delta$  makes the values arbitrarily close to  $f(x_0)$ .

(3) Now consider the following function defined on the whole real line

$$f(x) = \begin{cases} 1 & \text{if } x \in \mathbb{Q} \\ 0 & \text{if } x \notin \mathbb{Q}. \end{cases}$$

It is apparent from the definition that this function cannot have (even one-sided) limits at any point of its domain.

(4) The following function is even trickier than the previous one. Let  $f : \mathbb{R} \rightarrow \mathbb{R}$  be the function defined as follows:<sup>8</sup>

$$f(x) = \begin{cases} 1 & \text{if } x = 0 \\ \frac{1}{q} & \text{if } x = \frac{p}{q} \in \mathbb{Q}, p, q > 0 \text{ are co-prime,} \\ 0 & \text{if } x \notin \mathbb{Q}. \end{cases}$$

<sup>8</sup>This function is called the *Thomae function* after the German mathematician J. Thomae, 1840–1921. You may find it under many other names too: e.g. *Riemann function*, *pop-corn function*, *raindrop function* etc. It illustrates how badly dense the “discontinuity” points of a function can be even though it has limits everywhere.

**5.C.21.** Determine the limits

$$\lim_{n \rightarrow \infty} \left( \frac{n}{n+1} \right)^n, \quad \lim_{n \rightarrow \infty} \left( 1 + \frac{1}{n^2} \right)^n, \quad \lim_{n \rightarrow \infty} \left( 1 - \frac{1}{n} \right)^{n^2},$$

$$\lim_{x \rightarrow 0} \frac{\sin^2 x}{x}, \quad \lim_{x \rightarrow 0} \frac{x}{\sin^2 x}, \quad \lim_{x \rightarrow 0} \frac{\arcsin x}{x},$$

$$\lim_{x \rightarrow 0} \frac{3 \tan^2 x}{5x^2}, \quad \lim_{x \rightarrow 0} \frac{\sin(3x)}{\sin(5x)}, \quad \lim_{x \rightarrow 0} \frac{\tan(3x)}{\sin(5x)},$$

$$\lim_{x \rightarrow 0} \frac{e^{5x} - e^{2x}}{x}, \quad \lim_{x \rightarrow 0} \frac{e^{5x} - e^{-x}}{\sin(2x)}.$$

**Solution.** When calculating these limits, we will use our knowledge of the following limits ( $a \in \mathbb{R}$ ):

$$\lim_{n \rightarrow \infty} \left( 1 + \frac{a}{n} \right)^n = e^a, \quad \lim_{x \rightarrow 0} \frac{\sin x}{x} = 1, \quad \lim_{x \rightarrow 0} \frac{e^x - 1}{x} = 1.$$

Thus we know that

$$e^{-1} = \lim_{n \rightarrow \infty} \left( 1 - \frac{1}{n} \right)^n = \lim_{n \rightarrow \infty} \left( \frac{n-1}{n} \right)^n.$$

The substitution  $m = n - 1$  gives us

$$\begin{aligned} \lim_{n \rightarrow \infty} \left( \frac{n-1}{n} \right)^n &= \lim_{m \rightarrow \infty} \left( \frac{m}{m+1} \right)^{m+1} \\ &= \lim_{m \rightarrow \infty} \left( \frac{m}{m+1} \right)^m \cdot \lim_{m \rightarrow \infty} \frac{m}{m+1}. \end{aligned}$$

Altogether, we have

$$e^{-1} = \lim_{m \rightarrow \infty} \left( \frac{m}{m+1} \right)^m \cdot \lim_{m \rightarrow \infty} \frac{m}{m+1}.$$

Clearly, the second limit is equal to 1. Changing the variables (replacing  $n$  with  $m$ ), we can write the result

$$e^{-1} = \lim_{n \rightarrow \infty} \left( \frac{n}{n+1} \right)^n.$$

Further, it holds that

$$\begin{aligned} \lim_{n \rightarrow \infty} \left( 1 + \frac{1}{n^2} \right)^n &= \lim_{n \rightarrow \infty} \left( 1 + \frac{1}{n^2} \right)^{\frac{n^2}{n}} \\ &= \lim_{n \rightarrow \infty} \left( \left( 1 + \frac{1}{n^2} \right)^{n^2} \right)^{\frac{1}{n}} = e^0 = 1 \end{aligned}$$

and

$$\lim_{n \rightarrow \infty} \left( 1 - \frac{1}{n} \right)^{n^2} = \lim_{n \rightarrow \infty} \left( \left( 1 - \frac{1}{n} \right)^n \right)^n = 0.$$

Let us point out that the first result follows from the limits

$$\lim_{n \rightarrow \infty} \left( 1 + \frac{1}{n^2} \right)^{n^2} = \lim_{m \rightarrow \infty} \left( 1 + \frac{1}{m} \right)^m = e, \quad \lim_{n \rightarrow \infty} \frac{1}{n} = 0$$

and the second one from

$$\lim_{n \rightarrow \infty} \left( 1 - \frac{1}{n} \right)^n = e^{-1}, \quad \lim_{n \rightarrow \infty} n = +\infty,$$

where  $e^{-\infty} = 0$  ( $= \lim_{x \rightarrow -\infty} e^x = 0$ ).

Choose any point  $x_0$ , no matter whether rational or irrational. Our goal is show that  $\lim_{x \rightarrow x_0} f(x) = 0$ . Thus fix any  $\varepsilon > 0$  and look at the possible values of  $f(x)$  close to  $x_0$ . Notice that  $f(x) \geq \varepsilon$ , i.e.  $\frac{1}{q} \geq \varepsilon$  can be true for only finite number of  $q \in \mathbb{N}$ . This behaviour is illustrated on the diagram. In particular, there can be only a finite number of points  $x$  in the interval  $(x_0 - 1, x_0 + 1)$  for which  $f(x) \geq \varepsilon$ . Label them  $x_1, \dots, x_n$ . Finally, choose  $\delta$  smaller than the minimum of the distances of any two different points  $x_i$ . Then  $f(x) < \varepsilon$  for all  $x \in \mathcal{O}_\delta(x_0) \setminus \{x_0\}$ . This finishes the proof.

Notice that this limit equals the function value only at the irrational points.

**5.2.12. The squeeze theorem.** The following result is elementary, but extremely useful. We meet it when computing limits of all types discussed above, i.e. limits of sequences, limits of functions at interior points, one-sided limits, and so on.

**Theorem.** Let  $f, g, h$  be three real-valued functions with the same domain  $A$  and such that there is a deleted neighbourhood of a limit point  $x_0 \in \mathbb{R}$  of the domain where

$$f(x) \leq g(x) \leq h(x).$$

Suppose there are limits

$$\lim_{x \rightarrow x_0} f(x) = f_0, \quad \lim_{x \rightarrow x_0} h(x) = h_0$$

and  $f_0 = h_0$ . Then the limit

$$\lim_{x \rightarrow x_0} g(x) = g_0$$

exists, and it satisfies  $g_0 = f_0 = h_0$ .

**PROOF.** From the assumptions of the theorem, it follows that for any  $\varepsilon > 0$ , there is a neighbourhood  $\mathcal{O}(x_0)$  of the point  $x_0 \in A \subset \mathbb{R}$  in which both  $f(x)$  and  $h(x)$  lie in the interval  $(f_0 - \varepsilon, f_0 + \varepsilon)$ , for all  $x \neq x_0$ . From the condition  $f(x) \leq g(x) \leq h(x)$ , it follows that  $g(x) \in (f_0 - \varepsilon, f_0 + \varepsilon)$ , and so  $\lim_{x \rightarrow x_0} g(x) = f_0$ .

The above reasoning is easily modified for infinite limit values or for limits at infinite points  $x_0$ . In the first case, choose a large  $N$  instead of  $\varepsilon$ . The condition on the values reads: both  $f(x)$  and  $h(x)$  have values larger than  $N$  on the neighbourhood  $\mathcal{O}(x_0) \setminus \{x_0\}$ , and thus the same will be true for  $g(x)$ . In the second case, the neighbourhood  $\mathcal{O}$  will be an

We can easily get that

$$\lim_{x \rightarrow 0} \frac{\sin^2 x}{x} = \lim_{x \rightarrow 0} \sin x \cdot \lim_{x \rightarrow 0} \frac{\sin x}{x} = 0 \cdot 1 = 0.$$

Apparently,

$$\lim_{x \rightarrow 0} \frac{x}{\sin x} = 1^{-1} = 1$$

and the limit

$$\lim_{x \rightarrow 0} \frac{1}{\sin x}$$

does not exist (we write  $1/\pm 0$ ). If we used the rule for the limit of a product to determine the limit

$$\lim_{x \rightarrow 0} \frac{x}{\sin^2 x},$$

we would obtain  $1 \cdot 1/\pm 0 = 1/\pm 0$ . This means that the limit does not exist (this, again, is a determinate form). For the calculation of

$$\lim_{x \rightarrow 0} \frac{\arcsin x}{x},$$

we will make use of the identity  $x = \sin(\arcsin x)$  which holds for any  $x \in (-1, 1)$ , that is in some neighborhood of the point 0. Substituting  $y = \arcsin x$ , we get

$$\lim_{x \rightarrow 0} \frac{\arcsin x}{x} = \lim_{x \rightarrow 0} \frac{\arcsin x}{\sin(\arcsin x)} = \lim_{y \rightarrow 0} \frac{y}{\sin y} = 1.$$

Let us remark that  $y \rightarrow 0$  follows from substituting  $x = 0$  into  $y = \arcsin x$  and from continuity of this function at 0 (this also guarantees that such a substitution can be made).

We can immediately see that

$$\begin{aligned} \lim_{x \rightarrow 0} \frac{3 \tan^2 x}{5x^2} &= \lim_{x \rightarrow 0} \left( \frac{3}{5} \cdot \frac{\sin x}{x} \cdot \frac{\sin x}{x} \cdot \frac{1}{\cos^2 x} \right) \\ &= \frac{3}{5} \cdot \lim_{x \rightarrow 0} \frac{\sin x}{x} \cdot \lim_{x \rightarrow 0} \frac{\sin x}{x} \cdot \lim_{x \rightarrow 0} \frac{1}{\cos^2 x} \\ &= \frac{3}{5} \cdot 1 \cdot 1 \cdot 1 = \frac{3}{5}. \end{aligned}$$

By appropriate extension and substitution, we get

$$\begin{aligned} \lim_{x \rightarrow 0} \frac{\sin(3x)}{\sin(5x)} &= \lim_{x \rightarrow 0} \left( \frac{\sin(3x)}{3x} \cdot \frac{5x}{\sin(5x)} \cdot \frac{3}{5} \right) \\ &= \lim_{x \rightarrow 0} \frac{\sin(3x)}{3x} \cdot \lim_{x \rightarrow 0} \frac{5x}{\sin(5x)} \cdot \frac{3}{5} \\ &= \lim_{y \rightarrow 0} \frac{\sin y}{y} \cdot \lim_{z \rightarrow 0} \frac{z}{\sin z} \cdot \frac{3}{5} = 1 \cdot 1 \cdot \frac{3}{5} = \frac{3}{5}. \end{aligned}$$

Thanks to the previous result, it can easily be calculated that

$$\begin{aligned} \lim_{x \rightarrow 0} \frac{\tan(3x)}{\sin(5x)} &= \lim_{x \rightarrow 0} \left( \frac{\sin(3x)}{\sin(5x)} \cdot \frac{1}{\cos(3x)} \right) \\ &= \lim_{x \rightarrow 0} \frac{\sin(3x)}{\sin(5x)} \cdot \lim_{x \rightarrow 0} \frac{1}{\cos(3x)} = \frac{3}{5} \cdot 1 = \frac{3}{5}. \end{aligned}$$

interval  $(M, \infty)$ . The other infinite limit point  $-\infty$  is dealt with similarly.  $\square$

The next theorem reveals the elementary properties of limits, again for all types together. Think about the individual cases, including the limits taken at  $x_0 = \pm\infty$ !

**5.2.13. Theorem.** *Let  $A \subset \mathbb{R}$  be the domain of real or complex functions  $f$  and  $g$ , let  $x_0$  be a limit point of  $A$  and let the limits*

$$\lim_{x \rightarrow x_0} f(x) = a \in \mathbb{K}, \quad \lim_{x \rightarrow x_0} g(x) = b \in \mathbb{K}$$

exist. Then:

- (1) the limit  $a$  is unique,
- (2) the limit of the sum  $f + g$  exists and satisfies

$$\lim_{x \rightarrow x_0} (f(x) + g(x)) = a + b,$$

- (3) the limit of the product  $f \cdot g$  exists and satisfies

$$\lim_{x \rightarrow x_0} (f(x) \cdot g(x)) = a \cdot b.$$

*In particular, if  $f(x) = a$  is a constant function then  $\lim_{x \rightarrow x_0} a \cdot g(x) = a \cdot b$ ,*

- (4) if  $b \neq 0$ , the limit of the quotient  $f/g$  exists and satisfies

$$\lim_{x \rightarrow x_0} \frac{f(x)}{g(x)} = \frac{a}{b}.$$

**PROOF.** (1) Suppose  $a$  and  $a'$  are two values of the limit  $\lim_{x \rightarrow x_0} f(x)$ . If  $a \neq a'$ , then there are disjoint neighbourhoods  $\mathcal{O}(a)$  and  $\mathcal{O}(a')$ . However, for sufficiently small neighbourhoods of  $x_0$ , the values of  $f$  should lie in both neighbourhoods. This is a contradiction. Thus  $a = a'$ .

(2) Choose a neighbourhood of  $a+b$ , for instance  $\mathcal{O}_{2\varepsilon}(a+b)$ . For a sufficiently small neighbourhood of  $x_0$  and  $x \neq x_0$ , both  $f(x)$  and  $g(x)$  will lie in  $\varepsilon$ -neighbourhoods of the points  $a$  and  $b$ . Hence their sum will lie in the  $2\varepsilon$ -neighbourhood of  $a+b$ . The proposition is proved.

(3) Similarly to the above paragraph: choose  $\mathcal{O}_{\varepsilon^2}(ab)$ . For sufficiently small neighbourhoods of  $x_0$ , the values of both  $f$  and  $g$  will lie in  $\varepsilon$ -neighbourhoods of the values  $a$  and  $b$ . Therefore, their product will lie in the required  $\varepsilon^2$ -neighbourhood.

Clearly, the limit of the constant function  $f(x) = a$  is  $a$  at all limit points of its domain.

(4) In view of the previous results, it suffices to prove  $\lim_{x \rightarrow x_0} \frac{1}{g(x)} = \frac{1}{b}$  for  $b > 0$ . We need to be careful when considering complex valued functions. We need to estimate

$$\left| \frac{1}{g(x)} - \frac{1}{b} \right| = \left| \frac{b - g(x)}{g(x) \cdot b} \right|.$$

Since  $b > 0$ , we may restrict ourselves to a neighbourhood  $U$  of  $x_0$  such that  $|g(x)| > \frac{b}{2}$ . Then  $|g(x)| \cdot |b| > \frac{|b|^2}{2}$ . Thus, if  $|g(x) - b| < \varepsilon$ , then

$$\left| \frac{1}{g(x)} - \frac{1}{b} \right| < \frac{2|b - g(x)|}{|b|^2} < \frac{2\varepsilon}{|b|^2}.$$

This verifies the claim.  $\square$

Similarly, we can determine

$$\begin{aligned} \lim_{x \rightarrow 0} \frac{e^{5x} - e^{2x}}{x} &= \lim_{x \rightarrow 0} \left( e^{2x} \frac{e^{(5-2)x} - 1}{(5-2)x} (5-2) \right) \\ &= \lim_{x \rightarrow 0} e^{2x} \cdot \lim_{x \rightarrow 0} \frac{e^{3x} - 1}{3x} \cdot 3 \\ &= e^0 \cdot \lim_{y \rightarrow 0} \frac{e^y - 1}{y} \cdot 3 = 1 \cdot 1 \cdot 3 = 3 \end{aligned}$$

and also

$$\begin{aligned} \lim_{x \rightarrow 0} \frac{e^{5x} - e^{-x}}{\sin(2x)} &= \lim_{x \rightarrow 0} \left( \frac{e^{5x} - 1}{\sin(2x)} - \frac{e^{-x} - 1}{\sin(2x)} \right) \\ &= \lim_{x \rightarrow 0} \left( \frac{e^{5x} - 1}{5x} \cdot \frac{2x}{\sin(2x)} \cdot \frac{5}{2} \right. \\ &\quad \left. - \frac{e^{-x} - 1}{-x} \cdot \frac{2x}{\sin(2x)} \cdot \left( -\frac{1}{2} \right) \right) \\ &= \lim_{x \rightarrow 0} \frac{e^{5x} - 1}{5x} \cdot \lim_{x \rightarrow 0} \frac{2x}{\sin(2x)} \cdot \frac{5}{2} \\ &\quad - \lim_{x \rightarrow 0} \frac{e^{-x} - 1}{-x} \cdot \lim_{x \rightarrow 0} \frac{2x}{\sin(2x)} \cdot \left( -\frac{1}{2} \right) \\ &= \frac{5}{2} \lim_{u \rightarrow 0} \frac{e^u - 1}{u} \cdot \lim_{z \rightarrow 0} \frac{z}{\sin z} + \frac{1}{2} \lim_{v \rightarrow 0} \frac{e^v - 1}{v} \cdot \lim_{z \rightarrow 0} \frac{z}{\sin z} \\ &= \frac{5}{2} + \frac{1}{2} = 3. \end{aligned}$$

**5.C.22.** Calculate the limits

$$\lim_{x \rightarrow 0} \frac{1 - \cos(2x)}{x \sin x}; \quad \lim_{x \rightarrow 0} \frac{1 - \cos x}{x^2}.$$

**Solution.** We will utilize the fact that

$$\lim_{x \rightarrow 0} \frac{\sin x}{x} = 1.$$

Then we get

$$\begin{aligned} \lim_{x \rightarrow 0} \frac{1 - \cos(2x)}{x \sin x} &= \lim_{x \rightarrow 0} \frac{1 - (\cos^2 x - \sin^2 x)}{x \sin x} \\ &= \lim_{x \rightarrow 0} \frac{(1 - \cos^2 x) + \sin^2 x}{x \sin x} \\ &= \lim_{x \rightarrow 0} \frac{2 \sin^2 x}{x \sin x} = \lim_{x \rightarrow 0} 2 \frac{\sin x}{x} = 2; \end{aligned}$$

and

$$\begin{aligned} \lim_{x \rightarrow 0} \frac{1 - \cos x}{x^2} &= \lim_{x \rightarrow 0} \left( \frac{1 - \cos x}{x^2} \cdot \frac{1 + \cos x}{1 + \cos x} \right) \\ &= \lim_{x \rightarrow 0} \frac{1 - \cos^2 x}{x^2 (1 + \cos x)} = \lim_{x \rightarrow 0} \frac{\sin^2 x}{x^2 (1 + \cos x)} \\ &= \left( \lim_{x \rightarrow 0} \frac{\sin x}{x} \right)^2 \cdot \lim_{x \rightarrow 0} \frac{1}{1 + \cos x} = \frac{1}{2}. \end{aligned}$$

Let us remark that we could also use the identity

$$1 - \cos(2x) = 2 \sin^2 x, \quad x \in \mathbb{R}.$$

□

**5.2.14. Remarks on infinite values of limits.** The statement of the theorem can be extended to some infinite values of the limits of real-valued functions: For sums, either at least one of the two limits must be finite or both limits share the same sign. Then the limit of the sum is the sum of the limits, with the conventions from 5.2.9. However, “ $\infty - \infty$ ” is excluded.

For products, if one of the limits is infinite, then the other limit must be non-zero. Then the limit of the product is the product of the limits. The case “ $0 \cdot (\pm\infty)$ ” is excluded.

For a quotient, it may be that  $a \in \mathbb{R}$  and  $b = \pm\infty$ , then the resulting limit will be zero; or  $a = \pm\infty$  and  $b \in \mathbb{R}$ , then it will be  $\pm\infty$  according to the signs of the numerator and the denominator. The case “ $\frac{\infty}{\infty}$ ” is excluded.

The theorem also covers, as a special case, the corresponding statements about the convergence of sequences as well as about one-sided limits of functions defined on an interval.

The following provides a “convergence test” useful in many situations. It relates to limits of sequences and functions in general.

**5.2.15. Proposition.** Consider a real or complex valued function  $f$  defined on a set  $A \subset \mathbb{R}$  and a limit point  $x_0$  of the set  $A$ .  $f$  has a limit  $y$  at  $x_0$  if and only if for every sequence of points  $x_n \in A$  converging to  $x_0$ ,  $x_n \neq x_0$ , the sequence of the values  $f(x_n)$  has limit  $y$ .

□

### CONVERGENCE TEST

**PROOF.** Suppose first that the limit of  $f$  at  $x_0$  is  $y$ . Then for any neighbourhood  $U$  of the point  $y$ , there is a neighbourhood  $V$  of  $x_0$  such that for all  $x \in V \cap A$ ,  $x \neq x_0$ ,  $f(x) \in U$ . For every sequence  $x_n \rightarrow x_0$  of points different from  $x_0$ , the terms  $x_n$  lie in  $V$  for all  $n$  greater than a suitable  $N$ . Therefore, the sequence  $f(x_n)$  converges to  $y$ .

Now suppose that the function  $f$  does not converge to  $y$  at  $x \rightarrow x_0$ . Then for some neighbourhood  $U$  of  $y$ , there is a sequence of points  $x_m \neq x_0$  in  $A$  which are closer to  $x_0$  than  $1/m$ , with  $f(x_m)$  not belonging to  $U$ . In this way, there is constructed a sequence of points lying in  $A$  different from  $x_0$ , with  $\lim_{m \rightarrow \infty} x_m = x_0$ , for which the values  $f(x_n)$  do not converge to  $y$ . The proof is finished. □

**D. Continuity of functions**

**5.D.1.** Let us examine existence of limits and continuity of the function  $(x - 1)^{-\operatorname{sgn} x}$  at the points 0 and 1.

**Solution.** First, let us calculate the one-sided limits at the point 0:

$$\begin{aligned} \lim_{x \rightarrow 0^-} (x - 1)^{-\operatorname{sgn} x} &= \lim_{x \rightarrow 0^-} (x - 1) = -1, \\ \lim_{x \rightarrow 0^+} (x - 1)^{-\operatorname{sgn} x} &= \lim_{x \rightarrow 0^+} \frac{1}{x-1} = -1, \end{aligned}$$

whence  $\lim_{x \rightarrow 0} (x - 1)^{-\operatorname{sgn} x} = -1$ . However, the function value at 0 equals 1, so the examined function is not continuous at the point 0. Further, we have that

$$\begin{aligned} \lim_{x \rightarrow 1^-} (x - 1)^{-\operatorname{sgn} x} &= \lim_{x \rightarrow 1^-} \frac{1}{x-1} = -\infty, \\ \lim_{x \rightarrow 1^+} (x - 1)^{-\operatorname{sgn} x} &= \lim_{x \rightarrow 1^+} \frac{1}{x-1} = \infty. \end{aligned}$$

Both one-sided limits at the point 1 exist, yet they differ, which implies that the (two-sided) limit of this function at 1 does not exist, and the function is not continuous here, either.  $\square$

**5.D.2.** Without invoking the squeeze theorem, prove that the function

$$R(x) = \begin{cases} x, & x \in \{\frac{1}{n}; n \in \mathbb{N}\}; \\ 0, & x \in \mathbb{R} \setminus \{\frac{1}{n}; n \in \mathbb{N}\} \end{cases}$$

is continuous at the point 0.

**Solution.** The function  $R$  is continuous at the point 0 if and only if

$$\lim_{x \rightarrow 0} R(x) = R(0) = 0.$$

We will show that, by the definition of a limit, the examined limit equals 0. Let  $\delta > 0$  be arbitrary. For any  $x \in (-\delta, \delta)$  we have that  $R(x) = 0$ , or  $R(x) = x$ , hence (in both cases) we get  $R(x) \in (-\delta, \delta)$ . In other words, having chosen any  $\delta$ -neighborhood  $(-\delta, \delta)$  of the point  $a$ , we can take the  $\delta$ -neighborhood  $(-\delta, \delta)$  of the point  $x_0$  as then for any  $x \in (-\delta, \delta)$  (the considered neighborhood of  $x_0$ ) it holds that  $R(x) \in (-\delta, \delta)$  (here, the interval  $(-\delta, \delta)$  is the neighborhood of  $a$ ). This matches the definition of a limit (we did not even have to require  $x \neq x_0$ ).

The considered function  $R$  is called the Riemann function (hence the name  $R$ ). In literature, it can be found in many modifications. For instance, the function

$$f(x) = \begin{cases} 1, & x \in \mathbb{Z}; \\ \frac{1}{q}, & x = \frac{p}{q} \in \mathbb{Q}; p, q \text{ relatively prime, } q > 1; \\ 0, & x \notin \mathbb{Q} \end{cases}$$

is also “often” called the Riemann function.  $\square$

**5.2.16. Continuity.** Continuity was discussed intuitively when polynomials were discussed. Now all the tools for a proper formulation of continuity are prepared. This is the basic class of functions in the sequel.

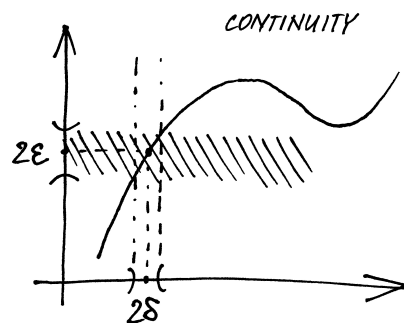

CONTINUITY OF FUNCTIONS

**Definition.** Let  $f$  be a real or complex valued function defined on an interval  $A \subset \mathbb{R}$ .  $f$  is *continuous at a point*  $x_0 \in A$  if and only if

$$\lim_{x \rightarrow x_0} f(x) = f(x_0).$$

The function  $f$  is continuous on an interval  $A$  if and only if it is continuous at every point  $x_0 \in A$ .

The diagram explains the meaning of continuity. Firstly, the limit has to exist. Thus, after choosing a neighbourhood  $U$  of the limit value  $f(x_0)$  (the  $\varepsilon$ -neighbourhood  $\mathcal{O}_\varepsilon(f(x_0))$  is shown), there is a neighbourhood of  $x_0$  (the  $\delta$ -neighbourhood is shown), for which all images lie in  $U$ . In words, if we decide how close we want to be to  $f(x_0)$ , we always may choose a sufficiently small neighbourhood of  $x_0$  where this is guaranteed.

Notice that for the boundary points of the interval  $A$ , the definition says that value of  $f$  equals the value of the one-sided limit there. The function is said to be *right-continuous* or *left-continuous* at such a point. Every polynomial is a continuous function on the whole  $\mathbb{R}$ , see 5.2.11(2). The Thomae function is continuous at irrational real numbers only although it has limits at all rational points as well, see 5.2.11(4).

The previous theorem 5.2.13 about limit properties implies immediately all of the following claims. The same properties are true for right-continuity or left-continuity, as is easily checked.

**5.2.17. Theorem.** Let  $f$  and  $g$  be (real or complex valued) functions defined on an interval  $A \subset \mathbb{R}$  and continuous at a point  $x_0 \in A$ . Then

- (1) the sum  $f + g$  is continuous at  $x_0$
- (2) the product  $f \cdot g$  is continuous at  $x_0$
- (3) if  $g(x_0) \neq 0$ , then the quotient  $f/g$  is well-defined on some neighbourhood of  $x_0$  and is continuous at  $x_0$ .
- (4) If a continuous function  $h$  is defined on a neighbourhood of  $f(x_0)$  of the real-valued function  $f$ , then the composite

**5.D.3.** By defining the values at the points  $-1$  and  $1$ , extend the function

$$f(x) = (x^2 - 1) \sin \frac{2x - 1}{x^2 - 1}, \quad x \neq \pm 1 (x \in \mathbb{R})$$

so that the resulting function is continuous on the whole  $\mathbb{R}$ .

**Solution.** The original function is continuous at every point of its domain. Thus the extended function will be continuous if and only if we set

$$\begin{aligned} f(-1) &:= \lim_{x \rightarrow -1} \left( (x^2 - 1) \sin \frac{2x - 1}{x^2 - 1} \right), \\ f(1) &:= \lim_{x \rightarrow 1} \left( (x^2 - 1) \sin \frac{2x - 1}{x^2 - 1} \right). \end{aligned}$$

If either of these limits did not exist (or were infinite), the function could not be extended to a continuous one. Clearly we have that

$$\left| \sin \frac{2x - 1}{x^2 - 1} \right| \leq 1, \quad x \neq \pm 1 (x \in \mathbb{R}),$$

whence it follows that

$$-|x^2 - 1| \leq f(x) \leq |x^2 - 1|, \quad x \neq \pm 1 (x \in \mathbb{R}).$$

Since

$$\lim_{x \rightarrow \pm 1} |x^2 - 1| = 0,$$

by the squeeze theorem, we get the result  $f(\pm 1) := 0$ .  $\square$

**5.D.4.** Determine whether the equation  $e^{2x} - x^4 + 3x^3 - 6x^2 = 5$  has a positive solution.

**Solution.** Let us consider the function

$$f(x) := e^{2x} - x^4 + 3x^3 - 6x^2 - 5, \quad x \geq 0,$$

for which

$$f(0) = -4, \quad \lim_{x \rightarrow +\infty} f(x) = \lim_{x \rightarrow +\infty} e^{2x} = +\infty.$$

From the fact that  $f$  is continuous on the whole domain it thus follows that it takes on all values  $y \in [-4, +\infty)$ . Especially, its graph necessarily intersects the positive semiaxis  $x$ , i.e. the equation  $f(x) = 0$  has a solution.  $\square$

**5.D.5.** At which points  $x \in \mathbb{R}$  is the function

$$y = \cos \left( \arctg \left( \left| 12x^{21} + 11 \right| \cdot \frac{e^{\cos(x+2)-x^3}}{-11 - x^{12}} \right) \right) + \sin(\sin(\sin x))$$

(considering maximum domain) continuous?  $\bigcirc$

function  $h \circ f$  is defined on a neighbourhood of  $x_0$  and is continuous at  $x_0$ .

**PROOF.** Statements (1) and (2) are clear. For property (3): if  $g(x_0) \neq 0$ , then the  $\varepsilon$ -neighbourhood of the number  $g(x_0)$  does not contain zero for a sufficiently small  $\varepsilon > 0$ . By the continuity of  $g$ , it follows that on a sufficiently small  $\delta$ -neighbourhood of the point  $x_0$ ,  $g$  is non-zero and the quotient  $f/g$  is thus well-defined there. It is continuous at  $x_0$  by the previous theorem.

(4) Choose a neighbourhood  $\mathcal{O}$  of  $h(f(x_0))$ . By the continuity of  $h$ , there is a neighbourhood  $\mathcal{O}'$  of  $f(x_0)$  which is mapped into  $\mathcal{O}$  by  $h$ . The continuous function  $f$  maps some sufficiently small neighbourhood of the point  $x_0$  into the neighbourhood  $\mathcal{O}'$ . This is the definition property of continuity, so the proof is finished.  $\square$

**5.2.18.** We consider some basic relations between continuous mappings and the topology of the real numbers. They exploit the highly non-trivial characterization of compact sets in Theorem 5.2.8.

TOPOLOGICAL CHARACTERIZATION OF CONTINUITY

**Theorem.** Let  $f : A \subset \mathbb{R} \rightarrow \mathbb{R}$  be a continuous function defined on an interval  $A$ . Then

- (1)  $f$  is continuous if and only if the inverse image  $f^{-1}(U)$  of every open set  $U \subset \mathbb{R}$  is an open set,
- (2) the inverse image  $f^{-1}(W)$  of every closed set  $W \subset \mathbb{R}$  is a closed set,
- (3) the image  $f(K)$  of every compact set  $K \subset A$  is a compact set,
- (4)  $f$  attains both its maximum and its minimum on every compact set  $K$ .

**PROOF.** (1) Consider a point  $x_0 \in f^{-1}(U)$ . There is a neighbourhood  $\mathcal{O}$  of  $f(x_0)$  which is contained in  $U$  since  $U$  is open. Hence there is a neighbourhood  $\mathcal{O}'$  of  $x_0$  which is mapped into  $\mathcal{O}$  and thus is contained in the inverse image. Therefore, every point of the inverse image is an interior point, which finishes the proof.

Conversely, if  $f^{-1}(U)$  is open for each open  $U$ , then taking any  $\varepsilon$ -neighbourhood of  $f(x_0)$ , its pre-image will be an open neighbourhood of  $x_0$  satisfying the condition from the definition of the continuity.

(2) Consider a limit point  $x_0$  of the inverse image  $f^{-1}(W)$  and a sequence  $x_i, f(x_i) \in W$ , which converges to  $x_0$ . From the continuity of  $f$ , it follows that  $f(x_i)$  converges to  $f(x_0)$  (cf. the convergence test 5.2.15). Since  $W$  is closed,  $f(x_0) \in W$ . Thus, all limit points of the inverse image of the set  $W$  are contained in  $W$ .

(3) Choose any open cover of  $f(K)$ . The inverse images of the particular intervals are unions of open intervals and thus create a cover of the set  $K$ . Select a finite subcover from it. Then finitely many of the corresponding images cover the original set  $f(K)$ .

5.D.6. Determine whether the function

$$f(x) = \begin{cases} x, & x < 0; \\ 0, & 0 \leq x < 1; \\ x, & x = 1; \\ 0, & 1 < x < 2; \\ x, & 2 \leq x \leq 3; \\ \frac{1}{x-3}, & x > 3 \end{cases}$$

is continuous; left-continuous; right-continuous at the points  $-\pi, 0, 1, 2, 3, \pi$ . ○

5.D.7. Extend the function

$$f(x) = \arctg \left( 1 + \frac{5}{x^2} \right) \cdot \sin^2 x^5, \quad x \in \mathbb{R} \setminus \{0\}$$

at  $x = 0$  so that it is continuous at this point. ○

5.D.8. Find all  $p \in \mathbb{R}$  for which the function

$$f(x) = \frac{\sin(6x)}{3x}, \quad x \in \mathbb{R} \setminus \{0\}; \quad f(0) = p$$

is continuous at the origin. ○

5.D.9. Choose a real number  $a$  so that the function

$$h(x) = \frac{x^4 - 1}{x - 1}, \quad x > 1; \quad h(x) = a, \quad x \leq 1$$

is continuous on  $\mathbb{R}$ . ○

5.D.10. Calculate

$$\lim_{x \rightarrow 0^+} \frac{\sin^8 x}{x^3}; \quad \lim_{x \rightarrow -\infty} \frac{\sin^8 x}{x^3}.$$
○

5.D.11. Find all possible values of the parameter  $a \in \mathbb{R}$  so that the inequality

$$(a - 2)x^2 - (a - 2)x + 1 > 0$$

holds for all real numbers  $x$ .

**Solution.** We can notice that for  $a = 2$ , the inequality holds trivially (there is constant 1 on the left side). For  $a \neq 2$ , the left side is a quadratic function  $f(x)$  in the variable  $x$ , and further  $f(0) = 1$ . Thanks to the function  $f(x)$  being continuous, the inequality  $f(x) > 0$  will hold for all real  $x$  if and only if there is no solution to the equation  $f(x) = 0$  in  $\mathbb{R}$  (the whole of the graph of the function  $f$  will then be “above” the  $x$ -axis). This will occur if and only if the discriminant of the quadratic equation  $(a - 2)x^2 - (a - 2)x + 1 = 0$  (in  $x$ ) will be negative. Thus we get the following necessary and sufficient condition:

$$D = (a - 2)^2 - 4(a - 2) = (a - 2)(a - 6) < 0.$$

This is true for  $a \in (2, 6)$ . Altogether, the inequality holds for all real  $x$  iff  $a \in [2, 6)$ . □

(4) Since the image of a compact set is again a compact set, the image must be bounded and it contains both the supremum and the infimum. Hence it follows that these must also be the maximum and the minimum, respectively. □

5.2.19. There are two very useful consequences of the previous theorem.

MAXIMA AND MINIMA OF CONTINUOUS FUNCTIONS<sup>9</sup>

**Corollary.** Let  $f : \mathbb{R} \rightarrow \mathbb{R}$  be continuous. Then

- (1) the image of every interval is again an interval,
- (2)  $f$  takes all the values between the maximal and the minimal one on the closed interval  $[a, b]$ .

**PROOF.** (1) Consider an open interval  $A$  and suppose there is a point  $y \in \mathbb{R}$  such that  $f(A)$  contains points less than  $y$  as well as points greater than  $y$ , but  $y \notin f(A)$ . Put  $B_1 = (-\infty, y)$  and  $B_2 = (y, \infty)$ . These are open sets, and the union of their inverse images  $A_1 = f^{-1}(B_1) \subset A$  and  $A_2 = f^{-1}(B_2) \subset A$  contains  $A$ .  $A_1$  and  $A_2$  are open, disjoint, and they both have a non-empty intersection with  $A$ . Thus there is a point  $x \in A$  which does not lie in  $A_1$  but is a limit point of  $A_1$ . It is in  $A_2$ , which is impossible for two disjoint open sets.

Thus it is proved that if there is a point  $y$  which does not belong to the image of the interval, then either all of the values must be above  $y$  or they all must be below. It follows that the image is again an interval. Notice that the boundary points of this interval may or may not lie in the image.

If the domain interval  $A$  contains one of its boundary points, then the continuous function must map it to a limit point or an interior point of the image of the interior of  $A$ . This verifies the statement.

(2) This statement immediately follows from the previous one (and the above theorem) since the image of a closed bounded interval (i.e. a compact set) is again a closed interval. □

5.2.20. We conclude this introductory discussion by two more theorems which provide useful tools for calculating limits. Notice that we assume that functions are defined on all of  $\mathbb{R}$ . Actually we are only interested in  $f$  on a neighbourhood of one point  $a$ , while  $g$  has to be defined on a neighbourhood of one point  $b$  only.

<sup>9</sup>This result is usually called the *Weierstrass theorem*, but it is also known (especially in Czech literature) as the *Bolzano's theorem*. Bernard Bolzano worked in Prague at the beginning of the 19th century and apparently used such the result as a technical lemma when proving his Bolzano-Weierstrass theorem mentioned earlier.

**5.D.12.** In  $\mathbb{R}$ , solve the equation

$$2^x + 3^x + 4^x + 5^x + 6^x = 5.$$

**Solution.** The function on the left side is a sum of five increasing functions on  $\mathbb{R}$ , so it must be increasing as well. For  $x = 0$ , its value is 5, which is thus the only solution of the equation.  $\square$

**5.D.13.** In  $\mathbb{R}$ , solve the equation

$$2^x + 3^x + 6^x = 1.$$

**5.D.14.** Determine whether the polynomial

$$P(x) = x^{37} + 5x^{21} - 4x^9 + 5x^4 - 2x - 3$$

has a real root in the interval  $(-1, 1)$ .

### E. Derivatives

First of all, let us show that the derivatives enlisted in the table of paragraph 5.3.1 are correct. We will derive them right from the definition of a derivative.

**5.E.1.** From the definition, (see 5.3.1) find the derivatives of the functions  $x^n$  ( $x$  is the variable,  $n$  is a constant positive integer),  $\sqrt{x}$ ,  $\sin x$ .

**Solution.** First, let us remark that by substituting  $h$  for  $x - x_0$  in the definition of a derivative, we get

$$\lim_{x \rightarrow x_0} \frac{f(x) - f(x_0)}{x - x_0} = \lim_{h \rightarrow 0} \frac{f(x_0 + h) - f(x_0)}{h}.$$

In the following calculations, we will work with the latter expression of the limit.

$$\begin{aligned} (x^n)' &= \lim_{h \rightarrow 0} \frac{(x+h)^n - x^n}{h} \\ &= \lim_{h \rightarrow 0} \frac{\binom{n}{1}x^{n-1}h + \binom{n}{2}x^{n-2}h^2 + \dots + h^n}{h} = \\ &= nx^{n-1} + \lim_{h \rightarrow 0} \left( \binom{n}{2}x^{n-2}h + \binom{n}{3}x^{n-3}h^2 + \dots + h^{n-1} \right) \\ &= nx^{n-1}, \end{aligned}$$

### LIMITS OF COMPOSITE FUNCTIONS

**Theorem.** Let  $f, g : \mathbb{R} \rightarrow \mathbb{R}$  be two functions and  $\lim_{x \rightarrow a} f(x) = b$ .

(1) If the function  $g$  is continuous at the point  $b$ , then

$$\lim_{x \rightarrow a} g(f(x)) = g\left(\lim_{x \rightarrow a} f(x)\right) = g(b).$$

(2) If the limit  $\lim_{y \rightarrow b} g(y)$  exists and  $f(x) \neq b$  holds for all  $x \neq a$  from some neighbourhood of the point  $a$ , then

$$\lim_{x \rightarrow a} g(f(x)) = \lim_{y \rightarrow b} g(y).$$

**PROOF.** The first proposition can be proved similarly to 5.2.17(4). From the continuity of  $g$  at the point  $b$ , it follows that for any neighbourhood  $V$  of the value  $g(b)$ , we can find a sufficiently small neighbourhood  $U$  of the point  $b$  whose values of  $g$  lies in  $V$ . However, if  $f$  has limit  $b$  at the point  $a$ , then  $f$  will hit  $U$  by all its values  $f(x)$  for  $x \neq a$  from some sufficiently small neighbourhood of the point  $a$ , which verifies the first statement.

(2) Even if we cannot use the continuity of  $g$  at the point  $b$ , the previous reasoning will be true if we ensure that all points  $x \neq a$  from sufficiently small neighbourhoods of  $a$  are mapped into a neighbourhood of  $b$  by the function  $f$ , but  $f(x) \neq b$  for all such points.  $\square$

**5.2.21. Who or what is in the ZOO.** We have begun to build a menagerie of functions with polynomials and functions which can be created from them “piece-wise”. Moreover, we have derived many properties for a huge class of continuous functions. However, except for polynomials, we do not have many practically manageable examples at our disposal. We consider the quotients of polynomials.

Let  $f$  and  $g$  be two polynomials in the real variable  $x$  with complex coefficients  $a_i \in \mathbb{C}$ .

The function  $h : \mathbb{R} \setminus \{x \in \mathbb{R}, g(x) = 0\} \rightarrow \mathbb{C}$ ,

$$h(x) = \frac{f(x)}{g(x)}$$

is well-defined for all real  $x$  except for the roots of the polynomial  $g$ . Such functions are called *rational functions*. From theorem 5.2.17, it follows that rational functions are continuous at all points of their domains. At the points where they are undefined, they can have

- a finite limit,

$$\begin{aligned}
 (\sqrt{x})' &= \lim_{h \rightarrow 0} \frac{\sqrt{x+h} - \sqrt{x}}{h} \\
 &= \lim_{h \rightarrow 0} \frac{(\sqrt{x+h} - \sqrt{x})(\sqrt{x+h} + \sqrt{x})}{h(\sqrt{x+h} + \sqrt{x})} \\
 &= \lim_{h \rightarrow 0} \frac{h}{h(\sqrt{x+h} + \sqrt{x})} = \lim_{h \rightarrow 0} \frac{1}{\sqrt{x+h} + \sqrt{x}} \\
 &= \frac{1}{2\sqrt{x}},
 \end{aligned}$$

$$\begin{aligned}
 (\sin x)' &= \lim_{h \rightarrow 0} \frac{\sin(x+h) - \sin x}{h} \\
 &= \lim_{h \rightarrow 0} \frac{\sin x \cos h + \cos x \sin h - \sin x}{h} \\
 &= \lim_{h \rightarrow 0} \frac{\cos x \sin h}{h} + \lim_{h \rightarrow 0} \frac{\sin x(\cos h - 1)}{h} \\
 &= \cos x \cdot \lim_{h \rightarrow 0} \frac{\sin h}{h} - \lim_{h \rightarrow 0} \frac{2(\sin \frac{h}{2})^2}{h} \\
 &= \cos x \cdot 1 + \lim_{t \rightarrow 0} \sin t \frac{\sin t}{t} \\
 &= \cos x.
 \end{aligned}$$

□

**5.E.2.** Differentiate:

- i)  $x \sin x$ ,
- ii)  $\frac{\sin x}{x}, x \neq 0$
- iii)  $\ln(x + \sqrt{x^2 - a^2}), a \neq 0, |x| \geq |a|$ ,
- iv)  $\arctan\left(\frac{x}{\sqrt{1-x^2}}\right), |x| < 1$ ,
- v)  $x^x, x > 0$ .

**Solution.** (i) By the formula for the derivative of a product (the Leibniz rule, see 5.3.4) we get

$$(x \sin x)' = x' \cdot \sin x + x \cdot (\sin x)' = \sin x + x \cos x.$$

(ii) By the formula for the derivative of a quotient (5.3.5), we have that

$$\frac{\sin x}{x} = \frac{(\sin x)' \cdot x - \sin x \cdot x'}{x^2} = \frac{x \cos x - \sin x}{x^2}.$$

(iii) This time, we will use the formula for the derivative of function composition (the chain rule, see 5.3.4). Setting  $h(x) = \ln(x), f(x) = x + \sqrt{x^2 - a^2}$ , we obtain

$$\begin{aligned}
 \ln(x + \sqrt{x^2 - a^2})' &= h(f(x))' = h'(f(x)) \cdot f'(x) \\
 &= \frac{(x + \sqrt{x^2 - a^2})'}{x + \sqrt{x^2 - a^2}} = \frac{1 + \frac{x}{x^2 - a^2}}{x + \sqrt{x^2 - a^2}},
 \end{aligned}$$

where we used the chain rule once again when differentiating  $\sqrt{x^2 - a^2}$ .

- an infinite limit, supposing the one-sided infinite limits are equal,
- different one-sided infinite limits.

For the case of a finite limit, it is necessary that the point is a common root of both  $f$  and  $g$  and that its multiplicity in  $f$  is at least as large as in  $g$ . Then the function's domain by this point can be extended by defining it to take the value of the limit there. Then the function is continuous at the same point.

The possibilities are illustrated in the diagram showing the values of the function

$$h(x) = \frac{(x - 0.05a)(x - 2 - 0.2a)(x - 5)}{x(x - 2)(x - 4)}$$

for  $a = 0$  on the left ( thus it is the rational function  $(x - 5)/(x - 4)$ ) and for  $a = 5/3$  on the right.

**5.2.22. Power functions and the exponential.**

We have met the simple power functions  $x \mapsto x^n$  with natural exponents  $n = 0, 1, 2, \dots$  when building the polynomials. The meaning of the function  $x \mapsto x^{-1}$ , defined for all  $x \neq 0$ , is also clear. Now, we extend this definition to a general *power function*  $x^a$  with an arbitrary  $a \in \mathbb{R}$ .

We use the well known properties of powers and roots. For a negative integer  $-a$ , we define

$$x^{-a} = (x^a)^{-1} = (x^{-1})^a.$$

Further, we want the equality  $b^n = x$  for  $n \in \mathbb{N}$  to imply that  $b$  is the  $n$ -th root of  $x$ , i.e.  $b = x^{\frac{1}{n}}$ . We verify that such  $b$ 's always exist for positive real numbers  $x$ .

By factoring out  $y_2 - y_1$  in  $y_2^n - y_1^n$ , or otherwise, the function  $y \mapsto y^n$  is strictly increasing for  $y > 0$ . Choose  $x > 0$  and consider the set  $B = \{y \in \mathbb{R}, y > 0, y^n \leq x\}$ . This is a non-empty set bounded from above, so set  $b = \sup B$ . A power function with natural exponent  $n$  is continuous,  $b^n = x$ . Indeed, surely  $b^n \leq x$ . if the inequality is strict, then there is a number  $y$  such that  $b^n < y^n < x$ , which implies that  $b < y$ . This contradicts the definition of  $b$  as a supremum.

Thus the power function is suitably defined for all rational numbers  $a = \frac{p}{q}$ . For  $x > 0$ , we set  $x^a = (x^p)^{\frac{1}{q}} = (x^{\frac{1}{q}})^p$ .

Finally, we notice that for the values  $0 < a \in \mathbb{Q}$  and fixed  $x > 1$ ,  $x^a$  is strictly increasing for rational  $a$ 's. Therefore, for general  $0 < a \in \mathbb{R}$  and  $1 < x$  we can define

$$x^a = \sup\{x^y, y \in \mathbb{Q}, y \leq a\}.$$

(iv) Again, we are looking for the derivative of a composed function:

$$\begin{aligned} \left[ \arctan \left( \frac{x}{\sqrt{1-x^2}} \right) \right]' &= \frac{1}{1 + \frac{x^2}{1-x^2}} \cdot \left( \frac{x}{\sqrt{1-x^2}} \right)' \\ &= \frac{1}{1 + \frac{x^2}{1-x^2}} \cdot \frac{\sqrt{1-x^2} + \frac{x^2}{\sqrt{1-x^2}}}{1-x^2} \\ &= \sqrt{1-x^2} + \frac{x^2}{\sqrt{1-x^2}} = \frac{1}{\sqrt{1-x^2}}. \end{aligned}$$

(v) First, we transform the function to a function with constant base (preferably the base  $e$ ) which we are able to differentiate.

$$\begin{aligned} (x^x)' &= ((e^{\ln x})^x)' = (e^{x \ln x})' \\ &= (x \ln x)' \cdot e^{x \ln x} = (1 + \ln x) \cdot x^x \end{aligned}$$

□

**5.E.3.** Find the derivative of the function  $y = x^{\sin x}$ ,  $x > 0$ .

**Solution.** We have

$$\begin{aligned} (x^{\sin x})' &= (e^{\sin x \ln x})' = e^{\sin x \ln x} \left( \cos x \ln x + \frac{\sin x}{x} \right) \\ &= x^{\sin x} \left( \cos x \ln x + \frac{\sin x}{x} \right). \end{aligned}$$

□

**5.E.4.** For positive  $x$ , determine the derivative of the function  $f(x) = x^{\ln x}$  ○

**5.E.5.** For  $x \in (0, \pi/2)$ , calculate the derivative of the function  $y = (\sin x)^{\cos x}$ . ○

We advise the reader to make up some functions and find their derivatives. The results can be verified in a great deal of mathematical programs. In the following exercise, we will look at the geometrical meaning of the derivative at a given point, namely that it determines the slope of the tangent line to the function graph at the given point (see 5.3.2).

**5.E.6.** Using differential, approximate  $\operatorname{arccotg} 1.02$ .

**Solution.** The differential of the function  $f$  having continuous derivative at the point  $x_0$  is equal to

$$f'(x_0) dx = f'(x_0) (x - x_0).$$

The equation of the tangent to  $f$ 's graph at the point  $[x_0, f(x_0)]$  is then

$$y - f(x_0) = f'(x_0) (x - x_0).$$

Hence we can see that the differential is the growth on the tangent line. However, the values on the tangent approximate those of  $f$ , supposing the difference  $x - x_0$  is "small". Thus

As before,  $x^{-a} = \frac{1}{x^a}$ .

For  $0 < x < 1$ , proceed analogously with care for the inequality signs, or set  $x^a = (\frac{1}{x})^{-a}$ . For  $x = 1$ , define  $1^a = 1$  for any  $a$ , while  $0^a = 0$ .

Now, the power function  $x \mapsto x^a$  is defined for all  $x \in [0, \infty)$  and  $a \in \mathbb{R}$ . There is another view of the construction: For every fixed real number  $c > 0$ , there is a well-defined function  $y \mapsto c^y$  on the whole real line. This function is called the *exponential function* with base  $c$ . The definition ensures that the resulting function  $c^y$  is continuous in  $y$  for fixed  $c$  and is continuous in  $c$  for fixed  $y$ .

The properties used when defining the power function and the exponential function  $f(y) = c^y$ , with  $f(0) = 1$ , can be summarized in a single inequality for any real  $x$  and real  $y$ :

$$(1) \quad f(x+y) = f(x) \cdot f(y)$$

together with the condition of continuity.

Indeed, for  $y = 0$   $f(0) = 1$ , and hence  $1 = f(0) = f(x-x) = f(x) \cdot (f(x))^{-1}$ . Eventually, for a natural number  $n$ ,  $f(nx) = (f(x))^n$ . Thus  $a^x$  is determined for all  $a > 0$  and  $x \in \mathbb{Q}$ . The continuity condition determines the function's values uniquely at the remaining points, if such a function exists. So we should check, that the above constructed function has the property 1. This should be clear from the continuity of the operations of sum and product in both arguments – the details are left to the reader.

Thus, the exponential function satisfies both the well-known formulas

$$(2) \quad a^x \cdot a^y = a^{x+y}, \quad (a^x)^y = a^{x \cdot y}.$$

**5.2.23. Logarithmic functions.** The exponential function  $f(x) = a^x$  is increasing for  $a > 1$  and decreasing for  $0 < a < 1$ . Thus in both cases, there is a function  $f^{-1}(x)$  inverse to it. This function is called the *logarithmic function with base  $a$* . We write  $\ln_a(x)$ .  $\ln_a(a^x) = x$  is the defining property.

The equalities (2) are thus equivalent to

$$\ln_a(x \cdot y) = \ln_a(x) + \ln_a(y), \quad \ln_a(x^y) = y \cdot \ln_a(x).$$

Logarithmic functions are defined only for positive arguments and they are, on the entire domain, increasing if  $a > 1$  and decreasing for  $0 < a < 1$ . Moreover,  $\ln_a(1) = 0$  holds for every  $a$ .

we obtain the following formula for approximating the function value by its differential:

$$f(x) \approx f(x_0) + f'(x_0)(x - x_0).$$

So, setting

$$f(x) := \operatorname{arccotg} x, \quad x_0 := 1,$$

we get

$$\operatorname{arccotg} 1.02 \approx \operatorname{arccotg} 1 + \frac{-1}{1+1^2} (1.02 - 1) = \frac{\pi}{4} - 0.01.$$

Eventually, let us remark that the point  $x_0$  is of course selected so that the expression  $x - x_0$  is as close to zero as possible, yet we must be able to calculate the values of  $f$  and  $f'$  at the point.  $\square$

5.E.7. Using differential, approximate  $\arcsin 0.497$ .  $\circ$

5.E.8. Using differential, approximate  $a = \arctan 1.02$  and  $b = \sqrt[3]{70}$ .  $\circ$

5.E.9. Using differential, approximate a)  $\sin\left(\frac{29\pi}{180}\right)$ ,  
b)  $\sin\left(\frac{46\pi}{180}\right)$ .  $\circ$

5.E.10. For which  $a \in \mathbb{R}$  is the cubic polynomial  $P$  which satisfies the conditions  $P(0) = 1$ ,  $P'(0) = 1$ ,  $P(1) = 2a + 2$ ,  $P'(1) = 5a + 1$ , a monotonic function on the whole  $\mathbb{R}$ ?

**Solution.** From the conditions  $P(0) = 1$  and  $P'(0) = 1$  it follows that  $P(x) = bx^3 + cx^2 + x + 1$  where  $b, c \in \mathbb{R}$ ; the two remaining conditions determine two equations for the variables  $b$  and  $c$ :  $b + c + 2 = 2a + 2$ ,  $3b + 2c + 1 = 5a + 1$  with the unique solution  $b = c = a$ . The polynomials which satisfy the desired conditions are thus of the form  $P(x) = ax^3 + ax^2 + x + 1$ ,  $a \in \mathbb{R}$ . The monotonicity of the polynomial is equivalent to having no local extrema. The extrema can occur only at those points where the derivative changes sign. Therefore, the polynomial is monotonic if and only if its derivative keeps the sign on the whole  $\mathbb{R}$ . The derivative is

$$P'(x) = 3ax^2 + 2ax + 1$$

and it will keep the sign iff the discriminant is non-positive. Thus we get the condition

$$\begin{aligned} 4a^2 - 12a &\leq 0 \\ 4a(a - 3) &\leq 0, \end{aligned}$$

which is true for  $a \in [0, 3]$ . However, for  $a = 0$  the polynomial  $P$  is monotonic, yet not cubic, Thus the set of satisfactory numbers  $a$  is the interval  $(0, 3]$ .  $\square$

There is an extremely important value of  $a$ , namely the number  $e$ , see the paragraph 5.4.1, sometimes known as Euler's number. The function  $\ln_e(x)$  is called the *natural logarithm* and is denoted by  $\ln(x)$  (i.e. omitting the base  $e$ ).

### 3. Derivatives

When talking about polynomials, the rate at which the function changes at a given point of its domain was already discussed (see the paragraph 5.1.6). It is the quotient 5.1.6(1), which expresses the slope of the secant line between the points  $[x, f(x)] \in \mathbb{R}^2$  and  $[x + \delta x, f(x + \delta x)] \in \mathbb{R}^2$  for a (small) change  $\delta x$  of the input variable. This reasoning is correct for any real or complex function  $f$ . It is only necessary to work with the concept of the limit, instead of the intuitive "small change"  $\delta x$ .

#### DERIVATIVE OF A FUNCTION OF A REAL VARIABLE

**5.3.1. Definition.** Let  $f$  be a real or complex function defined on an interval  $A \subset \mathbb{R}$  and  $x_0 \in A$ . If the limit

$$\lim_{x \rightarrow x_0} \frac{f(x) - f(x_0)}{x - x_0} = a$$

exists, the function  $f$  is said to be differentiable at  $x_0$ , provided  $a$  is finite. The value of the derivative at  $x_0$ , namely  $a$ , is denoted by  $f'(x_0)$  or  $\frac{df}{dx}(x_0)$  or  $\frac{d}{dx}f(x_0)$ .

If  $a$  is finite, the derivative is also sometimes called *proper*. If  $a$  is infinite, it is *improper*.

If  $x_0$  is one of the boundary points of  $A$ , we arrive at *one-sided derivatives* (i.e. left-sided derivative and right-sided derivative).

If a function has a derivative at  $x_0$ , the function is said to be *differentiable* at  $x_0$ . A function which is differentiable at every point of a given interval is said to be differentiable on the interval.

Obviously, the derivative of a complex valued function  $(f(x) + i g(x))$  exists if and only the derivatives of both real and imaginary parts  $f$  and  $g$  exist (see the elementary properties of limits). Then

$$(f(x) + i g(x))' = f'(x) + i g'(x).$$

**5.E.11.** Determine the parameter  $c \in \mathbb{R}$  so that the tangent line to the graph of the function  $\frac{\ln(cx)}{\sqrt{x}}$  at the point  $[1, 0]$  goes through the point  $[2, 2]$ .

**Solution.** From the statement of the problem it follows that the tangent's slope is  $\frac{2-0}{2-1} = 2$ . The slope is determined by the derivative at the given point, thus we get the condition

$$\left. \frac{2 - \ln(cx)}{2x\sqrt{x}} \right|_{x=1} = 2, \text{ that is } 2 - \ln(c) = 4,$$

hence  $c = \frac{1}{e^2}$ . Yet for  $c = \frac{1}{e^2}$ , the function  $\frac{\ln(cx)}{\sqrt{x}}$  takes the value  $-2$  at the point 1. Therefore, there is no such  $c$ .  $\square$

**5.E.12.** A highway patrol helicopter is flying 3 kilometers above a highway at the speed of 120 kph. Its pilot localizes a car whose straight-line distance from the helicopter is 5 kilometers. The car goes in the opposite direction and approaches the helicopter at 160 kph (with regard to the helicopter). Determine the car's speed with regard to a tin lying on the highway.

**Solution.** For the sake of simplicity, we will omit units of measurement (distances will be expressed in kilometers and times in hours, speeds in kph, then). The helicopter's position at time  $t$  can be expressed by the point  $[y(t), 3]$ , and the car's position by  $[x(t), 0]$ , then. (We choose the axes so that the helicopter and the car are moving along the  $x$ -axis.) Let us denote by  $s(t)$  the straight-line distance of the car from the helicopter and by  $t_0$  the moment mentioned in the problem's statement. Let us calculate the car's speed with respect to the origin. We can suppose that  $x(t) > y(t) > 0$ , then  $x'(t) \leq 0$ ,  $y'(t) \geq 0$  for the considered time moments  $t$  since the car is approaching the point  $[0, 0]$  from the right – the value  $x(t)$  decreases as  $t$  increases, therefore  $x'(t) \leq 0$ . Similarly we can get that  $y'(t) \geq 0$  and also  $s'(t) \leq 0$ . Let us add that, for instance,  $y'(t)$  determines the rate of change of the function  $y$  at time  $t$ , i. e. the helicopter's speed

We know that

$$s(t_0) = 5, \quad s'(t_0) = -160, \quad y'(t_0) = 120$$

and that ( $s(t)$  is the hypotenuse of the right triangle)

$$(1) \quad (x(t) - y(t))^2 + 3^2 = s^2(t).$$

Hence it follows ( $x(t) > y(t) > 0$ ) that

$$(x(t_0) - y(t_0))^2 + 3^2 = 5^2, \quad \text{i. e. } x(t_0) - y(t_0) = 4.$$

By differentiating the identity (1), we get

$$2(x(t) - y(t))(x'(t) - y'(t)) = 2s(t)s'(t)$$

and then for  $t = t_0$ ,

Derivatives are handled rather easily, but it takes time to derive the proper formulae for derivatives of the elementary functions in the zoo. Therefore, we present a table of derivatives of several such functions in advance. In the last column, there are references to the corresponding paragraph where the result is proved. Notice that even though we are unable to express inverse functions to some of our functions by elementary means, we can calculate their derivatives; see 5.3.6.

DERIVATIVES OF SOME FUNCTIONS

function	domain	derivative	
polynomials $f(x)$	whole $\mathbb{R}$	$f'(x)$ is again a polynomial	5.1.6
cubic splines $h(x)$	whole $\mathbb{R}$	only the first derivative $h'(x)$ is continuous	5.1.9
rational functions $f(x)/g(x)$	whole $\mathbb{R}$ , except for roots of $g$	rational functions: $\frac{f'(x)g(x) - f(x)g'(x)}{g(x)^2}$	5.3.5
power functions $f(x) = x^a$	interval $(0, \infty)$	$f'(x) = ax^{a-1}$	5.3.7
exponential functions $f(x) = a^x$ , $a > 0, a \neq 1$	whole $\mathbb{R}$	$f'(x) = \ln(a) \cdot a^x$	5.3.7
logarithmic function $f(x) = \ln_a(x)$ , $a > 0, a \neq 1$	interval $(0, \infty)$	$f'(x) = (\ln(a))^{-1} \cdot \frac{1}{x}$	5.3.7

The initial idea of the definition suggests that  $f'(x_0)$  allows an approximation to the function  $f$  by the straight line

$$y = f(x_0) + f'(x_0)(x - x_0).$$

This is the meaning of the following lemma, which says that replacing the constant coefficient  $f'(x_0)$  in the line's equation with a certain continuous function gives exactly the values of  $f$ . The difference between  $\psi(x)$  and  $\psi(x_0)$  on a neighbourhood of  $x_0$  then says how much the slopes of the secant lines and the tangent line at  $x_0$  differ.

**Lemma.** A real or complex function  $f(x)$  has a finite derivative at  $x_0$  if and only if there is a neighbourhood  $\mathcal{O}$  of  $x_0$  and a function  $\psi$  defined on this neighbourhood which is continuous at  $x_0$  and such that for all  $x \in \mathcal{O}$ ,

$$f(x) = f(x_0) + \psi(x)(x - x_0).$$

Furthermore,  $\psi(x_0) = f'(x_0)$ , and  $f$  is continuous at the point  $x_0$ .

**PROOF.** If  $\psi$  exists, it is of the form

$$\psi(x) = \frac{f(x) - f(x_0)}{x - x_0}$$

$$2 \cdot 4(x'(t_0) - 120) = 2 \cdot 5 \cdot (-160), \quad \text{i. e. } x'(t_0) = -80.$$

We have calculated that the car is approaching the tin at 80 kph. It suffices to realize with which units of measurement we worked. Having obtained a negative value is caused by our choice of the coordinate system.  $\square$

**5.E.13.** A 13 feet long ladder is leaned against a house. Suddenly the base of the ladder slips off and the ladder begins to go down (still touching the house at its other end). When the base of the ladder is 12 feet from the house, it is moving at 5 feet per second from it. At this moment:

- (a) What is the speed of the top of the ladder?
- (b) What is the rate of change of the area of the triangle delimited by the house, the ladder, and ground?
- (c) What is the rate of change of the angle enclosed by the ladder and the ground?

$\circ$

**5.E.14.** Determine whether there is a point in the interval  $(0, 4)$  such that the tangent line at this point to the polynomial  $x(x - 4)^5$  is parallel to the  $x$ -axis.  $\circ$

**5.E.15.** Let  $p \in (0, +\infty)$ . Write the equation of the tangent to the parabola  $2py = x^2$  at a general point  $[x_0, ?]$ .  $\circ$

**5.E.16.** Find the equation of the normal line to the graph of the function  $y = 1 - e^{\frac{x}{2}}$ ,  $x \in \mathbb{R}$  at the point where the graph intersects the  $x$ -axis.  $\circ$

**5.E.17.** Find the equations of the tangent and normal lines to the curve  $y = (x + 1) \sqrt[3]{3 - x}$ ,  $x \in \mathbb{R}$ , at the point  $[-1, 0]$ .  $\circ$

**5.E.18.** Let the function  $y = \frac{\ln(2x^3 + 4x^2 - x)}{1 + x}$ ,  $x \in (\frac{1}{2}, +\infty)$  be given. Determine the equations of the tangent and normal lines to the graph of this function at the point  $[1, ?]$ .  $\circ$

**5.E.19.** At which points is the tangent to the parabola  $y = 2 + x - x^2$ ,  $x \in \mathbb{R}$ , parallel to the  $x$ -axis?  $\circ$

**5.E.20.** Determine the equations of the tangent line  $t$  and the normal line  $n$  to the graph of the function

$$y = \sqrt{x^2 - 3x + 11}, \quad x \in \mathbb{R}$$

at the point  $[2, ?]$ . Further, determine all points at which the tangent is parallel to the  $x$ -axis.  $\circ$

**5.E.21.** What is the angle between the  $x$ -axis and the graph of the function  $y = \ln x$ ? (We mean the angle between the

for all  $x \in \mathcal{O} \setminus \{x_0\}$ .

Suppose  $f'(x_0)$  is the proper derivative. Then we can define the value at the point  $x_0$  as  $\psi(x_0) = f'(x_0)$ . Certainly,

$$\lim_{x \rightarrow x_0} \psi(x) = f'(x_0) = \psi(x_0).$$

Thus  $\psi$  is continuous at  $x_0$  as desired.

On the other hand if such a function  $\psi$  exists, the same procedure calculates its limit at  $x_0$ . Thus the derivative  $f'(x_0)$  exists as well and equals  $\psi(x_0)$ .

The function  $f$  is expressed in terms of the sum and product of functions continuous at  $x_0$ . Thus  $f$  is continuous at  $x_0$ .  $\square$

**5.3.2. Geometrical meaning of the derivative.** The previ-

ous lemma leads to a geometric interpretation of the derivative in terms of the slope of the secant lines of the graph of  $f$  through  $[x_0, f(x_0)]$ . The derivative exists if and only if the slope of the secant line through the points  $[x_0, f(x_0)]$  and  $[x, f(x)]$  changes continuously when approaching the argument  $x = x_0$ . If so, the limit of this slope is the value of the derivative. This observation leads to the important corollary:

**FUNCTIONS INCREASING AND DECREASING AT A POINT**

**Corollary.** *If a real-valued function  $f$  has derivative  $f'(x_0) > 0$  at a point  $x_0 \in \mathbb{R}$ , then there is a neighbourhood  $\mathcal{O}(x_0)$  such that  $f(x) > f(x_0)$  for all points  $x \in \mathcal{O}(x_0)$ ,  $x > x_0$ , and  $f(x) < f(x_0)$  holds for all  $x \in \mathcal{O}(x_0)$ ,  $x < x_0$ .*

*On the other hand, if the derivative satisfies  $f'(x_0) < 0$ , then there is a neighbourhood  $\mathcal{O}(x_0)$  such that  $f(x) < f(x_0)$  for all points  $x \in \mathcal{O}(x_0)$ ,  $x > x_0$ , and  $f(x) > f(x_0)$  for all  $x \in \mathcal{O}(x_0)$ ,  $x < x_0$ .*

**PROOF.** Suppose  $f$  is increasing at  $x_0$ . By the previous lemma,  $f(x) = f(x_0) + \psi(x)(x - x_0)$  and  $\psi(x_0) > 0$ . Since  $\psi$  is continuous at  $x_0$ , there exists a neighbourhood  $\mathcal{O}(x_0)$  on which  $\psi(x) > 0$ . If  $x$  increases,  $x > x_0$ ,  $f(x)$  increases as well,  $f(x) > f(x_0)$ . Analogously for  $x < x_0$ . The case with a negative derivative is proved similarly.  $\square$

A function is called *increasing at  $x_0$*  of its domain, if for all points  $x$  of some neighbourhood of a point  $x_0$ ,  $f(x) > f(x_0)$  if  $x > x_0$  and  $f(x) < f(x_0)$  if  $x < x_0$ . A function is *increasing on an interval  $A$*  if  $f(x) - f(y) > 0$  for all  $x > y$ ,  $x, y \in A$ .

Similarly, a function is said to be *decreasing at a point  $x_0$*  if and only if there is a neighbourhood of the point  $x_0$  such that  $f(x) < f(x_0)$  for all  $x > x_0$ , while  $f(x) > f(x_0)$  for all  $x < x_0$  from this neighbourhood. A function is *decreasing on an interval  $A$*  if  $f(x) - f(y) < 0$  for all  $x > y$ ,  $x, y \in A$ .

Thus a function having a non-zero finite derivative at a point is either increasing or decreasing at that point, according to the sign of the derivative.

tangent line and the positive  $x$ -axis in the “positive sense of rotation”, ie. counterclockwise.) □

**5.E.22.** Determine the equations of the tangent and normal line to the curve given by the equation  $x^3 + y^3 - 2xy = 0$  at the point  $[1, 1]$ . □

**5.E.23.** Prove:  $\frac{x}{1+x} < \ln(1+x) < x$  for all  $x > 0$ . □

**F. Extremal problems**

The simple observation 5.3.2 about the geometrical meaning of the derivative also tells us that a differentiable real-valued function of a real variable can have extremes only at the points where its derivative is zero. We can utilize this mere fact when solving miscellaneous practical problems.

**5.F.1.** Consider the parabola  $y = x^2$ . Determine the  $x$ -coordinate  $x_A$  of the parabola’s point which is nearest to the point  $A = [1, 2]$ .

**Solution.** It is not difficult to realize that there is a unique solution to this problem and that we are actually looking for the absolute minimum of the function

$$f(x) = \sqrt{(x-1)^2 + (x^2-2)^2}, \quad x \in \mathbb{R}.$$

Since taking the square root is an increasing function, the function  $f$  takes the least value at the same point where the function

$$g(x) = (x-1)^2 + (x^2-2)^2, \quad x \in \mathbb{R}$$

does. Since

$$g'(x) = 4x^3 - 6x - 2, \quad x \in \mathbb{R},$$

by solving the equation  $0 = 2x^3 - 3x - 1$ , we first get the stationary point  $x = -1$  and after dividing the polynomial  $2x^3 - 3x - 1$  by the polynomial  $x + 1$ , we then obtain the remaining two stationary points

$$\frac{1-\sqrt{3}}{2} \quad \text{and} \quad \frac{1+\sqrt{3}}{2}.$$

As the function  $g$  is a polynomial (differentiable on the whole domain), from the geometrical sense of the problem, we get

$$x_A = \frac{1+\sqrt{3}}{2}.$$

□

**5.F.2.** Consider an isosceles triangle with base length  $b$  and height (above the base)  $h$ . Inscribe the rectangle having the greatest possible area into it (one of the rectangle’s sides will lie on the triangle’s base). Determine the area  $S$  of this rectangle.

A function increasing on an interval is increasing at each of its points. The converse is true as well. In order to see this, assume that  $f$  is increasing at all points of the interval  $A$ . Consider two points  $x < y$  in  $A$  with  $f(y) \leq f(x)$ . By the assumption, there is a  $\delta$ -neighbourhood of  $y$  on which  $z < y$  implies  $f(z) < f(y)$ . Let  $\delta_0$  be the infimum of all such  $\delta \leq y - x$  and  $w = y - \delta_0$ . Then  $f(w)$  cannot be larger than  $f(y)$  (there would be such a point on the right of it too, which is excluded). But, unless  $w = x$ ,  $w$  is a limit point of a sequence of points less than  $w$ , for which the value of  $f$  is larger than  $f(y) \geq f(w)$ . This is a contradiction with  $f$  increasing in  $w$ . But if  $w$  were  $x$  then there would be the contradiction with the assumption  $f(x) > f(z)$  for points  $z > x$  arbitrarily close to  $x$ .

The same arguments work for decreasing functions. The following is now proved:

**Proposition.** A function is increasing or decreasing on an open interval  $A$  if and only if it is increasing or decreasing in each its point, respectively.

**5.3.3. Examples.** There is a function which is increasing at the origin  $x_0 = 0$  but is neither increasing or decreasing on any neighbourhood of  $x_0$ . Consider the (continuous) function

$$f(x) = x + 5x^2 \sin(1/x), \quad f(0) = 0.$$

The choice  $f(0)$  makes  $f$  a continuous function on  $\mathbb{R}$  (sin is a bounded function with values between 1 and  $-1$ ). Its derivative at zero exists too.

$$\lim_{x \rightarrow 0} \frac{x + 5x^2 \sin(1/x)}{x} = \lim_{x \rightarrow 0} (1 + 5x \sin(1/x)) = 1.$$

For  $x \neq 0$ ,

$$f'(x) = 1 + 10x \sin(1/x) - 5 \cos(1/x)$$

(cf. the rules for computing derivatives in 5.3.4 below). The derivative is not continuous at the origin.

$f$  is increasing at  $x = 0$  but is not increasing on any neighbourhood of this point. The one-sided derivatives of this function do not exist at zero either.

As another illustration of a simple usage of the relation between the derivatives and the properties of being an increasing (or decreasing) function, we can consider the existence of inverses to polynomials.

Polynomials of degree at least two need not be either increasing or decreasing functions. Hence we cannot anticipate that there would be a globally defined inverse function to

**Solution.** To solve this problem, it suffices to consider the problem of inscribing the largest rectangle into a right triangle with legs of lengths  $b/2$  and  $h$  so that two of the rectangle's sides lie on the legs of the triangle. Thus we reduce the problem to maximizing the function

$$f(x) = x \left( h - \frac{2hx}{b} \right)$$

on the interval  $I = [0, b/2]$ . Since we have that

$$f'(x) = h - \frac{4hx}{b} \quad \text{for all } x \in I$$

and further

$$f(0) = f\left(\frac{b}{2}\right) = 0, \quad f(x) \geq 0, \quad x \in I,$$

the function  $f$  must take the greatest value on  $I$  at its only stationary point  $x_0 = b/4$ . Thus the sides of the wanted rectangle are  $b/2$  long (twice  $x_0$ : considering the original problem) and  $h/2$  (which can be obtained by substituting  $b/4$  for  $x$  into the expression  $h - 2hx/b$ ). Hence we get  $S = hb/4$ .  $\square$

**5.F.3.** Among rectangles such that two of their vertices lie on the  $x$ -axis and the other two have positive  $y$ -coordinates and lie on the parabola  $y = 8 - 2x^2$ , find the one which has the greatest area.

**Solution.** The base of the largest rectangle is  $4/\sqrt{3}$  long, the rectangle's height is then  $16/3$ . This result can be obtained by finding the absolute maximum of the function

$$S(x) = 2x(8 - 2x^2)$$

on the interval  $I = [0, 2]$ . Since this function is non-negative on  $I$ , takes zero at  $I$ 's boundary points, is differentiable on the whole of  $I$  and its derivative is zero at a unique point of  $I$ , namely  $x = 2/\sqrt{3}$ , it has the maximum there.  $\square$

**5.F.4.** Let the ellipse  $3x^2 + y^2 = 2$  be given. Write the equation of its tangent line which forms the smallest triangle possible in the first quadrant and determine the triangle's area.

**Solution.** The line corresponding to the equation  $ax + by + c = 0$  intersects the axes at the points  $[-\frac{c}{a}, 0]$ ,  $[0, -\frac{c}{b}]$  and the area of the triangle whose vertices are these two points and the origin is  $S = \frac{c^2}{2ab}$ . The line which touches the ellipse at  $[x_T, y_T]$  has the equation  $3xx_T + yy_T - 2 = 0$ . The area of the triangle corresponding to it is thus  $S = \frac{2}{3x_T y_T}$ . Further, in the first quadrant, we have that  $x_T, y_T > 0$ . To minimize this area means to maximize the product  $x_T y_T = x_T \sqrt{2 - 3x_T^2}$ , which is (in the first quadrant) the same as to maximize  $(x_T y_T)^2 = x_T^2(2 - 3x_T^2) = -3(x_T^2 - \frac{1}{3})^2 + \frac{1}{3}$ . Hence, the wanted minimum is at  $x_T = \frac{1}{\sqrt{3}}$ . The tangent's equation is  $\sqrt{3}x + y = 2$  and the triangle's area is  $S_{min} = \frac{2\sqrt{3}}{9}$ .  $\square$

them. On the other hand, the inverse exists to every restriction of  $f$  to an interval between adjacent roots of the derivative  $f'$ , i.e. where the derivative of the polynomial is non-zero and keeps the sign. These inverse functions will never be polynomials, except for the case of polynomials of degree one. The equation

$$y = ax + b$$

implies

$$x = \frac{1}{a}(y - b).$$

For a polynomial of degree two, the equation

$$y = ax^2 + bx + c$$

leads to the equation

$$x = \frac{-b \pm \sqrt{b^2 - 4a(c - y)}}{2a}.$$

Thus the inverse (given by the above equation) exists only for those  $x$  which are in either of the intervals  $(-\infty, -\frac{b}{2a})$ ,  $(-\frac{b}{2a}, \infty)$ .

It can be shown that the roots of polynomials of order larger than four cannot in general be expressed by means of power functions. Thus piece-wise defined inverses to polynomials may represent new items in the zoo.

### 5.3.4. Elementary properties of derivatives.

We introduce several basic facts about the calculation of derivatives. We shall see that the derivatives are quite nicely compatible with the algebraic operations of addition and multiplication of real or complex functions. The last formula then allows us to efficiently determine the derivatives of composite functions. It is also called the *chain rule*.

Intuitively, they can be understood very easily if we imagine that the derivative of a function  $y = f(x)$  is the quotient of the rates of increase of the output variable  $y$  and the input variable  $x$ :

$$f' = \frac{\delta y}{\delta x}.$$

Of course, for  $y = h(x) = f(x) + g(x)$ , the increase in  $y$  is given by the sum of the increases of  $f$  and  $g$ , and the increase of the input variable is still the same. Therefore, the derivative of a sum is the sum of the derivatives.

The derivative of a product is not the product of the derivatives. For  $y = f(x)g(x)$ , the increase is

$$\begin{aligned} \delta y &= f(x + \delta x)g(x + \delta x) - f(x)g(x) \\ &= f(x + \delta x)(g(x + \delta x) - g(x)) + (f(x + \delta x) - f(x))g(x) \end{aligned}$$

Now, if we make the increase  $\delta x$  small, we actually calculate the limit of a sum of products, which is the sum of the products of the limits. Thus the derivative of a product  $fg$  is given by the expression  $f'g + fg'$ , which is called the *Leibniz rule*<sup>10</sup>.

<sup>10</sup>Gottfried Wilhelm von Leibniz (1646-1716) was a great German mathematician and philosopher. He developed the differential and integral calculus in terms of the infinitesimal quantities, arguing similarly as above.

**5.F.5.** At the time  $t = 0$ , the three points  $P, Q, R$  began moving in the plane as follows: The point  $P$  is moving from the point  $[-2, 1]$  in the direction  $(3, 1)$  at the constant speed  $\sqrt{10}$  m/s. the point  $Q$  is moving from  $[0, 0]$  in the direction  $(-1, 1)$  with the constant acceleration  $2\sqrt{2}$  m/s<sup>2</sup> (beginning at zero speed) and the point  $R$  is going from  $[0, 1]$  in the direction  $(1, 0)$  at the constant speed 2 m/s. At which time will the area of the triangle  $PQR$  be minimal?

**Solution.** The equations of the points  $P, Q, R$  in time are

$$\begin{aligned} P &: [-2, 1] + (3, 1)t, \\ Q &: [0, 0] + (-1, 1)t^2, \\ R &: [0, 1] + (2, 0)t. \end{aligned}$$

The area of the triangle  $PQR$  is determined, for instance, by half the absolute value of the determinant whose rows are the coordinates of the vectors  $PQ$  and  $QR$  (see 1.5.11). So we minimize the determinant:

$$\begin{vmatrix} -2+t & t \\ -t^2-2t & -1+t^2 \end{vmatrix} = 2t^3 - t + 2.$$

The derivative is  $6t^2 - 1$ , so the extrema occur at  $t = \pm \frac{1}{\sqrt{6}}$ . Thanks to considering non-negative time only, we are interested in  $t = \frac{1}{\sqrt{6}}$ . The second derivative of the considered function is positive at this point, thus the function has a local minimum there. Further, its value at this point is positive and less than the value at the point 0 (the boundary point of the interval where we are looking for the extremum), so this point is the wanted global minimum.  $\square$

**5.F.6.** At 9 o'clock in the morning, the old wolf left his den  $D$  and as a part of his everyday warm-up, he began running counterclockwise around his favorite stump  $S$  at the constant speed 4 kph (not very quick, is he), keeping the constant distance of 1 km from it. At the same time, Little Red Riding Hood set out from her house  $H$  straight to her Grandma's cottage  $C$  at the constant speed 4 kph. When will they be closest to each other and what will their distance be at that time? The coordinates (in kilometers) are:  $D = [2, 3]$ ,  $S = [2, 2]$ ,  $H = [0, 0]$ ,  $C = [5, 5]$ .

**Solution.** The wolf is moving along a unit circle, so his angular speed equals his absolute speed and his position in time can be described by the following parametric equations:

$$x(t) = 2 - \cos(4t), \quad y(t) = 2 - \sin(4t),$$

The derivative of a composite function is even more interesting: Consider a function

$$g = h \circ f,$$

where the domain of the function  $z = h(y)$  contains the codomain of the function  $y = f(x)$ . By writing out the increases,

$$g' = \frac{\delta z}{\delta x} = \frac{\delta z}{\delta y} \frac{\delta y}{\delta x}.$$

Thus we expect that the formula will be of the form

$$(h \circ f)'(x) = h'(f(x))f'(x).$$

Now we provide correct formulations together with proofs:

RULES FOR DIFFERENTIATION

**Theorem.** Let  $f$  and  $g$  be real or complex functions defined on a neighbourhood of a point  $x_0 \in \mathbb{R}$  and having finite derivatives at this point. Then

(1) for every real or complex number  $c$ , the function  $x \mapsto c \cdot f(x)$  has a derivative at  $x_0$  and

$$(cf)'(x_0) = c(f'(x_0)),$$

(2) the function  $f + g$  has a derivative at  $x_0$ , and

$$(f + g)'(x_0) = f'(x_0) + g'(x_0),$$

(3) the function  $f \cdot g$  has a derivative at  $x_0$ , and

$$(f \cdot g)'(x_0) = f'(x_0)g(x_0) + f(x_0)g'(x_0).$$

(4) Further, suppose  $h$  is a function defined on a neighbourhood of the image  $y_0 = f(x_0)$  with a derivative at  $y_0$ . Then the composite function  $h \circ f$  also has a derivative at  $x_0$ , and

$$(h \circ f)'(x_0) = h'(f(x_0)) \cdot f'(x_0).$$

**PROOF.** (1) and (2): A straightforward application of the theorem about sums and products of function limits yields the result.

(3) Rewrite the quotient of the increases (already mentioned), in the following way:

$$\frac{(fg)(x) - (fg)(x_0)}{x - x_0} = f(x) \frac{g(x) - g(x_0)}{x - x_0} + \frac{f(x) - f(x_0)}{x - x_0} g(x_0).$$

The limit of this as  $x \rightarrow x_0$  gives the desired result because  $f$  is continuous at  $x_0$ .

(4) By lemma 5.3.1, there are functions  $\psi$  and  $\varphi$  which are continuous at  $x_0$  and  $y_0 = f(x_0)$ . Further they satisfy  $h(y) = h(y_0) + \varphi(y)(y - y_0)$ ,  $f(x) = f(x_0) + \psi(x)(x - x_0)$  on some neighbourhoods of  $x_0$  and  $y_0$ . They satisfy  $\psi(x_0) = f'(x_0)$  and  $\varphi(y_0) = h'(y_0)$ . Then,

$$\begin{aligned} h(f(x)) - h(f(x_0)) &= \varphi(f(x))(f(x) - f(x_0)) \\ &= \varphi(f(x))\psi(x)(x - x_0) \end{aligned}$$

for all  $x$  from the neighbourhood of  $x_0$ . However, the product  $\varphi(f(x))\psi(x)$  is a function which is continuous at  $x_0$  and

Little Red Riding Hood is then moving along the line

$$x(t) = 2\sqrt{2}t, \quad y(t) = 2\sqrt{2}t.$$

Let us find the extrema of the (squared) distance  $\rho$  of their paths in time:

$$\begin{aligned} \rho(t) &= [2 - \cos(4t) - 2\sqrt{2}t]^2 + [2 - \sin(4t) - 2\sqrt{2}t]^2, \\ \rho'(t) &= 16(\cos(4t) - \sin(4t))(\sqrt{2}t - 1) + 32t + \\ &\quad + 4\sqrt{2}(\cos(4t) + \sin(4t)) - 16\sqrt{2}. \end{aligned}$$

It is impossible to solve the equation  $\rho'(t) = 0$  algebraically, we can only find the solution numerically (using some computational software). Apparently, there will be infinitely many extrema: every round, the wolf's direction is at some moment parallel to that of Little Red Riding Hood, so their distance is decreasing for some period; however, Little Red Riding Hood is moving away from the wolf's favorite stump around which he is moving. We find out that the first local minimum occurs at  $t \doteq 0.31$ , and then at  $t \doteq 0.97$ , when the distance of our heroes will be approximately 5 meters. Clearly this is the global maximum as well.

The situation when we cannot solve a given problem explicitly is quite common in practice and the use of numerical methods is of great importance.  $\square$

**5.F.7. Halley's problem, 1686.** A basketball player is standing in front of a basket, at distance  $l$  from its rim which is at height  $h$  from the throwing point. Determine the minimal initial speed  $v_0$  which the player must give to the ball in order to score, and the angle  $\varphi$  corresponding to this  $v_0$ . See the picture.

**Solution.** Once again, we will omit units of measurement: we can assume that distances are given in meters, times in seconds (and speeds in meters per second then). Suppose the player throws the ball at time  $t = 0$  and it goes through the rim at time  $t_0 > 0$ . We will express the ball's position (while flying) by the points  $[x(t), y(t)]$  for  $t \in [0, t_0]$ , and we require that  $x(0) = 0, y(0) = 0, x(t_0) = l, y(t_0) = h$ .

Apparently,

$$x'(t) = v_0 \cos \varphi, \quad y'(t) = v_0 \sin \varphi - gt$$

for  $t \in (0, t_0)$ , where  $g$  is the gravity of Earth, since the values  $x'(t)$  and  $y'(t)$  are, respectively, the horizontal and vertical speed of the ball. By integrating these equations, we get

$$x(t) = v_0 t \cos \varphi + c_1, \quad y(t) = v_0 t \sin \varphi - \frac{1}{2}gt^2 + c_2$$

for  $t \in (0, t_0)$  and  $c_1, c_2 \in \mathbb{R}$ . From the initial conditions

its value at  $x_0$  is just the desired derivative of the composite function, again by lemma 5.3.1.  $\square$

**5.3.5. Derivative of quotients.** Consider first the special case of  $h(x) = x^{-1}$ . From the definition of the derivative,

$$\begin{aligned} h'(x) &= \lim_{\delta x \rightarrow 0} \frac{\frac{1}{x+\delta x} - \frac{1}{x}}{\delta x} = \lim_{\delta x \rightarrow 0} \frac{x - x - \delta x}{\delta x(x^2 + x\delta x)} \\ &= \lim_{\delta x \rightarrow 0} \frac{-1}{x^2 + x\delta x} = -x^{-2}. \end{aligned}$$

Thus, the above leads to:

DERIVATIVE OF A QUOTIENT

**Corollary.** Let  $f$  and  $g$  be real-valued functions which have finite derivatives at a point  $x_0$  and  $g(x_0) \neq 0$ . Then the function  $h(x) = f(x)(g(x))^{-1}$  satisfies

$$h'(x_0) = \left(\frac{f}{g}\right)'(x_0) = \frac{f'(x_0)g(x_0) - f(x_0)g'(x_0)}{(g(x_0))^2}.$$

**PROOF.** Using the formula  $(x^{-1})' = -x^{-2}$ , the chain rule says

$$(g^{-1})' = -g^{-2} \cdot g'.$$

The Leibniz rule implies

$$(f/g)' = (f \cdot g^{-1})' = f'g^{-1} - fg^{-2}g' = \frac{f'g - gf'}{g^2}.$$

**5.3.6. Derivatives of inverse functions.** In paragraph 1.6.1, while talking about relations and mappings in general, the concept of an *inverse function* was introduced. If the inverse function  $f^{-1}$  to a given function  $f : \mathbb{R} \rightarrow \mathbb{R}$  exists (do not confuse this notation with the function  $x \mapsto (f(x))^{-1}$ ), then it is uniquely determined by either of the following identities

$$f^{-1} \circ f = \text{id}_{\mathbb{R}}, \quad f \circ f^{-1} = \text{id}_{\mathbb{R}},$$

Then the other identity is also true. If  $f$  is defined on a set  $A \subset \mathbb{R}$  and  $f(A) = B$ , the existence of  $f^{-1}$  is conditioned by the same statements with identity mappings  $\text{id}_A$  and  $\text{id}_B$ , respectively, on the right-hand sides. As seen in the diagram, the graph of the inverse function is obtained simply by interchanging the axes of the input and output variables.

$$\lim_{t \rightarrow 0^+} x(t) = x(0) = 0, \quad \lim_{t \rightarrow 0^+} y(t) = y(0) = 0,$$

it follows that  $c_1 = c_2 = 0$ . Substituting the remaining conditions

$$\lim_{t \rightarrow t_0^-} x(t) = x(t_0) = l, \quad \lim_{t \rightarrow t_0^-} y(t) = y(t_0) = h$$

then gives

$$l = v_0 t_0 \cos \varphi, \quad h = v_0 t_0 \sin \varphi - \frac{1}{2} g t_0^2.$$

According to the first equation, we have that

$$(1) \quad t_0 = \frac{l}{v_0 \cos \varphi},$$

and thus we get only one equation

$$(2) \quad h = l \tan \varphi - \frac{g l^2}{2 v_0^2 \cos^2 \varphi},$$

where  $v_0 \in (0, +\infty)$ ,  $\varphi \in (0, \pi/2)$ .

Let us remind that our task is to determine the minimal  $v_0$  and the corresponding  $\varphi$  which satisfies this equation. To be more comprehensible, we want to find the minimal value of  $v_0$  for which there is an angle  $\varphi$  satisfying (2). Since

$$\frac{1}{\cos^2 \varphi} = \frac{\cos^2 \varphi + \sin^2 \varphi}{\cos^2 \varphi} = 1 + \tan^2 \varphi, \quad \varphi \in (0, \frac{\pi}{2}),$$

the equation (2) can be written in the form

$$h - l \tan \varphi + \frac{g l^2}{2 v_0^2} (1 + \tan^2 \varphi) = 0,$$

i. e.

$$\tan^2 \varphi - \frac{2 v_0^2}{g l} \tan \varphi + \frac{2 h v_0^2}{g l^2} + 1 = 0.$$

From the last equation (quadratic equation in  $p = \tan \varphi$ ), it follows that

$$\tan \varphi = \frac{\frac{2 v_0^2}{g l} \pm \sqrt{\frac{4 v_0^4}{g^2 l^2} - 4 \left( \frac{2 h v_0^2}{g l^2} + 1 \right)}}{2},$$

i. e.

$$(3) \quad \tan \varphi = \frac{v_0^2}{g l} \pm \frac{\sqrt{v_0^4 - 2 h v_0^2 g - g^2 l^2}}{g l}.$$

Therefore, the angle  $\varphi$  satisfying (2) exists if and only if

$$v_0^4 - 2 g h v_0^2 - g^2 l^2 \geq 0.$$

Once again, a suitable substitution (this time  $q = v_0^2$ ) allows us to reduce the left side to a quadratic expression and subsequently to get

$$(v_0^2 - g [h + \sqrt{h^2 + l^2}]) (v_0^2 - g [h - \sqrt{h^2 + l^2}]) \geq 0.$$

As  $h < \sqrt{h^2 + l^2}$ , it must be that

$$v_0^2 \geq g [h + \sqrt{h^2 + l^2}], \quad \text{i. e.} \quad v_0 \geq \sqrt{g [h + \sqrt{h^2 + l^2}]}.$$

The least value

$$(4) \quad v_0 = \sqrt{g [h + \sqrt{h^2 + l^2}]}$$

If it is known that the inverse  $y = f^{-1}(x)$  of a differentiable function  $x = f(y)$  is also differentiable, then the chain rule yields immediately

$$1 = (\text{id})'(x) = (f \circ f^{-1})'(x) = f'(y) \cdot (f^{-1})'(x).$$

Notice that  $f'(y)$  must be non-zero.

This corresponds to the intuitive idea that for  $y = f(x)$ , the value of  $f'$  is approximately  $\frac{\delta y}{\delta x}$  while for  $x = f^{-1}(y)$  it is approximately  $(f^{-1})'(y) = \frac{\delta x}{\delta y}$ . And this indeed is the way the derivatives of inverse functions are calculated.

#### DERIVATIVE OF THE INVERSE FUNCTION

**Theorem.** *If  $f$  is a real-valued function differentiable at  $y_0$ , such that the inverse  $f^{-1}(x)$  exists on a neighbourhood of the value  $x_0 = f(y_0)$  and  $f'(y_0) \neq 0$ , then*

$$(1) \quad (f^{-1})'(x_0) = \frac{1}{f'(f^{-1}(x_0))} = \frac{1}{f'(y_0)}.$$

**PROOF.** To prove the proposition, it suffices to read the proof of the fourth statement of theorem 5.3.4. We work with the composition  $f \circ f^{-1} = \text{id}$  there. The composite function is differentiable. By lemma 5.3.1, there is a function  $\varphi$  continuous at  $y_0$  such that

$$f(y) - f(y_0) = \varphi(y)(y - y_0),$$

on some neighbourhood of  $y_0$ . Further, it satisfies  $\varphi(y_0) = f'(y_0) \neq 0$  and  $\varphi$  has constant sign on a neighbourhood of  $x_0$ . Next, notice that the existence of the inverse  $f^{-1}$  around the point  $x_0$  and the continuity of  $f$  at  $y_0$  guarantees the continuity of  $f^{-1}$  at  $x_0$ , (the  $\varepsilon$  and  $\delta$  neighbourhoods map each to the other bijectively). The substitution  $y = f^{-1}(x)$  then yields

$$x - x_0 = \varphi(f^{-1}(x))(f^{-1}(x) - f^{-1}(x_0)),$$

for all  $x$  lying in some neighbourhood  $\mathcal{O}(x_0)$  of  $x_0$ . Further,  $f^{-1}(x_0) = y_0$ , and  $\varphi(f^{-1}(x))$  is continuous at  $x_0$  and remains non-zero on a neighbourhood  $\mathcal{O}(x_0)$  of  $x_0$  with constant sign. Thus

$$\frac{f^{-1}(x) - f^{-1}(x_0)}{x - x_0} = \frac{1}{\varphi(f^{-1}(x))} \neq 0,$$

for all  $x \in \mathcal{O}(x_0) \setminus \{x_0\}$ . The right-hand side of this expression is continuous at  $x_0$ . The limit is

$$\lim_{x \rightarrow x_0} \frac{1}{\varphi(f^{-1}(x))} = \frac{1}{\varphi(f^{-1}(x_0))} = \frac{1}{f'(y_0)}.$$

Therefore, the limit of the left-hand side also exists, and it follows that

$$(f^{-1})'(x_0) = \frac{1}{f'(y_0)}$$

as required.  $\square$

is then matched (see (3)) by

$$(5) \quad \tan \varphi = \frac{v_0^2}{gl} = \frac{h + \sqrt{h^2 + l^2}}{l},$$

i. e.  $\varphi = \operatorname{arctg} \frac{h + \sqrt{h^2 + l^2}}{l}.$

The previous calculation was based upon the conditions  $x(t_0) = l, y(t_0) = h$  only. However, these only talk about the position of the ball at the time  $t_0$ , but the ball could get through the rim from below. Therefore, let us add the condition  $y'(t_0) < 0$  which says that the ball was falling at the time, and let us prove that it holds for  $v_0$  from (4) and  $\varphi$  from (5).

Let us remind that we have (see (1), (2))

$$t_0 = \frac{l}{v_0 \cos \varphi}, \quad v_0^2 = \frac{gl^2}{2(l \tan \varphi - h) \cos^2 \varphi}.$$

Using this, from

$$y'(t_0) = \lim_{t \rightarrow t_0^-} y'(t) = v_0 \sin \varphi - gt_0 < 0$$

we get

$$\frac{gl^2}{2(l \tan \varphi - h) \cos^2 \varphi} = v_0^2 < v_0 \cdot \frac{gt_0}{\sin \varphi} = \frac{gl}{\sin \varphi \cos \varphi},$$

i. e. the equality

$$l \sin \varphi \cos \varphi < 2(l \tan \varphi - h) \cos^2 \varphi,$$

from which we can easily see that

$$\frac{2h}{l} < \tan \varphi.$$

By confrontation with (5), we get that the last inequality really holds because

$$\tan \varphi = \frac{h + \sqrt{h^2 + l^2}}{l} > \frac{h + \sqrt{h^2}}{l} = \frac{2h}{l}.$$

Thus we have shown that for the initial speed from (4), the player is able to score.

During the free throw, supposing the player lets the ball go at the height of 2 m, we have

$$h = 1.05 \text{ m}, \quad l = 4.225 \text{ m}, \quad g = 9.80665 \text{ m} \cdot \text{s}^{-2},$$

and so the minimal initial speed of the ball is

$$v_0 = \sqrt{9.80665 \left[ 1.05 + \sqrt{(1.05)^2 + (4.225)^2} \right]} \text{ m} \cdot \text{s}^{-1} \doteq 7.28 \text{ m} \cdot \text{s}^{-1}.$$

The corresponding angle is then

$$\varphi = \operatorname{arctg} \frac{v_0^2}{9.80665 \cdot 4.225} \doteq 0.907 \text{ rad} \approx 52^\circ.$$

Let us think for a while about the obtained value of the angle  $\varphi$  for the initial speed  $v_0$ . According to the picture, we have

$$2\beta + (\pi - \alpha) = \pi \quad \text{and} \quad \alpha + \gamma = \frac{\pi}{2},$$

whence it follows that

$$\beta = \frac{\alpha}{2} = \frac{\pi}{4} - \frac{\gamma}{2}.$$

So it holds that

**5.3.7. Derivatives of the elementary functions.** Consider the exponential function  $f(x) = a^x$  for any fixed real  $a > 0$ . If the derivative of  $a^x$  exists for all  $x$ , then

$$f'(x) = \lim_{\delta x \rightarrow 0} \frac{a^{x+\delta x} - a^x}{\delta x} = a^x \lim_{\delta x \rightarrow 0} \frac{a^{\delta x} - 1}{\delta x} = f'(0)a^x.$$

On the other hand, if the derivative at zero exists, then this formula guarantees the existence of the derivative at any point of the domain and also determines its value. At the same time, the validity of this formula for one-sided derivatives is also verified.

Unfortunately, it takes some time to verify that the derivatives of exponential functions indeed exist (see 5.4.2, i, and 6.3.7).

There is an especially important base  $e$ , sometimes known as Euler's number, for which the derivative at zero equals one.

Remember the formula  $(e^x)' = e^x$  for a while and draw on its consequences.

For the general exponential function, (using standard rules of differentiation),

$$(a^x)' = (e^{\ln(a)x})' = \ln(a)(e^{\ln(a)x}) = \ln(a) \cdot a^x.$$

Thus exponential functions are special since their derivatives are proportional to their values.

Next, we determine the derivative  $(\ln_e(x))'$ . The definition of the natural logarithm as the inverse to  $e^x$ ,

$$e^{\ln x} = x,$$

allows the calculation:

$$(1) \quad (\ln)'(y) = (\ln)'(e^x) = \frac{1}{(e^x)'} = \frac{1}{e^x} = \frac{1}{y}.$$

The formula

$$(2) \quad (x^a)' = ax^{a-1}$$

for differentiating a general power function can also be derived using the derivatives of the exponential and logarithmic functions:

$$(x^a)' = (e^{a \ln x})' = e^{a \ln x} (a \ln x)' = a \frac{x^a}{x} = ax^{a-1}.$$

**5.3.8. Mean value theorems.** Before continuing the journey of finding new interesting functions, we derive several simple statements about derivatives. The meaning of all of them is intuitively clear from the diagrams. The proofs follow the visual imagination.

$$\varphi = \frac{\pi}{2} - \beta = \frac{\pi}{4} + \frac{\gamma}{2} = \frac{1}{2} \left( \frac{\pi}{2} + \gamma \right) = \frac{1}{2} \left( \frac{\pi}{2} + \operatorname{arctg} \frac{h}{l} \right).$$

We have obtained that the elevation angle corresponding to the throw with minimal energy is the arithmetic mean of the right angle and the angle at which the rim is seen (from the ball's position).

The problem of finding the minimal speed of the thrown ball was actually solved by Edmond Halley as early as in 1686, when he determined the minimal amount of gunpowder necessary for a cannonball to hit a target which lies at greater height (beyond a rampart, for instance). Halley proved (the so-called Halley's calibration rule) that to hit a target at the point  $[l, h]$  (shooting from  $[0, 0]$ ) one needs the same minimal amount of gunpowder as when hitting a horizontal target at distance  $h + \sqrt{h^2 + l^2}$  (at the angle  $\varphi = 45^\circ$ ). Halley also demonstrated that the value of  $\varphi$  is stable with regard to small difference of the amount of used gunpowder and insignificant errors in estimating the target's distance.  $\square$

**5.F.8.** A bullet is shot at angle  $\varphi$  from a point at height  $h$  above ground at initial speed  $v_0$ . It will fall on the ground at distance  $R$  from the point of shot (see the picture). Determine the angle  $\varphi$  for which the value of  $R$  is maximal.

**Solution.** We will express the bullet's position in time by the points  $[x(t), y(t)]$ . We assume that it was shot at time  $t = 0$  from the point  $[0, 0]$  and it will fall on the ground at the point  $[R, -h]$  at certain time  $t = t_0$ , i. e.  $x(0) = 0, y(0) = 0, x(t_0) = R, y(t_0) = -h$ . Similarly to Halley's problem, we will consider the equations

$$x'(t) = v_0 \cos \varphi, \quad y'(t) = v_0 \sin \varphi - gt, \quad t \in (0, t_0)$$

for the horizontal and vertical speeds of the bullet, where  $g$  is the gravity of Earth.

We can continue as when solving the previous problem: by integrating these equations (taking  $x(0) = y(0) = 0$  into consideration), we get

ROLLE'S THEOREM<sup>11</sup>

**Theorem.** Assume that the function  $f : \mathbb{R} \rightarrow \mathbb{R}$  is continuous on a closed bounded interval  $[a, b]$  and differentiable inside this interval. If  $f(a) = f(b)$ , then there is a number  $c \in (a, b)$  such that  $f'(c) = 0$ .

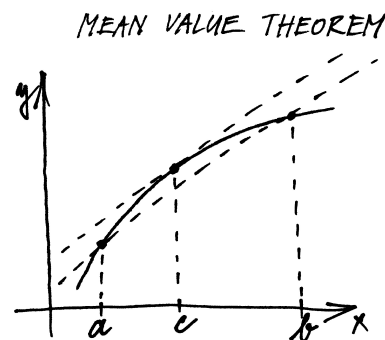

**PROOF.** Since the function  $f$  is continuous on the closed interval (i.e. on a compact set), it attains its maximum and its minimum there. Either its maximum value is greater than  $f(a) = f(b)$ , or the minimum value is less than  $f(a) = f(b)$ , or  $f$  is constant. If the third case applies, the derivative is zero at all points of the interval  $(a, b)$ . If the second case applies, then the first case applies to the function  $-f$ . If the first case applies, it occurs at an interior point  $c$ . If  $f'(c) \neq 0$  then the function  $f$  would be either increasing or decreasing at  $c$  (see 5.3.2), implying the existence of larger values than  $f(c)$  in a neighbourhood of  $c$ , contradicting that  $f(c)$  is a maximum value.  $\square$

**5.3.9.** The latter result immediately implies the following corollary.

LAGRANGE'S MEAN VALUE THEOREM

**Theorem.** Assume the function  $f : \mathbb{R} \rightarrow \mathbb{R}$  is continuous on an interval  $[a, b]$  and differentiable at all points inside this interval. Then there is a number  $c \in (a, b)$  such that

$$f'(c) = \frac{f(b) - f(a)}{b - a}.$$

<sup>11</sup>The French mathematician Michel Rolle (1652-1719) proved this theorem only for polynomials. The principle was perhaps known much earlier, but the rigorous proof comes from the 19th century only.

$$x(t) = v_0 t \cos \varphi, \quad y(t) = v_0 t \sin \varphi - \frac{1}{2} g t^2, \quad t \in (0, t_0),$$

and from the conditions  $\lim_{t \rightarrow t_0^-} x(t) = x(t_0) = R$ ,  $\lim_{t \rightarrow t_0^-} y(t) = y(t_0) = -h$ , we then have that

$$R = v_0 t_0 \cos \varphi, \quad -h = v_0 t_0 \sin \varphi - \frac{1}{2} g t_0^2.$$

From the first equation, it follows that

$$t_0 = \frac{R}{v_0 \cos \varphi},$$

so we can express the previous two equations by the single equation

$$(1) \quad -h = R \tan \varphi - \frac{g R^2}{2 v_0^2 \cos^2 \varphi},$$

where  $\varphi \in (0, \pi/2)$ .

Unlike with Halley's problem, the value of  $v_0$  is given and  $R$  is variable (dependent on  $\varphi$ ). So, actually, there is a function  $R = R(\varphi)$  (in variable  $\varphi$ ) which must satisfy (1) (it is determined by the equation (1)). Thus, this function is given implicitly. The equation (1) can be written as ( $R$  is substituted by  $R(\varphi)$ )

$$R(\varphi) \tan \varphi \cdot 2 v_0^2 \cos^2 \varphi - g R^2(\varphi) + h \cdot 2 v_0^2 \cos^2 \varphi = 0.$$

Using the relation

$$2 \tan \varphi \cos^2 \varphi = \sin 2\varphi,$$

we can transform (1) into the form

$$(2) \quad R(\varphi) v_0^2 \sin 2\varphi - g R^2(\varphi) + 2 h v_0^2 \cos^2 \varphi = 0.$$

Differentiating with respect to  $\varphi$  now gives

$$R'(\varphi) v_0^2 \sin 2\varphi + 2 R(\varphi) v_0^2 \cos 2\varphi - 2 g R(\varphi) R'(\varphi) - 2 h v_0^2 (2 \cos \varphi \sin \varphi) = 0,$$

i. e.

$$R'(\varphi) [v_0^2 \sin 2\varphi - 2 g R(\varphi)] = -2 R(\varphi) v_0^2 \cos 2\varphi + 2 h v_0^2 \sin 2\varphi.$$

Thus we have calculated that

$$R'(\varphi) = \frac{2 v_0^2 [h \sin 2\varphi - R(\varphi) \cos 2\varphi]}{v_0^2 \sin 2\varphi - 2 g R(\varphi)}, \quad \varphi \in (0, \frac{\pi}{2}).$$

It suffices to verify that  $v_0^2 \sin 2\varphi - 2 g R(\varphi) \neq 0$  for every  $\varphi \in (0, \pi/2)$ . Let us suppose the contrary and substitute

$$R = \frac{v_0^2 \sin 2\varphi}{2g} = \frac{v_0^2 \sin \varphi \cos \varphi}{g}$$

into (1), obtaining

$$-h = \frac{v_0^2 \sin \varphi \cos \varphi}{g} \tan \varphi - \frac{g v_0^4 \sin^2 \varphi \cos^2 \varphi}{2 g^2 v_0^2 \cos^2 \varphi}.$$

Simple rearrangements lead to

$$-h = \frac{v_0^2 \sin^2 \varphi}{2g},$$

which cannot happen (the left side is surely negative while the right one is positive).

**PROOF.** The proof is a simple statement of the geometrical meaning of the theorem: The secant line between the points  $[a, f(a)]$  and  $[b, f(b)]$  has a tangent line which is parallel to it (have a look at the diagram). The equation of the secant line is

$$y = g(x) = f(a) + \frac{f(b) - f(a)}{b - a} (x - a).$$

The difference  $h(x) = f(x) - g(x)$  determines the (vertical) distance of the graph and the secant line (in the values of  $y$ ). Surely  $h(a) = h(b) = 0$  and

$$h'(x) = f'(x) - \frac{f(b) - f(a)}{b - a}.$$

By the previous theorem, there is a point  $c$  at which  $h'(c) = 0$ .  $\square$

The mean value theorem can also be written in the form:

$$(1) \quad f(b) = f(a) + f'(c)(b - a).$$

In the case of a parametrically given curve in the plane, i.e. a pair of functions  $y = f(t)$ ,  $x = g(t)$ , the same result about the existence of a tangent line parallel to the secant line going through the boundary points is described by *Cauchy's mean value theorem*:

#### CAUCHY'S MEAN VALUE THEOREM

**Corollary.** Let functions  $y = f(t)$  and  $x = g(t)$  be continuous on an interval  $[a, b]$  and differentiable inside this interval, and further let  $g'(t) \neq 0$  for all  $t \in (a, b)$ . Then there is a point  $c \in (a, b)$  such that

$$\frac{f(b) - f(a)}{g(b) - g(a)} = \frac{f'(c)}{g'(c)}.$$

**PROOF.** Put

$$h(t) = (f(b) - f(a))g(t) - (g(b) - g(a))f(t).$$

Now  $h(a) = f(b)g(a) - f(a)g(b)$ ,  $h(b) = f(b)g(b) - f(a)g(b)$ , so by Rolle's theorem, there is a number  $c \in (a, b)$  such that  $h'(c) = 0$ .

Finally, the function  $g$  is either strictly increasing or decreasing on  $[a, b]$  and thus  $g(b) \neq g(a)$ . Moreover,  $g'(c) \neq 0$  and the desired formula follows.  $\square$

**5.3.10.** A reasoning similar to the one in the above proof leads to a supremely useful tool for calculating limits of quotients of functions.

So we were able to determine  $R'(\varphi)$  for all  $\varphi \in (0, \pi/2)$ . What is more, we can immediately see that this derivative is zero if and only if

$$h \sin 2\varphi = R(\varphi) \cos 2\varphi, \quad \text{i. e.} \quad R(\varphi) = h \tan 2\varphi.$$

Since the function  $R$  must have a maximum on the interval  $(0, \pi/2)$  (according to the physical meaning of the problem, for  $\varphi \rightarrow 0+$  and for  $\varphi \rightarrow \pi/2-$  the value of  $R$  decreases) and is differentiable at every point of this interval, it has its maximum at the point where its derivative is zero. This means that  $R(\varphi)$  can be maximal only if

$$(3) \quad R(\varphi) = h \tan 2\varphi.$$

Let us thus substitute (3) into (2). We obtain

$$h \tan 2\varphi v_0^2 \sin 2\varphi - gh^2 \tan^2 2\varphi + 2hv_0^2 \cos^2 \varphi = 0,$$

and let us transform this equation:

$$\begin{aligned} \tan 2\varphi v_0^2 \sin 2\varphi + 2v_0^2 \cos^2 \varphi &= gh \tan^2 2\varphi, \\ v_0^2 \frac{\sin^2 2\varphi}{\cos 2\varphi} + v_0^2 (\cos 2\varphi + 1) &= gh \frac{\sin^2 2\varphi}{\cos^2 2\varphi}, \\ v_0^2 \sin^2 2\varphi + v_0^2 \cos^2 2\varphi + v_0^2 \cos 2\varphi &= gh \frac{\sin^2 2\varphi}{\cos 2\varphi} \\ v_0^2 + v_0^2 \cos 2\varphi &= gh \frac{1 - \cos^2 2\varphi}{\cos 2\varphi}, \\ v_0^2 (1 + \cos 2\varphi) &= gh \frac{(1 - \cos 2\varphi)(1 + \cos 2\varphi)}{\cos 2\varphi}, \\ v_0^2 \cos 2\varphi &= gh (1 - \cos 2\varphi), \text{ and } \cos 2\varphi = \frac{gh}{v_0^2 + gh}. \end{aligned}$$

However, by this we have uniquely determined the point

$$\varphi_0 = \frac{1}{2} \arccos \frac{gh}{v_0^2 + gh},$$

at which  $R$  is highest. Since  $\sin 2\varphi_0 = \sqrt{1 - \cos^2 2\varphi_0} = \sqrt{1 - \frac{g^2 h^2}{(v_0^2 + gh)^2}} = \frac{\sqrt{v_0^4 + 2ghv_0^2}}{v_0^2 + gh}$ , we have

$$\begin{aligned} R(\varphi_0) &= h \tan 2\varphi_0 = h \frac{\frac{\sqrt{v_0^4 + 2ghv_0^2}}{v_0^2 + gh}}{\frac{gh}{v_0^2 + gh}} = \frac{\sqrt{v_0^4 + 2ghv_0^2}}{g} \\ &= \frac{v_0}{g} \sqrt{v_0^2 + 2gh}. \end{aligned}$$

Let, for instance, javelin thrower Barbora Špotáková give a javelin the speed  $v_0 = 27.778 \text{ m/s} \doteq 100 \text{ km/h}$  at the height  $h = 1.8 \text{ m}$  (with  $g = 9.80665 \text{ m} \cdot \text{s}^{-2}$ ). Then the javelin can fly up to the distance

$$R(\varphi_0) = \frac{27.778}{9.80665} \sqrt{27.778^2 + 2 \cdot 9.80665 \cdot 1.8} \text{ m} \doteq 80.46 \text{ m}.$$

This distance was achieved for

$$\varphi_0 = \frac{1}{2} \arccos \frac{9.80665 \cdot 1.8}{27.778^2 + 9.80665 \cdot 1.8} \doteq 0.7742 \text{ rad} \approx 44.36^\circ.$$

However, the world record of Barbora Špotáková does not even approach 80 m although the impact of other phenomena (air resistance, for example) can be neglected. Still we must not forget that from 1 April 1999, the center of gravity of the women's javelin was moved towards its tip upon the decision of IAAF (International Association of Athletics Federation). This reduced the flight distance by around 10 %.

L'HOPITAL'S RULE<sup>12</sup>

**Theorem.** Suppose  $f$  and  $g$  are functions differentiable on some neighbourhood of a point  $x_0 \in \mathbb{R}$ , yet not necessarily at  $x_0$  itself. Suppose

$$\lim_{x \rightarrow x_0} f(x) = 0, \quad \lim_{x \rightarrow x_0} g(x) = 0.$$

If the limit

$$\lim_{x \rightarrow x_0} \frac{f'(x)}{g'(x)}$$

exists, then the limit

$$\lim_{x \rightarrow x_0} \frac{f(x)}{g(x)}$$

also exists, and the two limits are equal.

**PROOF.** Without loss of generality, the functions  $f$  and  $g$  are zero at the point  $x_0$ . The quotient of the values then corresponds to the slope of the secant line between the points  $[0, 0]$  and  $[f(x), g(x)]$ . At the same time, the quotient of the derivatives corresponds to the slope of the tangent line at the given point. Thus it is necessary to verify that the limit of the slopes of the secant lines exists from the fact that the limit of the slopes of the tangent lines exists.

Technically, we can use the mean value theorem in Cauchy's parametric form. First of all, the existence of the expression  $f'(x)/g'(x)$  on some neighbourhood of the point  $x_0$  (excluding  $x_0$  itself) is implicitly assumed. Thus especially for points  $c$  sufficiently close to  $x_0$ ,  $g'(c) \neq 0$ .<sup>13</sup> By the mean value theorem,

$$\lim_{x \rightarrow x_0} \frac{f(x)}{g(x)} = \lim_{x \rightarrow x_0} \frac{f(x) - f(x_0)}{g(x) - g(x_0)} = \lim_{x \rightarrow x_0} \frac{f'(c_x)}{g'(c_x)},$$

<sup>12</sup>Guillaume François Antoine, Marquis de l'Hôpital, (1661-1704) became famous for his textbook on Calculus. This rule was first published there, perhaps originally proved by one of the famous Bernoulli brothers.

<sup>13</sup>This is not always necessary for the existence of the limit in a general sense. Nevertheless, for the statement of l'Hospital's rule, it is. A thorough discussion can be found (googled) in the popular article 'R. P. Boas, Counterexamples to L'Hospital's Rule, The American Mathematical Monthly, October 1986, Volume 93, Number 8, pp. 644-645.'

The original record (with “correctly balanced” javelin) was 80.00 m.

The performed reasoning and the obtained result can be applied to other athletic disciplines and sports. In golf, for instance,  $h$  is close to 0, and thus it is just the angle

$$\varphi_0 = \lim_{h \rightarrow 0^+} \frac{1}{2} \arccos \frac{gh}{v_0^2 + gh} = \frac{1}{2} \arccos 0 = \frac{\pi}{4} \text{ rad} = 45^\circ$$

at which the ball falls at the greatest distance

$$R(\varphi_0) = \lim_{h \rightarrow 0^+} \frac{v_0}{g} \sqrt{v_0^2 + 2gh} = \frac{v_0^2}{g}.$$

Let us realize that our calculation cannot be used for  $h = 0$  ( $\varphi_0 = \pi/4$ ) since then we would get the undefined expression  $\tan(\pi/2)$  for the distance  $R$ . However, we have solved the problem for any  $h > 0$ , and therefore we could get a helping hand from the corresponding one-sided limit.  $\square$

### 5.F.9. Regiomontanus’ problem, 1471.

In the museum, there is a painting on the wall. Its lower edge is  $a$  meters above ground and its upper edge  $b$  meters, then (its height thus equals  $b - a$ ). A tourist is looking at the painting, her eyes being at height  $h < a$  meters above ground.

(The reason for the inequality  $h < a$  can, for instance, be to allow more equally tall visitors to view the painting simultaneously in several rows.) How far from the wall should the tourist stand if she wants to maximize her angle of view at the painting?

**Solution.** Let us denote by  $x$  the distance (in meters) of the tourist from the wall and by  $\varphi$  her angle of view at the painting. Further, let us set (see the picture) the angles  $\alpha, \beta \in (0, \pi/2)$  by

$$\tan \alpha = \frac{b-h}{x}, \quad \tan \beta = \frac{a-h}{x}.$$

Our task is to maximize  $\varphi = \alpha - \beta$ . Let us add that for  $h > b$ , one can proceed analogously and for  $h \in [a, b]$ , the angle  $\varphi$  increases as  $x$  decreases ( $\varphi = \pi$  for  $x = 0$  and  $h \in (a, b)$ ).

where  $c_x$  is a number lying between  $x_0$  and  $x$ , dependent on  $x$ . From the existence of the limit

$$\lim_{x \rightarrow x_0} \frac{f'(x)}{g'(x)},$$

it follows that this value will be shared by the limit of any sequence created by substituting the values  $x = x_n$  approaching  $x_0$  into  $f'(x)/g'(x)$  (cf. the convergence test 5.2.15). Especially, we can substitute any sequence  $c_{x_n}$  for  $x_n \rightarrow x_0$ , and thus the limit

$$\lim_{x \rightarrow x_0} \frac{f'(c_x)}{g'(c_x)}$$

exist, and the last two limits are equal. Hence the desired limit exists and has the same value.  $\square$

From the proof of the theorem, it is true for one-sided limits as well.

**5.3.11. Corollaries.** L’Hospital’s rule can easily be extended for limits at the improper points  $\pm\infty$  and for the case of infinite values of the limits. If, for instance, we have

$$\lim_{x \rightarrow \infty} f(x) = 0, \quad \lim_{x \rightarrow \infty} g(x) = 0,$$

then  $\lim_{x \rightarrow 0^+} f(1/x) = 0$  and  $\lim_{x \rightarrow 0^+} g(1/x) = 0$ .

At the same time, from existence of the limit of the quotient of the derivatives at infinity,

$$\begin{aligned} \lim_{x \rightarrow 0^+} \frac{(f(1/x))'}{(g(1/x))'} &= \lim_{x \rightarrow 0^+} \frac{f'(1/x)(-1/x^2)}{g'(1/x)(-1/x^2)} \\ &= \lim_{x \rightarrow 0^+} \frac{f'(1/x)}{g'(1/x)} = \lim_{x \rightarrow \infty} \frac{f'(x)}{g'(x)}. \end{aligned}$$

Applying the previous theorem, the limit

$$\lim_{x \rightarrow \infty} \frac{f(x)}{g(x)} = \lim_{x \rightarrow 0^+} \frac{f(1/x)}{g(1/x)} = \lim_{x \rightarrow \infty} \frac{f'(x)}{g'(x)}$$

exists in this case as well.

The limit calculation is even simpler in the case when

$$\lim_{x \rightarrow x_0} f(x) = \pm\infty, \quad \lim_{x \rightarrow x_0} g(x) = \pm\infty.$$

Then it suffices to write

$$\lim_{x \rightarrow x_0} \frac{f(x)}{g(x)} = \lim_{x \rightarrow x_0} \frac{1/g(x)}{1/f(x)},$$

which is already the case of usage of l’Hospital’s rule from the previous theorem. It can be proved that l’Hospital’s rule has the same form for infinite limits as well:

**Theorem.** Let  $f$  and  $g$  be functions differentiable on some neighbourhood of a point  $x_0 \in \mathbb{R}$ , not necessarily at  $x_0$  itself. Further, let the limits  $\lim_{x \rightarrow x_0} f(x) = \pm\infty$  and  $\lim_{x \rightarrow x_0} g(x) = \pm\infty$  exist. If the limit

$$\lim_{x \rightarrow x_0} \frac{f'(x)}{g'(x)}$$

exists, then the limit

$$\lim_{x \rightarrow x_0} \frac{f(x)}{g(x)}$$

also exists and they equal each other.

From the condition  $h < a$  it follows that the angle  $\varphi$  is acute, i. e.  $\varphi \in (0, \pi/2)$ . Since the function  $y = \tan x$  is increasing on the interval  $(0, \pi/2)$ , we can turn our attention to maximizing the value  $\tan \varphi$ . We have that

$$\tan \varphi = \tan(\alpha - \beta) = \frac{\tan \alpha - \tan \beta}{1 + \tan \alpha \tan \beta} = \frac{\frac{b-h}{x} - \frac{a-h}{x}}{1 + \frac{b-h}{x} \cdot \frac{a-h}{x}} = \frac{x(b-a)}{x^2 + (b-h)(a-h)}.$$

So it suffices to find the global maximum of the function

$$f(x) = \frac{x(b-a)}{x^2 + (b-h)(a-h)}, \quad x \in [0, +\infty).$$

From the expression

$$f'(x) = \frac{(b-a)[x^2 + (b-h)(a-h)] - 2x^2(b-a)}{[x^2 + (b-h)(a-h)]^2} = \frac{(b-a)[(b-h)(a-h) - x^2]}{[x^2 + (b-h)(a-h)]^2}, \quad x \in (0, +\infty),$$

we can see that

$$\begin{aligned} f'(x) &> 0 \quad \text{for } x \in \left(0, \sqrt{(b-h)(a-h)}\right), \\ f'(x) &< 0 \quad \text{for } x \in \left(\sqrt{(b-h)(a-h)}, +\infty\right). \end{aligned}$$

Hence the function  $f$  has its global maximum at the point  $x_0 = \sqrt{(b-h)(a-h)}$  (let us remind the inequalities  $h < a < b$ ).

The point  $x_0$  can, of course, be determined by other means. For instance, we can (instead of looking for the maximum of the positive function  $f$  on the interval  $(0, +\infty)$ ) try to find the global minimum of the function

$$g(x) = \frac{1}{f(x)} = \frac{x^2 + (b-h)(a-h)}{x(b-a)} = \frac{x}{b-a} + \frac{(b-h)(a-h)}{x(b-a)}, \quad x \in (0, +\infty)$$

with the help of the so-called AM-GM inequality (between the arithmetic and geometric means)

**PROOF.** Apply the mean value theorem. The key step is to express the quotient in a form where the derivative arises:

$$\frac{f(x)}{g(x)} = \frac{f(x)}{f(x) - f(y)} \cdot \frac{f(x) - f(y)}{g(x) - g(y)} \cdot \frac{g(x) - g(y)}{g(x)},$$

where  $y$  is fixed, from a selected neighbourhood of  $x_0$  and  $x$  is approaching  $x_0$ . Since the limits of  $f$  and  $g$  at  $x_0$  are infinite, we can surely assume that the differences of the values of both functions at  $x$  and  $y$ , having fixed  $y$ , are non-zero.

Using the mean value theorem, replace the fraction in the middle with the quotient of the derivatives at an appropriate point  $c$  between  $x$  and  $y$ . The expression of the examined limit thus gets the form

$$\frac{f(x)}{g(x)} = \frac{1 - \frac{g(y)}{g(x)}}{1 - \frac{f(y)}{f(x)}} \cdot \frac{f'(c)}{g'(c)},$$

where  $c$  depends on both  $x$  and  $y$ . As  $x$  approaches  $x_0$ , the former fraction converges to one. If  $y$  is simultaneously moved towards  $x_0$ , the latter fraction becomes arbitrarily close to the limit value of the quotient of the derivatives.  $\square$

**5.3.12. Example.** By making suitable modifications of the examined expressions, one can also apply l'Hopital's rule on forms of the types  $\infty - \infty$ ,  $1^\infty$ ,  $0 \cdot \infty$ , and so on. Often one simply rearranges the expressions or uses some continuous function, for instance the exponential one.

For an illustration of such a procedure, we show the connection between the arithmetic and geometric means of  $n$  non-negative values  $x_i$ . The *arithmetic mean*

$$M^1(x_1, \dots, x_n) = \frac{x_1 + \dots + x_n}{n}$$

is a special case of the *power mean with exponent  $r$* , also known as the generalized mean:

$$M^r(x_1, \dots, x_n) = \left( \frac{x_1^r + \dots + x_n^r}{n} \right)^{\frac{1}{r}}.$$

The special value  $M^{-1}$  is called the *harmonic mean*. Calculate the limit value of  $M^r$  for  $r$  approaching zero. For this purpose, determine the limit by l'Hopital's rule (we treat it as an expression of the form  $0/0$  and differentiate with respect to  $r$ , with  $x_i$  as constant parameters).

The following calculation uses the chain rule and knowledge of the derivative of the power function, must be read in reverse. The existence of the last limit implies the existence of the last-but-one, and so on.

$$\begin{aligned} \lim_{r \rightarrow 0} \ln(M^r(x_1, \dots, x_n)) &= \lim_{r \rightarrow 0} \frac{\ln\left(\frac{1}{n}(x_1^r + \dots + x_n^r)\right)}{r} \\ &= \lim_{r \rightarrow 0} \frac{\frac{x_1^r \ln x_1 + \dots + x_n^r \ln x_n}{n}}{\frac{x_1^r + \dots + x_n^r}{n}} \\ &= \frac{\ln x_1 + \dots + \ln x_n}{n} = \ln \sqrt[n]{x_1 \cdots x_n}. \end{aligned}$$

Hence

$$\lim_{r \rightarrow 0} M^r(x_1, \dots, x_n) = \sqrt[n]{x_1 \cdots x_n},$$

$$\frac{y_1+y_2}{2} \geq \sqrt{y_1 y_2}, \quad y_1, y_2 \geq 0,$$

where the equality occurs iff  $y_1 = y_2$ . The choice

$$y_1(x) = \frac{x}{b-a}, \quad y_2(x) = \frac{(b-h)(a-h)}{x(b-a)}$$

then gives

$$g(x) = y_1(x) + y_2(x) \geq 2 \sqrt{y_1(x) y_2(x)} = \frac{2}{b-a} \sqrt{(b-h)(a-h)}.$$

Therefore, if there is a number  $x > 0$  for which  $y_1(x) = y_2(x)$ , then the function  $g$  has the global minimum at  $x$ . The equation

$$y_1(x) = y_2(x), \quad \text{i. e.} \quad \frac{x}{b-a} = \frac{(b-h)(a-h)}{x(b-a)},$$

has a unique positive solution  $x_0 = \sqrt{(b-h)(a-h)}$ .

We have determined the ideal distance of the tourist from the wall in two different ways. The angle corresponding to  $x_0$  is

$$\varphi_0 = \arctan \frac{x_0(b-a)}{x_0^2 + (b-h)(a-h)} = \arctan \frac{b-a}{2\sqrt{(b-h)(a-h)}}.$$

When looking at the painting from the ground (being an ant, for instance), we have  $h = 0$ , and so

$$x_0 = \sqrt{ab}, \quad \varphi_0 = \arctan \frac{b-a}{2\sqrt{ab}}.$$

If the painting is 1 meter high and its lower edge is 2 meters above ground ( $a = 2, b = 3$ ), then the ant will see the painting at the largest angle  $\varphi_0 \doteq 0.2014 \text{ rad} \approx 11.5^\circ$  at the distance  $x_0 \doteq 2.45$  meters from the wall. If this painting is viewed by a man whose eyes are at the height of 1,8 meters, together with his son whose eyes are 1 meter above ground, then the father should stand  $x_0 \doteq 0.49$  meters from the wall and his son  $x_0 \doteq 1.41$  meters, then. We can notice that the father has  $\varphi_0 \doteq 0.7956 \text{ rad} \approx 45.6^\circ$  whereas his son has  $\varphi_0 \doteq 0.3398 \text{ rad} \approx 19.5^\circ$ . The quotient

$$\frac{0.7956}{0.3398} \approx \frac{45.6}{19.5} \doteq 2.3$$

proves what a strongly better view the father has.  $\square$

**5.F.10. Snell's law.** Determine the refracted light ray between the point  $A$  in a homogeneous space with speed of light  $v_1$  and the point  $B$  in a homogeneous space with speed of light  $v_2$ . See the picture.

**Solution.** Once again, we will omit units of measurement. We can assume that distances are given in meters, speeds  $v_1, v_2$  in meters per second (and time in seconds, then). The ray is determined by Fermat's principle of least time: of all the paths between the points  $A$  and  $B$ , the light will go along the one which can be traversed in the least time. In homogeneous spaces, the ray will be a straight line (in this case, we will consider its segment). So it suffices to determine the

which is known as the *geometric mean*.

#### 4. Infinite sums and power series

The last part of this chapter is mainly devoted to infinite sums of numbers, aiming at infinite extension of polynomials – the so called power series.

We first complete the basic discussion of the exponential function, expressing it as a limit of polynomial approximations. This illustrates the more general need to develop effective tools to deal with sequences of numbers or functions. If the reader finds the next paragraphs too demanding, we suggest jumping to 5.4.3 starting the general discussion on infinite sums of numbers and maybe return later.

**5.4.1. The calculation of  $e^x$ .** For numerical computations, manipulation with limits of sequences is needed as well as addition and multiplication of scalars. Thus it might be a good idea to approximate non-polynomial functions by sequences of numbers that can be calculated easily, keeping control of the approximation errors.

We approach the function  $e^x$  this way. In view of the expected property  $(e^x)' = e^x$  (cf. 5.3.7), we look for a function whose rate of increase equals the function's value at every point. This can be imagined as a splendid interest rate equal to the current value of your money.

If we apply the interest rate per year once a month, once a day, once an hour, and so on, we obtain the following values for the yield  $x$  of the deposit after one year:

$$\left(1 + \frac{x}{12}\right)^{12}, \quad \left(1 + \frac{x}{365}\right)^{365}, \quad \left(1 + \frac{x}{8760}\right)^{8760}, \dots$$

Therefore, we could guess that

$$e^x = \lim_{n \rightarrow \infty} \left(1 + \frac{x}{n}\right)^n.$$

At the same time, we can imagine that the finer we apply the interest, the higher the yield will be. So the sequence on the right-hand side should be an increasing sequence.

In detail, we examine the sequence of numbers

$$a_n = \left(1 + \frac{1}{n}\right)^n.$$

*Bernoulli's inequality* will come in handy:

**Lemma.** For every real number  $b \geq -1, b \neq 0$ , and a natural number  $n \geq 2, (1+b)^n > 1+nb$ .

**PROOF.** For  $n = 2$ ,

$$(1+b)^2 = 1 + 2b + b^2 > 1 + 2b.$$

Proceed by induction on  $n$ , supposing  $b > -1$ . Assume that the proposition holds for some  $k \geq 2$  and calculate:

$$\begin{aligned} (1+b)^{k+1} &= (1+b)^k(1+b) > (1+kb)(1+b) \\ &= 1 + (k+1)b + kb^2 > 1 + (k+1)b \end{aligned}$$

The statement is, of course, true for  $b = -1$  as well.  $\square$

point  $R$  (given by the value  $x$ ) where the ray refracts. The distance between the points  $A$  and  $R$  is  $\sqrt{h_1^2 + x^2}$ , between points  $R$  and  $B$  it is  $\sqrt{h_2^2 + (d-x)^2}$ , then. The total time of the transmission of energy between the points  $A$  and  $B$  is thus given by the function

$$T(x) = \frac{\sqrt{h_1^2 + x^2}}{v_1} + \frac{\sqrt{h_2^2 + (d-x)^2}}{v_2}$$

in the variable  $x \in [0, d]$ . Let us emphasize that we want to find the point  $x \in [0, d]$  at which the value  $T(x)$  is minimal.

The derivative

$$T'(x) = \frac{x}{v_1 \sqrt{h_1^2 + x^2}} - \frac{d-x}{v_2 \sqrt{h_2^2 + (d-x)^2}}$$

is a continuous function on the interval  $[0, d]$ , so its sign can be easily described by its zero points. From the equation

$$T'(x) = 0, \quad \text{i. e.} \quad \frac{x}{v_1 \sqrt{h_1^2 + x^2}} = \frac{d-x}{v_2 \sqrt{h_2^2 + (d-x)^2}},$$

it follows that

$$\frac{\frac{x}{\sqrt{h_1^2 + x^2}}}{\frac{d-x}{\sqrt{h_2^2 + (d-x)^2}}} = \frac{v_1}{v_2}.$$

This expression is useful for us because (see the picture)

$$\sin \varphi_1 = \frac{x}{\sqrt{h_1^2 + x^2}}, \quad \sin \varphi_2 = \frac{d-x}{\sqrt{h_2^2 + (d-x)^2}}.$$

Thus there is at most one stationary point; it is determined by

$$(1) \quad \frac{\sin \varphi_1}{\sin \varphi_2} = \frac{v_1}{v_2}.$$

Let us realize that as  $\varphi_1 \in [0, \pi/2]$  increases (when  $x$  increases), the angle  $\varphi_2 \in [0, \pi/2]$  decreases. The sine is non-negative and increasing on the interval  $[0, \pi/2]$ , so the quotient  $(\sin \varphi_1)/(\sin \varphi_2)$  is increasing with respect to  $x$ . Since  $T'(0) < 0$  and  $T'(d) > 0$ , there is exactly one stationary point  $x_0$ . From the inequalities  $T'(x) < 0$  for  $x \in [0, x_0]$  and  $T'(x) > 0$  for  $x \in (x_0, d]$ , it follows that there is the global minimum at the stationary point  $x_0$ .

Let us summarize the preceding: The ray is given by the point  $R$  of refraction (i. e. the value  $x_0$ ), and the point  $R$  is given by the identity (1), which is called Snell's law in physics.

The quotient of  $v_1$  and  $v_2$  is constant for the given homogeneous spaces and determines an important quantity which describes the interface of optical spaces. It is called a refractive index and denoted by  $n$ . Usually, the first space is vacuum, i. e.  $v_1 = c$ , and  $v_2 = v$ , thus obtaining the (absolute) index of refraction  $n = c/v$ . For vacuum, we get  $n = 1$ , of course. This value is also used for air since its refractive index at the standard conditions (i. e. pressure of 101 325 Pa, temperature of 293 K and absolute humidity of 0.9 g m<sup>-3</sup>) is

Now

$$\begin{aligned} \frac{a_n}{a_{n-1}} &= \frac{(1 + \frac{1}{n})^n}{(1 + \frac{1}{n-1})^{n-1}} = \frac{(n^2 - 1)^n n}{n^{2n} (n-1)} \\ &= \left(1 - \frac{1}{n^2}\right)^n \frac{n}{n-1} > \left(1 - \frac{1}{n}\right) \frac{n}{n-1} = 1. \end{aligned}$$

by using Bernoulli's inequality with  $b = -\frac{1}{n^2}$ . So  $a_n > a_{n-1}$  for all natural numbers, and it follows that the sequence  $a_n$  is indeed increasing.

The following similar calculation (also using Bernoulli's inequality) verifies that the sequence of numbers

$$b_n = \left(1 + \frac{1}{n}\right)^{n+1} = \left(1 + \frac{1}{n}\right) \left(1 + \frac{1}{n}\right)^n$$

is decreasing. Notice that  $b_n > a_n$ . Also,

$$\begin{aligned} \frac{b_n}{b_{n+1}} &= \frac{n}{n+1} \left(\frac{\frac{n+1}{n}}{\frac{n+2}{n+1}}\right)^{n+2} = \frac{n}{n+1} \left(\frac{n^2 + 2n + 1}{n^2 + 2n}\right)^{n+2} \\ &= \frac{n}{n+1} \left(1 + \frac{1}{n(n+2)}\right)^{n+2} \\ &\geq \frac{n}{n+1} \left(1 + \frac{n+2}{n(n+2)}\right) = 1. \end{aligned}$$

Thus the sequence  $a_n$  is increasing and bounded from above, so the set of its terms has a supremum which equals the limit of the sequence. At the same time, this value is also the limit of the decreasing sequence  $b_n$  because

$$\lim_{n \rightarrow \infty} b_n = \lim_{n \rightarrow \infty} \left(1 + \frac{1}{n}\right) a_n = \lim_{n \rightarrow \infty} a_n.$$

This limit determines one of the most important numbers in mathematics (besides the numbers 0, 1, and  $\pi$ ), namely *Euler's number*<sup>14</sup>  $e$ . Thus

$$e = \lim_{n \rightarrow \infty} \left(1 + \frac{1}{n}\right)^n.$$

**5.4.2. Power series for  $e^x$ .** The exponential function has been defined as the only continuous function satisfying  $f(1) = e$  and  $f(x+y) = f(x) \cdot f(y)$ . The base  $e$  is now expressed as the limit of the sequence  $a_n$ , thus necessarily

$$e^x = \lim_{n \rightarrow \infty} (a_n)^x.$$

Fix a real number  $x \neq 0$ . If we replace  $n$  with  $n/x$  in the numbers  $a_n$  from the previous paragraph, we arrive again at the same limit. (Think this out in detail!) Hence

$$e = \lim_{n \rightarrow \infty} \left(1 + \frac{x}{n}\right)^{\frac{n}{x}}, \quad e^x = \lim_{n \rightarrow \infty} \left(1 + \frac{x}{n}\right)^n.$$

<sup>14</sup>The ingenious Swiss mathematician, physicist, astronomer, logician and engineer Leonhard Euler (1707-1783) was behind extremely many inventions, including original mathematical techniques and tools.

$n \doteq 1.000272$ . Other spaces have  $n > 1$  ( $n = 1.31$  for ice,  $n = 1.33$  for water,  $n = 1.5$  for glass).

However, the refractive index also depends on the wave length of the electromagnetic radiation in question (for example, for water and light, it ranges from  $n \doteq 1.331$  to  $n \doteq 1.344$ ), where the index ordinarily decreases as the wave length increases. The speed of light in an optical space having  $n > 1$  depends on its frequency. We talk about the dispersion of light. The dispersion causes rays of different colors to refract at different angles. (The violet ray refracts the most and the red ray refracts the least.) This is also the origin of a rainbow. We can further remind the well-known Newton's experiment with a glass prism from 1666.

Eventually, let us remark that our task always has a solution because we can choose the point  $R$  arbitrarily. If, together with the speeds  $v_1$  and  $v_2$ , the angle  $\varphi_1$  were given as well (our task could then be to calculate where the ray going from the point  $A$  intersects the line  $y = c$  for a certain  $c < 0$  when the interface of optical spaces is on the  $x$ -axis), then the angle  $\varphi_2 \in (0, \pi/2)$  satisfying (1) might not exist. This corresponds to the total reflection (there is no refracted light at all).  $\square$

Further miscellaneous problems concerning extrema of functions of a real variable can be found at ??

**5.F.11.** Prove, that the polynomial  $P(x) = x^5 - x^4 + 2x^3 - x^2 + x + 1$  has exactly one real root.

**Solution.** Any odd degree polynomial has at least one real root, since for big (in absolute value) negative  $x$  are the values  $P(x)$  big (in absolute value) negative, for big positive  $x$  are the values  $P(x)$  big positive and since  $P(x)$  is a continuous function, it must attain the zero value. One can also argue with the fundamental theorem of algebra (12.2.8). We know, that the polynomial  $P(x)$  has to have five roots over the field of complex numbers and that complex roots of the polynomial with real coefficients come in pairs of conjugated numbers. Therefore the polynomial has to have at least one real root.

If there were at least two roots, then according to the mean value theorem (it suffices the Rolle's version, cf. 5.3.8) there must be a  $c \in (a, b)$ , such that  $P'(c) = 0$ . But  $P'(x) = 5x^4 - 4x^3 + 6x^2 - 2x + 1 = 2x^2(x - 1)^2 + 3x^4 + 3x^2 + (x - 1)^2 > 0$ . Thus the polynomial has exactly one real root.  $\square$

Denote the  $n$ -th term of this sequence by  $u_n(x) = (1 + \frac{x}{n})^n$  and express it by the binomial theorem:

$$\begin{aligned} u_n(x) &= 1 + n \frac{x}{n} + \frac{n(n-1)x^2}{2!n^2} + \dots + \frac{n!x^n}{n!n^n} \\ &= 1 + x + \frac{x^2}{2!} \left(1 - \frac{1}{n}\right) \\ &+ \frac{x^3}{3!} \left(1 - \frac{1}{n}\right) \left(1 - \frac{2}{n}\right) + \dots \\ &+ \frac{x^n}{n!} \left(1 - \frac{1}{n}\right) \left(1 - \frac{2}{n}\right) \dots \left(1 - \frac{n-1}{n}\right). \end{aligned} \tag{1}$$

Look at  $u_n(x)$  for very large  $n$ . It seems that many of the first summands of  $u_n(x)$  will be fairly close to the values  $\frac{1}{k!}x^k$ ,  $k = 0, 1, \dots$ . Thus it is plausible that the numbers  $u_n(x)$  should be very close to  $v_n(x) = \sum_{j=0}^n \frac{1}{j!}x^j$  and thus both these sequences should have the same limit.

The following theorem is perhaps one of the most important results of Mathematics:

THE POWER SERIES FOR  $e^x$

**Theorem.** The exponential function  $e^x$  equals, for each  $x \in \mathbb{R}$ , the limit  $\lim_{k \rightarrow \infty} v_k(x)$  of the partial sums in the expression

$$e^x = 1 + x + \frac{1}{2}x^2 + \dots + \frac{1}{n!}x^n + \dots = \sum_{i=0}^{\infty} \frac{1}{i!}x^i.$$

The function  $e^x$  is differentiable at each point  $x$  and its derivative is  $(e^x)' = e^x$ .

**PROOF.** The technical proof makes the above idea precise. Fix  $x$  and recall that  $v_n(x)$  is the sequences defined as the sums of the first  $n$  terms of the formal infinite expression

$$\sum_{j=0}^{\infty} c_j = \sum_{j=0}^{\infty} \frac{1}{j!}x^j.$$

While  $v_n(x)$  is strictly increasing if  $x > 0$ , for all  $m > n$

$$|v_m(x) - v_n(x)| \leq \sum_{k=n+1}^m \frac{1}{k!}|x|^k = v_m(|x|) - v_n(|x|).$$

Hence  $v_n(x)$  is a Cauchy sequence, and thus convergent, if  $v_n(x)$  is always bounded (and thus convergent) for  $x > 0$ .

The quotient of adjacent terms in the series is  $c_{j+1}/c_j = x/(j+1)$ . Thus for every fixed  $x$ , there is a number  $N \in \mathbb{N}$  such that  $|c_{j+1}/c_j| < 1/2$  for all  $j \geq N$ . However, such large indices  $j$  satisfy  $|c_{j+1}| < \frac{1}{2}|c_j| < 2^{-(j-N+1)}|c_N|$ .

Recall that sums of a geometric series is computed from the equality  $(1 - q)(1 + q + \dots + q^k) = 1 - q^{k+1}$ . This means that the partial sums of the first  $n > N$  terms of our formal sum with  $x > 0$  can be estimated as follows

$$|v_n(x) - \sum_{j=0}^{N-1} \frac{1}{j!}x^j| < \frac{1}{N!}x^N \sum_{j=0}^{n-N} \frac{1}{2^j}.$$

**5.F.12.** Let  $f : \mathbb{R} \rightarrow (0, \infty)$  be a continuously differentiable function. Prove that there exists  $\xi \in (0, 1)$  such that

$$e^{f'(\xi)} f(0)^{f(x)} = f(1)^{f(\xi)}.$$

**Solution.** We can equivalently transform the equation:

$$e^{f'(\xi)} = \left(\frac{f(1)}{f(0)}\right)^{f(\xi)}$$

$$\frac{f'(\xi)}{f'(\xi)} = \ln f(1) - \ln f(0).$$

The existence of such a  $x$  is guaranteed by the Lagrange's mean value theorem (cf. 5.3.9) for the function  $g(x) = \ln(f(x))$  (there is  $g'(x) = \frac{f'(x)}{f(x)}$ ).  $\square$

### G. L'Hospital's rule

**5.G.1.** Verify that the limit

(a)

$$\lim_{x \rightarrow 0} \frac{\sin(2x) - 2 \sin x}{2e^x - x^2 - 2x - 2} \quad \text{is of the type } \frac{0}{0};$$

(b)

$$\lim_{x \rightarrow 0^+} \frac{\ln x}{\cot x} \quad \text{is of the type } \frac{\infty}{\infty};$$

(c)

$$\lim_{x \rightarrow 1^+} \left( \frac{x}{x-1} - \frac{1}{\ln x} \right) \quad \text{is of the type } \infty - \infty;$$

(d)

$$\lim_{x \rightarrow 1^+} (\ln(x-1) \cdot \ln x) \quad \text{is of the type } 0 \cdot \infty;$$

(e)

$$\lim_{x \rightarrow 0^+} (\cot x)^{\frac{1}{\ln x}} \quad \text{is of the type } \infty^0;$$

(f)

$$\lim_{x \rightarrow 0} \left( \frac{\sin x}{x} \right)^{\frac{1}{x^2}} \quad \text{is of the type } 1^\infty;$$

(g)

$$\lim_{x \rightarrow 1^-} \left( \cos \frac{\pi x}{2} \right)^{\ln x} \quad \text{is of the type } 0^0.$$

Then calculate it using l'Hospital's rule.

**Solution.** We can immediately assert that

(a)

$$\lim_{x \rightarrow 0} (\sin(2x) - 2 \sin x) = 0 - 0 = 0,$$

$$\lim_{x \rightarrow 0} (2e^x - x^2 - 2x - 2) = 2 - 0 - 0 - 2 = 0;$$

(b)

$$\lim_{x \rightarrow 0^+} \ln x = -\infty, \quad \lim_{x \rightarrow 0^+} \cot x = +\infty;$$

In particular, the limit of the expressions on the right-hand side for  $n$  approaching infinity surely exists, and so the limit of the increasing sequence  $v_n$  also exists.

Now examine the sequence of numbers  $u_n$ , whose limit is  $e^x$ . Consider  $n > N$  for some fixed  $N$  (imagine already  $N$  is very large) and choose a fixed number  $k < N$ . Write  $u_{n,k}$  for the sum of the first  $k$  summands in the expression (1) for  $u_n$ . Having fixed  $x$  and some  $\varepsilon > 0$ , we can choose  $k$  big enough to ensure  $|u_{n,k} - u_n| < \varepsilon$  (remind  $u_n$  is a convergent and thus Cauchy sequence). Indeed, the absolute values of the omitted terms are less than those in  $v_n$ .

If  $N$  is large enough,  $|u_{n,k} - v_k| < \varepsilon$  for all  $n > N$ . Indeed, there is only a fixed number of the brackets in the summands of  $u_{n,k}$  and they will all be arbitrarily close to 1, if  $n$  is large enough.

Summarizing, for each  $\varepsilon > 0$  the choices of  $k$  and  $n$  lead to the estimate  $|v_k - u_n| \leq |v_k - u_{n,k}| + |u_{n,k} - u_n| < 2\varepsilon$ . Choosing a sequence of  $\varepsilon_i = 1/2^i$ , we find subsequences  $v_{k_i}$  and  $u_{n_i}$  satisfying  $|v_{k_i} - u_{n_i}| < \frac{1}{i}$ . Thus the two convergent sequences must both have the same limit:

$$\lim_{k \rightarrow \infty} v_k = \lim_{n \rightarrow \infty} u_n.$$

This is the first claim we had to prove.

Remind we already know that  $(e^x)' = e^x$  if and only if the derivative equals 1 at the origin, see 5.3.7. Thus, it remains to compute

$$\lim_{x \rightarrow 0} \frac{(1 + x + \frac{1}{2}x^2 + \dots) - 1}{x} = \lim_{x \rightarrow 0} \frac{x + \frac{1}{2}x^2 + \frac{1}{6}x^3 + \dots}{x}.$$

This seems to be tricky, since there are two limit expressions there (notice that an  $x$  may be cancelled since this is a constant in the inner limit):

$$\lim_{x \rightarrow 0} \left( \lim_{n \rightarrow \infty} \sum_{k=1}^n \frac{1}{k!} x^{k-1} \right) = 1 + \lim_{x \rightarrow 0} \left( \lim_{n \rightarrow \infty} \sum_{k=2}^n \frac{1}{k!} x^{k-1} \right).$$

Next, for each  $\varepsilon > 0$  we can find  $N$  such that  $\lim_{n \rightarrow \infty} |\sum_{k=N}^n \frac{1}{k!} x^k| \leq \lim_{n \rightarrow \infty} \sum_{k=N}^n \frac{1}{k!} < \varepsilon$  for all  $x \in [-1, 1]$ . Next we restrict the interval for  $x$  enough to ensure that the remaining first terms yield  $\sum_{k=2}^{N-1} \frac{1}{k!} x^k < \varepsilon$ , too. This shows that the limit expression on the right-hand side must be zero. Thus the derivative exists and equals to one, as expected.  $\square$

Readers who skipped the preceding paragraphs (it doesn't matter whether on purpose or in need) can stay calm – we deduce all the results on the exponential function later again, using more general tools. In particular, we will see that all power series are always differentiable and can be differentiated term by term. We see later that the conditions  $f'(x) = f(x)$  and  $f(0) = 1$  determine a function uniquely.

(c)

$$\lim_{x \rightarrow 1^+} \frac{x}{x-1} = +\infty, \quad \lim_{x \rightarrow 1^+} \frac{1}{\ln x} = +\infty;$$

(d)

$$\lim_{x \rightarrow 1^+} \ln x = 0, \quad \lim_{x \rightarrow 1^+} \ln(x-1) = -\infty;$$

(e)

$$\lim_{x \rightarrow 0^+} \cot x = +\infty, \quad \lim_{x \rightarrow 0^+} \frac{1}{\ln x} = 0;$$

(f)

$$\lim_{x \rightarrow 0} \frac{\sin x}{x} = 1, \quad \lim_{x \rightarrow 0} \frac{1}{x^2} = +\infty;$$

(g)

$$\lim_{x \rightarrow 1^-} \cos \frac{\pi x}{2} = 0, \quad \lim_{x \rightarrow 1^-} \ln x = 0.$$

The case (a). Applying l'Hospital's rule transforms the limit

$$\lim_{x \rightarrow 0} \frac{\sin(2x) - 2 \sin x}{2e^x - x^2 - 2x - 2}$$

into the limit

$$\lim_{x \rightarrow 0} \frac{2 \cos(2x) - 2 \cos x}{2e^x - 2x - 2},$$

which is of the type 0/0. Two more applications of the rule lead to

$$\lim_{x \rightarrow 0} \frac{-4 \sin(2x) + 2 \sin x}{2e^x - 2}$$

and (the above limit is also of the type 0/0)

$$\lim_{x \rightarrow 0} \frac{-8 \cos(2x) + 2 \cos x}{2e^x} = \frac{-8 + 2}{2} = -3.$$

Altogether, we have (returning to the original limit)

$$\lim_{x \rightarrow 0} \frac{\sin(2x) - 2 \sin x}{2e^x - x^2 - 2x - 2} = -3.$$

Let us remark that multiple application of l'Hospital's rule in an exercise is quite common.

From now on, we will set the limits of quotients of derivatives obtained by l'Hospital's rule equal the limits of the original quotients. We can do this if the gained limits on the right sides really exist, i. e. actually we will make sure that what we write is sensible only afterwards.

The case (b). This time, differentiation of the numerator and the denominator gives

$$\lim_{x \rightarrow 0^+} \frac{\ln x}{\cot x} = \lim_{x \rightarrow 0^+} \frac{\frac{1}{x}}{\frac{-1}{\sin^2 x}} = \lim_{x \rightarrow 0^+} \frac{-\sin^2 x}{x}.$$

The last limit can be determined easily (we even know it). From

$$\lim_{x \rightarrow 0^+} -\sin x = 0, \quad \lim_{x \rightarrow 0^+} \frac{\sin x}{x} = 1,$$

**5.4.3. Number series.** When deriving the previous theorems about the function  $e^x$ , we have automatically used several extraordinarily useful concepts and tools. Now, we come back to them in detail:

When deriving the previous theorems about the function  $e^x$ , we have automatically used several extraordinarily useful concepts and tools. Now, we come back to them in detail:

#### INFINITE NUMBER SERIES

**Definition.** An *infinite series of numbers* is an expression

$$\sum_{n=0}^{\infty} a_n = a_0 + a_1 + a_2 + \dots + a_k + \dots,$$

where the  $a_n$ 's are real or complex numbers. The sequence of *partial sums* is given by the terms  $s_k = \sum_{n=0}^k a_n$ . The series converges and equals  $s$  if the limit

$$s = \lim_{k \rightarrow \infty} s_k$$

of the partial sums exists and is finite.

If the sequence of partial sums has an improper limit, the series *diverges* to  $\infty$  or  $-\infty$ . If the limit of the partial sums does not exist, the series *oscillates*.

**5.4.4. Properties of series.** For the sequence of partial sums  $s_n$  to converge, it is necessary and sufficient that it is a Cauchy sequence; that is

$$|s_m - s_n| = |a_{n+1} + \dots + a_m|$$

must be arbitrarily small for sufficiently large  $m > n$ . Since

$$|a_{n+1}| + \dots + |a_m| > |a_{n+1} + \dots + a_m|,$$

the convergence of the series  $\sum_{k=0}^{\infty} |a_n|$  implies the convergence of the series  $\sum_{k=0}^{\infty} a_n$ .

#### ABSOLUTELY CONVERGENT SERIES

A series  $\sum_{k=0}^{\infty} a_n$  is *absolutely convergent* if the series  $\sum_{n=0}^{\infty} |a_n|$  converges.

Absolute convergence is introduced because it is often much easier verified. The following theorem shows that all simple algebraic operations behave "very well" for series that converge absolutely.

the result  $0 = 0 \cdot 1$  follows. We could also have used l'Hospital's rule again (now for the expression  $0/0$ ), obtaining the result

$$\lim_{x \rightarrow 0^+} \frac{-\sin^2 x}{x} = \lim_{x \rightarrow 0^+} \frac{-2 \cdot \sin x \cdot \cos x}{1} = \frac{-2 \cdot 0 \cdot 1}{1} = 0.$$

The case (c). By mere transforming to a common denominator:

$$\lim_{x \rightarrow 1^+} \left( \frac{x}{x-1} - \frac{1}{\ln x} \right) = \lim_{x \rightarrow 1^+} \frac{x \ln x - (x-1)}{(x-1) \ln x}$$

we have obtained the type  $0/0$ . We have that

$$\begin{aligned} \lim_{x \rightarrow 1^+} \frac{x \ln x - (x-1)}{(x-1) \ln x} &= \lim_{x \rightarrow 1^+} \frac{\ln x + \frac{x}{x-1} - 1}{\frac{x-1}{x} + \ln x} \\ &= \lim_{x \rightarrow 1^+} \frac{\ln x}{1 - \frac{1}{x} + \ln x}. \end{aligned}$$

We have the quotient  $0/0$ , which (again by l'Hospital's rule) satisfies

$$\lim_{x \rightarrow 1^+} \frac{\ln x}{1 - \frac{1}{x} + \ln x} = \lim_{x \rightarrow 1^+} \frac{\frac{1}{x}}{\frac{1}{x^2} + \frac{1}{x}} = \frac{1}{1+1} = \frac{1}{2}.$$

Returning to the original limit, we write the result

$$\lim_{x \rightarrow 1^+} \left( \frac{x}{x-1} - \frac{1}{\ln x} \right) = \frac{1}{2}.$$

The case (d). We transform the assigned expression into the type  $\infty/\infty$  (to be precise, into the type  $-\infty/\infty$ ) by creating the fraction

$$\lim_{x \rightarrow 1^+} \ln(x-1) \cdot \ln x = \lim_{x \rightarrow 1^+} \frac{\ln(x-1)}{\frac{1}{\ln x}}.$$

By l'Hospital's rule,

$$\lim_{x \rightarrow 1^+} \frac{\ln(x-1)}{\frac{1}{\ln x}} = \lim_{x \rightarrow 1^+} \frac{\frac{1}{x-1}}{-\frac{1}{\ln^2 x} \cdot \frac{1}{x}} = \lim_{x \rightarrow 1^+} \frac{-x \ln^2 x}{x-1}.$$

This indeterminate form (of the type  $0/0$ ) can once again be determined by l'Hospital's rule:

$$\lim_{x \rightarrow 1^+} \frac{-x \ln^2 x}{x-1} = \lim_{x \rightarrow 1^+} \frac{-\ln^2 x - 2x \ln x \cdot \frac{1}{x}}{1} = \frac{0+0}{1} = 0.$$

The cases (e), (f), (g). Since

$$\begin{aligned} \lim_{x \rightarrow 0^+} (\cot x)^{\frac{1}{\ln x}} &= e^{\lim_{x \rightarrow 0^+} \frac{\ln(\cot x)}{\ln x}}; \\ \lim_{x \rightarrow 0} \left( \frac{\sin x}{x} \right)^{\frac{1}{x^2}} &= e^{\lim_{x \rightarrow 0} \frac{\ln \frac{\sin x}{x}}{x^2}}; \\ \lim_{x \rightarrow 1^-} \left( \cos \frac{\pi x}{2} \right)^{\ln x} &= e^{\lim_{x \rightarrow 1^-} (\ln x \cdot \ln(\cos \frac{\pi x}{2}))}, \end{aligned}$$

PROPERTIES OF SERIES

**Theorem.** Let  $S = \sum_{n=0}^{\infty} a_n$  and  $T = \sum_{n=0}^{\infty} b_n$  be two absolutely convergent series. Then

(1) their sum converges absolutely to the sum

$$S + T = \sum_{n=0}^{\infty} a_n + \sum_{n=0}^{\infty} b_n = \sum_{n=0}^{\infty} (a_n + b_n),$$

(2) their difference converges absolutely to the difference

$$S - T = \sum_{n=0}^{\infty} a_n - \sum_{n=0}^{\infty} b_n = \sum_{n=0}^{\infty} (a_n - b_n),$$

(3) their product converges absolutely to the product

$$S \cdot T = \left( \sum_{n=0}^{\infty} a_n \right) \cdot \left( \sum_{n=0}^{\infty} b_n \right) = \sum_{n=0}^{\infty} \left( \sum_{k=0}^n a_{n-k} b_k \right),$$

(4) the value  $S$  of the sum does not depend on any rearrangement of the series, i.e.,  $\sum_{n=0}^{\infty} a_{\sigma(n)} = S$  for any permutation  $\sigma : \mathbb{N} \rightarrow \mathbb{N}$  of integers.

**PROOF.** Both the first and the second statements are a straightforward consequence of the corresponding properties of limits. The third statement is not so simple. Write

$$c_n = \sum_{k=0}^n a_{n-k} b_k.$$

From the assumptions and from the rule for the limit of a product,

$$\left( \sum_{n=0}^k a_n \right) \cdot \left( \sum_{n=0}^k b_n \right) \rightarrow \left( \sum_{n=0}^{\infty} a_n \right) \cdot \left( \sum_{n=0}^{\infty} b_n \right).$$

Thus it suffices to prove that

$$0 = \lim_{k \rightarrow \infty} \left( \left( \sum_{n=0}^k a_n \right) \cdot \left( \sum_{n=0}^k b_n \right) - \sum_{n=0}^k c_n \right).$$

Consider the expressions

$$\begin{aligned} \left( \sum_{n=0}^k a_n \right) \cdot \left( \sum_{n=0}^k b_n \right) &= \sum_{0 \leq i, j \leq k} a_i b_j, \\ c_n &= \sum_{\substack{i+j=n \\ 0 \leq i, j \leq k}} a_i b_j, \quad \sum_{n=0}^k c_n = \sum_{\substack{i+j \leq k \\ 0 \leq i, j \leq k}} a_i b_j. \end{aligned}$$

along with the bound

$$\begin{aligned} \left| \left( \sum_{n=0}^k a_n \right) \cdot \left( \sum_{n=0}^k b_n \right) - \sum_{n=0}^k c_n \right| &= \left| \sum_{\substack{i+j > k \\ 0 \leq i, j \leq k}} a_i b_j \right| \\ &\leq \sum_{\substack{i+j > k \\ 0 \leq i, j \leq k}} |a_i b_j|. \end{aligned}$$

If the sum of the indices is to be larger than  $k$ , then at least one of them must be larger than  $k/2$ . The expression does not decrease if more terms are added into it. Take all as in

it suffices to calculate the limits given in the argument of the exponential function. By l'Hospital's rule and simple rearrangements, we get

$$\begin{aligned} \lim_{x \rightarrow 0^+} \frac{\ln(\cot x)}{\ln x} & \left[ \text{type } \frac{+\infty}{-\infty} \right] = \lim_{x \rightarrow 0^+} \frac{\frac{1}{\cot x} \cdot \frac{-1}{\sin^2 x}}{\frac{1}{x}} \\ & = \lim_{x \rightarrow 0^+} \frac{-x}{\cos x \cdot \sin x} \left[ \text{type } \frac{0}{0} \right] = \lim_{x \rightarrow 0^+} \frac{-1}{\cos^2 x - \sin^2 x} \\ & = \frac{-1}{1-0} = -1; \end{aligned}$$

$$\begin{aligned} \lim_{x \rightarrow 0} \frac{\ln \frac{\sin x}{x}}{x^2} & \left[ \text{type } \frac{0}{0} \right] = \lim_{x \rightarrow 0} \frac{\frac{x}{\sin x} \cdot \frac{x \cos x - \sin x}{x^2}}{2x} \\ & = \lim_{x \rightarrow 0} \frac{x \cos x - \sin x}{2x^2 \sin x} \left[ \text{type } \frac{0}{0} \right] \\ & = \lim_{x \rightarrow 0} \frac{\cos x - x \sin x - \cos x}{4x \sin x + 2x^2 \cos x} \\ & = \lim_{x \rightarrow 0} \frac{-\sin x}{4 \sin x + 2x \cos x} \left[ \text{type } \frac{0}{0} \right] \\ & = \lim_{x \rightarrow 0} \frac{-\cos x}{4 \cos x + 2 \cos x - 2x \sin x} = \frac{-1}{4+2-0} = -\frac{1}{6}, \end{aligned}$$

hence

$$\begin{aligned} \lim_{x \rightarrow 0^+} (\cot x)^{\frac{1}{\ln x}} & = e^{-1} = \frac{1}{e}; \\ \lim_{x \rightarrow 0} \left( \frac{\sin x}{x} \right)^{\frac{1}{x^2}} & = e^{-\frac{1}{6}} = \frac{1}{\sqrt[6]{e}}. \end{aligned}$$

We can proceed similarly when determining the last limit. We have that

$$\begin{aligned} \lim_{x \rightarrow 1^-} (\ln x) \cdot \ln \left( \cos \frac{\pi x}{2} \right) & \\ & = \lim_{x \rightarrow 1^-} \frac{\ln \left( \cos \frac{\pi x}{2} \right)}{\frac{1}{\ln x}} = \left[ \text{type } \frac{-\infty}{-\infty} = \frac{\infty}{\infty} \right] \\ & = \lim_{x \rightarrow 1^-} \frac{\frac{1}{\cos \frac{\pi x}{2}} \left( -\sin \frac{\pi x}{2} \right) \frac{\pi}{2}}{-\frac{1}{\ln^2 x} \cdot \frac{1}{x}} \\ & = \frac{\pi}{2} \lim_{x \rightarrow 1^-} \frac{x \sin \frac{\pi x}{2} \cdot \ln^2 x}{\cos \frac{\pi x}{2}}. \end{aligned}$$

Since this form is of the type 0/0, we could continue by using l'Hospital's rule; instead, we will go from

$$\lim_{x \rightarrow 1^-} \frac{x \sin \frac{\pi x}{2} \cdot \ln^2 x}{\cos \frac{\pi x}{2}}$$

over to the product of limits

$$\lim_{x \rightarrow 1^-} \left( x \sin \frac{\pi x}{2} \right) \cdot \lim_{x \rightarrow 1^-} \frac{\ln^2 x}{\cos \frac{\pi x}{2}} = 1 \cdot \lim_{x \rightarrow 1^-} \frac{\ln^2 x}{\cos \frac{\pi x}{2}}.$$

Only now we apply l'Hospital's rule for

$$\lim_{x \rightarrow 1^-} \frac{\ln^2 x}{\cos \frac{\pi x}{2}} = \left[ \text{type } \frac{0}{0} \right] = \lim_{x \rightarrow 1^-} \frac{2 \ln x \cdot \frac{1}{x}}{\left( -\frac{\pi}{2} \right) \sin \frac{\pi x}{2}} = \frac{0}{-\frac{\pi}{2}} = 0.$$

the product and remove only those whose indices are both at most  $k/2$ .

$$\sum_{\substack{i+j>k \\ 0 \leq i, j \leq k}} |a_i b_j| \leq \sum_{0 \leq i, j \leq k} |a_i b_j| - \sum_{0 \leq i, j \leq k/2} |a_i b_j|.$$

However, both the expressions of the difference are the partial sums for the product  $S \cdot T$ . Therefore, they share the same limit and their difference goes to zero.

The last claim seems to be a little tricky. Notice, for each small  $\varepsilon > 0$  we can find a common bound  $\alpha$  such that for all  $N > \alpha$  both estimates are true:

$$\sum_{n=N}^{\infty} |a_n| < \varepsilon, \quad \left| \sum_{n=0}^N a_n - S \right| < \varepsilon.$$

Now, consider any permutation  $\sigma$  of the indices and write  $I_\sigma = \{\sigma^{-1}(0), \dots, \sigma^{-1}(\alpha)\}$ . Then, for each  $N > \max I_\sigma$  clearly

$$\begin{aligned} \left| \sum_{n=0}^N a_{\sigma(n)} - S \right| & = \left| \sum_{n \in I_\sigma} a_{\sigma(n)} - S + \sum_{n \notin I_\sigma} a_{\sigma(n)} \right| \\ & \leq \left| \sum_{n=0}^{\alpha} a_n - S \right| + \sum_{n \notin I_\sigma} |a_{\sigma(n)}| \end{aligned}$$

Next, notice that  $n \notin I_\sigma$  means  $\sigma(n) > \alpha$ . Thus, the latter term is at most equal to  $\sum_{\alpha+1}^{\infty} a_n$  and thus the entire expression is bounded by  $2\varepsilon$ . This shows that the rearranged series converges to the same value  $S$  again.  $\square$

**5.4.5. Simple tests.** The following theorem collects some useful conditions for deciding on the convergence of series.

Altogether, we have

$$\lim_{x \rightarrow 1^-} \left( \ln x \cdot \ln \left( \cos \frac{\pi x}{2} \right) \right) = \frac{\pi}{2} \cdot 1 \cdot 0 = 0,$$

i. e.

$$\lim_{x \rightarrow 1^-} \left( \cos \frac{\pi x}{2} \right)^{\ln x} = e^0 = 1. \quad \square$$

**5.G.2.** As we have implicitly mentioned, using l'Hospital's rule can lead to a non-existing limit even though the original limit exists: Determine the limit

$$\lim_{x \rightarrow \infty} \frac{x + \sin x}{x}$$

**Solution.** The limit is of the type  $\frac{\infty}{\infty}$ , by l'Hospital's rule, we get that

$$\lim_{x \rightarrow \infty} \frac{x + \sin x}{x} = \lim_{x \rightarrow \infty} \frac{1 + \cos x}{1},$$

and since the limit  $\lim_{x \rightarrow \infty} \cos x$  does not exist, nor does the limit  $\lim_{x \rightarrow \infty} 1 + \cos x$ . However, the original limit exists because

$$\frac{x-1}{x} \leq \frac{x + \sin x}{x} \leq \frac{x+1}{x},$$

and by the squeeze theorem,

$$1 = \lim_{x \rightarrow \infty} \frac{x-1}{x} \leq \lim_{x \rightarrow \infty} \frac{x + \sin x}{x} \leq \lim_{x \rightarrow \infty} \frac{x+1}{x} = 1. \quad \square$$

**5.G.3.** Determine

$$\lim_{x \rightarrow +\infty} \frac{\ln x}{x}, \quad \lim_{x \rightarrow 0^+} x \ln \frac{1}{x}, \quad \lim_{x \rightarrow 0^+} x e^{\frac{1}{x}},$$

$$\lim_{x \rightarrow 0^-} x e^{-\frac{1}{x}}, \quad \lim_{x \rightarrow 0} \frac{e^{-\frac{1}{x^2}}}{x^{100}}, \quad \lim_{x \rightarrow +\infty} (\ln x - x),$$

$$\lim_{x \rightarrow +\infty} \frac{x}{x + \ln x \cdot \cos x}, \quad \lim_{x \rightarrow +\infty} \frac{\sqrt[3]{x+1}}{\sqrt[5]{x+3}}, \quad \lim_{x \rightarrow +\infty} \frac{x}{\sqrt{x^2+1}}.$$

**Solution.** It can easily be shown (for instance, by  $n$ -fold use of l'Hospital's rule) that for any  $n \in \mathbb{N}$ , it holds that

$$\lim_{x \rightarrow +\infty} \frac{x^n}{e^x} = 0, \quad \text{i. e.} \quad \lim_{x \rightarrow +\infty} \frac{e^x}{x^n} = +\infty.$$

The squeeze theorem implies the following generalization for real numbers  $a > 0$ :

$$\lim_{x \rightarrow +\infty} \frac{x^a}{e^x} = 0, \quad \text{i. e.} \quad \lim_{x \rightarrow +\infty} \frac{e^x}{x^a} = +\infty.$$

Taking into account that the graphs of the functions  $y = e^x$  and  $y = \ln x$  (the inverse function to  $y = e^x$ ) are symmetric with regard to the line  $y = x$ , we further see that

$$\lim_{x \rightarrow +\infty} \frac{\ln x}{x} = 0, \quad \text{i. e.} \quad \lim_{x \rightarrow +\infty} \frac{x}{\ln x} = +\infty.$$

CONVERGENCE TESTS

**Theorem.** Let  $S = \sum_{n=0}^{\infty} a_n$  be an infinite series of real or complex numbers. Let  $T = \sum_{n=0}^{\infty} b_n$  be another series with all  $b_n \geq 0$  real.

- (1) If the series  $S$  converges, then  $\lim_{n \rightarrow \infty} a_n = 0$ .
- (2) (The comparison test) If  $T$  converges and  $|a_n| < b_n$ , then  $S$  converges absolutely. If  $b_n < |a_n|$  and  $T$  diverges, then  $S$  does not converge absolutely.
- (3) (The limit comparison test). If both  $a_n$  and  $b_n$  are positive real numbers and the finite limit  $\lim_{n \rightarrow \infty} \frac{a_n}{b_n} = r > 0$  exists, then  $S$  converges if and only if  $T$  converges.
- (4) (The ratio test) Suppose that the limit of the quotients of adjacent terms of the series exists and

$$\lim_{n \rightarrow \infty} \left| \frac{a_{n+1}}{a_n} \right| = q.$$

Then the series  $S$  converges absolutely for  $|q| < 1$  and does not converge for  $|q| > 1$ . If  $|q| = 1$  the series may or may not converge.

- (5) (The root test) If the limit

$$\lim_{n \rightarrow \infty} \sqrt[n]{|a_n|} = q$$

exists, then the series converges absolutely for  $q < 1$ . It does not converge for  $q > 1$ . If  $q = 1$ , the series may or may not converge.

**PROOF.** (1) The existence and the potential value of the limit of a sequence of complex numbers is given by the limits of the real parts and the imaginary parts. Thus it suffices to prove the first proposition for sequences of real numbers. If  $\lim_{n \rightarrow \infty} a_n$  does not exist or is non-zero, then for a sufficiently small number  $\varepsilon > 0$ , there are infinitely many terms  $a_k$  with  $|a_k| > \varepsilon$ . There are either infinitely many positive terms or infinitely many negative terms among them. But then, adding any one of them into the partial sum, the difference of the adjacent terms  $s_n$  and  $s_{n+1}$  is at least  $\varepsilon$ . Thus the sequence of partial sums cannot be a Cauchy sequence and, therefore, it cannot be convergent.

(2) The result is a straightforward consequence of the squeeze theorem, cf. 5.2.12.

(3) Since limit  $r = \lim_{n \rightarrow \infty} \frac{a_n}{b_n}$  exists, for any given  $\varepsilon > 0$  and sufficiently big  $n > N_\varepsilon$ ,

$$(r - \varepsilon)b_n < a_n < (r + \varepsilon)b_n.$$

Thus, after choosing  $\varepsilon < r$  it follows that  $a_n < (r + \varepsilon)b_n$  and  $b_n < \frac{1}{r - \varepsilon}a_n$ . The result follows from the previous claim (2).

(4) To prove absolute convergence, it can be assumed that the terms of the series are real numbers  $a_n > 0$ . Suppose  $q < r < 1$  for a real number  $r$ . From the existence of the limit of the quotients, for every  $j$  greater than a sufficiently large  $N$ ,

$$a_{j+1} < r \cdot a_j \leq r^{(j-N+1)} a_N,$$

Thus we have obtained the first result. That could also be derived from l'Hospital's rule because

$$\lim_{x \rightarrow +\infty} \frac{\ln x}{x} = \lim_{x \rightarrow +\infty} \frac{\frac{1}{x}}{1} = \lim_{x \rightarrow +\infty} \frac{1}{x} = 0.$$

Let us point out that l'Hospital's rule can be used to calculate all of the following five limits. However, it is possible to determine these limits by much simpler means. For instance, the substitution  $y = 1/x$  leads to

$$\begin{aligned} \lim_{x \rightarrow 0^+} x \ln \frac{1}{x} &= \lim_{y \rightarrow +\infty} \frac{\ln y}{y} = 0; \\ \lim_{x \rightarrow 0^+} x e^{\frac{1}{x}} &= \lim_{y \rightarrow +\infty} \frac{e^y}{y} = +\infty. \end{aligned}$$

Of course,  $x \rightarrow 0^+$  gives  $y = 1/x \rightarrow +\infty$  (we write  $1/0^+ = +\infty$ ).

By the substitutions  $u = -1/x$ ,  $v = 1/x^2$  we get that, respectively,

$$\begin{aligned} \lim_{x \rightarrow 0^-} x e^{-\frac{1}{x}} &= \lim_{u \rightarrow +\infty} -\frac{e^u}{u} = -\infty; \\ \lim_{x \rightarrow 0} \frac{e^{-\frac{1}{x^2}}}{x^{100}} &= \lim_{v \rightarrow +\infty} \frac{v^{50}}{e^v} = 0, \end{aligned}$$

where  $x \rightarrow 0^-$  corresponds to  $u = -1/x \rightarrow +\infty$  (we write  $-1/0^- = +\infty$ ) and then  $x \rightarrow 0$  to  $v = 1/x^2 \rightarrow +\infty$  (again  $1/0^+ = +\infty$ ). We have also clarified that

$$\lim_{x \rightarrow +\infty} (\ln x - x) = \lim_{x \rightarrow +\infty} -x = -\infty.$$

Potential doubts can be scattered by the limit

$$\lim_{x \rightarrow +\infty} \frac{\ln x - x}{\ln x} = \lim_{x \rightarrow +\infty} \left(1 - \frac{x}{\ln x}\right) = -\infty,$$

which proves that even when decreasing the absolute value of the considered expression (without changing the sign), the absolute value of the expression remains unbounded.

We can equally easily determine

$$\begin{aligned} \lim_{x \rightarrow +\infty} \frac{x}{x + \ln x \cdot \cos x} &= \lim_{x \rightarrow +\infty} \frac{x}{x} = 1; \\ \lim_{x \rightarrow +\infty} \frac{\sqrt[3]{x+1}}{\sqrt[5]{x+3}} &= \lim_{x \rightarrow +\infty} \frac{\sqrt[3]{x}}{\sqrt[5]{x}} = +\infty; \\ \lim_{x \rightarrow +\infty} \frac{x}{\sqrt{x^2+1}} &= \lim_{x \rightarrow +\infty} \frac{x}{\sqrt{x^2}} = 1. \end{aligned}$$

We have seen that the l'Hospital's rule may not be the best method for calculating limits of types  $0/0$ ,  $\infty/\infty$ . The three preceding exercises illustrate that it even cannot be applied in all cases (for indeterminate forms). If we had applied it to the first problem, we would have obtained, for  $x > 0$ , the quotient

$$\frac{1}{1 + \frac{\cos x}{x} - \ln x \cdot \sin x} = \frac{x}{x + \cos x - x \ln x \cdot \sin x},$$

where the last equality follows from the general equality  $(1-r)(1+r^2+\dots+r^k) = 1-r^{k+1}$ . But this means that the partial sums  $s_n$  are, for large  $n > N$ , bounded from above by the sums

$$s_n < \sum_{j=0}^N a_j + a_N \sum_{j=0}^{n-N} r^j = \sum_{j=0}^N a_j + a_N \frac{1-r^{n-N+1}}{1-r}.$$

Since  $0 < r < 1$ , the set of all partial sums is an increasing sequence bounded from above, and thus its limit equals to its supremum.

In the case  $q > r > 1$ , a similar technique can be used. However, this time, from the existence of the limit of the quotients,

$$a_{j+1} > r \cdot a_j \geq r^{(j-N+1)} a_N > 0.$$

This implies that the absolute values of the particular terms of the series do not converge to zero, and thus the series cannot be convergent, by the already proved part (1) of the theorem.

(5) The proof is similar to the previous case. From the existence of the limit  $q < 1$ , it follows that for any  $r$ ,  $q < r < 1$ , there is an  $N$  such that for all  $n > N$ ,  $\sqrt[n]{|a_n|} < r$  holds. Exponentiation then gives  $|a_n| < r^n$ , there is a comparison with a geometric series. Thus the proof can be finished in the same way as in the case of the ratio test.  $\square$

In the proofs of the last two statements of the theorem, a much weaker assumption is used than the existence of the limit. It is only necessary to know that the examined sequences of non-negative terms are, from a given index on, either all larger or all less than a given number.

For this purpose however, it suffices to consider, for a given sequence of terms  $b_n$ , the supremum of the terms with index higher than  $n$ . These suprema always exist and create a non-increasing sequence. Its infimum is then called *upper limit* of the sequence and denoted by

$$\limsup_{n \rightarrow \infty} b_n.$$

The advantage is that the upper limit always exists. Therefore, we can reformulate the previous result (without having to change the proof) in a stronger form:

**Corollary.** Let  $S = \sum_{n=0}^{\infty} a_n$  be an infinite series of real or complex numbers.

(1) If

$$q = \limsup_{n \rightarrow \infty} \left| \frac{a_{n+1}}{a_n} \right|,$$

then the series  $S$  converges absolutely for  $q < 1$  and does not converge for  $q > 1$ . For  $q = 1$ , it may or may not converge.

(2) If

$$q = \limsup_{n \rightarrow \infty} \sqrt[n]{|a_n|},$$

the series converges absolutely for  $q < 1$  while it does not converge for  $q > 1$ . For  $q = 1$ , it may or may not converge.

which is more complicated than the original one. The limit for  $x \rightarrow +\infty$  does not even exist, so one of the prerequisites of l'Hospital's rule is not satisfied. In the second case, any number of multiple uses of l'Hospital's rule leads to indeterminate forms. For the last problem, l'Hospital's rule sends us back to the original limit: first it gives the fraction

$$\frac{1}{\frac{2x}{2\sqrt{x^2+1}}} = \frac{\sqrt{x^2+1}}{x}$$

and then

$$\frac{\frac{2x}{2\sqrt{x^2+1}}}{1} = \frac{x}{\sqrt{x^2+1}}.$$

From here, we can deduce that the limit equals 1 (we are looking for a non-negative real number  $a \in \mathbb{R}$  such that  $a = a^{-1}$ ) only if we have already shown it exists at all.  $\square$

Other examples concerning calculation of limits by l'Hospital's rule can be found at page 355.

### H. Infinite series

Infinite series naturally appear in a series (of problems).

**5.H.1. Sierpiński carpet.** The unit square is divided into nine equal squares and the middle one is removed. Each of the eight remaining squares is again divided into nine equal subsquares and the middle subsquare (of each of the eight squares) is removed again. Having applied this procedure ad infinitum, determine the area of the resulting figure.

**Solution.** In the first step, a square having the area of  $1/9$  is removed. In the second steps, eight squares (each having the area of  $9^{-2}$ , i. e. totaling to  $8 \cdot 9^{-2}$ ) are removed. Every further iteration removes eight times more squares than in the previous steps, but the squares are nine times smaller. The sum of areas of all the removed squares is

$$\frac{1}{9} + \frac{8}{9^2} + \frac{8^2}{9^3} + \dots = \sum_{n=0}^{\infty} \frac{8^n}{9^{n+1}}.$$

The area of the remaining figure (known as Sierpiński carpet) thus equals

$$1 - \sum_{n=0}^{\infty} \frac{8^n}{9^{n+1}} = 1 - \frac{1}{9} \sum_{n=0}^{\infty} \left(\frac{8}{9}\right)^n = 1 - \frac{1}{9} \cdot \frac{1}{1-\frac{8}{9}} = 0.$$

$\square$

**5.H.2. Koch snowflake, 1904.** Create a "snowflake" by the following procedure: At the beginning, consider an equilateral triangle with sides of length 1. With each of its three sides, do the following: Cut it into three equally long parts, build another equilateral triangle above (i. e. pointing out

**5.4.6. Alternating series.** The condition  $a_n \rightarrow 0$  is a necessary but not sufficient condition for the convergence of the series  $\sum_{n=0}^{\infty} a_n$ . However, there is the *Leibniz criterion* of convergence.

#### LEIBNIZ CRITERION FOR ALTERNATING SERIES

The series  $\sum_{n=0}^{\infty} (-1)^n a_n$ , where  $a_n$  is a non-increasing sequence of non-negative real numbers, is called an *alternating series*.

**Theorem.** An alternating series converges if and only if  $\lim_{n \rightarrow \infty} a_n = 0$ . Its value  $a = \sum_{n=0}^{\infty} (-1)^n a_n$  differs from the partial sum  $s_{2k}$  by at most  $a_{2k+1}$ .

**PROOF.** By the definition the partial sums  $s_k$  of an alternating series satisfy

$$s_{2(k+1)+1} = s_{2k+1} + a_{2k+2} - a_{2k+3} \geq s_{2k+1}$$

$$s_{2(k+1)} = s_{2k} - a_{2k+1} + a_{2k+2} \leq s_{2k}$$

$$s_{2k+1} - s_{2k} = -a_{2k+1} \rightarrow 0$$

$$s_2 \geq s_{2k} \geq s_{2k+1} \geq s_1.$$

Thus, the even partial sums are a non-decreasing sequence, while the odd ones are non-increasing. The last line reveals that the bounded sequence of the odd partial sums converges to its supremum, while the even ones converge to the infimum. The previous line says they coincide, if and only if  $\lim_{n \rightarrow \infty} a_n = 0$  which proves the first claim.

At the same the limit value  $a$  of the series is always at most  $s_{2k+1}$  and at least  $s_{2k}$ . Thus, the latter partial sums cannot differ by more than  $a_{2k+1}$ .  $\square$

**Remark.** As obvious from the latter theorem, convergent alternating series are often not converging absolutely. This phenomenon is called *conditionally converging series*. Unlike the independence on the order in which we sum up the terms of an absolutely convergent series (cf. (4) of Theorem 5.4.4), there is the famous Riemann series theorem saying that conditionally convergent series can be brought to any finite or infinite value by appropriate rearrangement of the terms in the sum. We shall not go into the proof here.

**5.4.7. Convergence rate.** The proofs of the tests derived in the previous two paragraphs allow also for straightforward estimates of the speed of the convergence. Indeed, both the tests for the absolute convergence are based on the comparison with the geometric series either for  $q = \limsup_{n \rightarrow \infty} \left| \frac{a_{n+1}}{a_n} \right|$  or  $q = \limsup_{n \rightarrow \infty} \sqrt[n]{|a_n|}$ , and  $0 < q < 1$ . In the estimate of the error of approximation of the limit  $s_{\infty}$  by the  $n$ -th partial sum  $s_n$

$$|s_{\infty} - s_n| < |a_n| \sum_{j=0}^{\infty} r^j = |a_n| r^{n-N} \frac{1}{1-r} = Cr^n$$

where  $N$  and  $q < r < 1$  are the two related choices from the proof of the test and  $C$  is the resulting constant non dependent of  $n$ . Thus the convergence rate is quite fast, in particular if

from, not into, the original triangle) the middle part and remove the middle part. This transforms the original equilateral triangle into a six-pointed star. Once again, repeat this step ad infinitum, thus obtaining the desired snowflake. Prove that the created figure has infinite perimeter. Then determine its area.

**Solution.** The perimeter of the original triangle is equal to 3. In each step, the perimeter increases by one third since three parts of every line segment are replaced with four equally long ones. Hence it follows that the snowflake's perimeter can be expressed as the limit

$$d_n = 3 \left(\frac{4}{3}\right)^n \quad \text{and} \quad \lim_{n \rightarrow \infty} d_n = +\infty.$$

The figure's area is apparently increasing during the construction. To determine it, it thus suffices to catch the rise between two consecutive steps. The number of the figure's sides is four times higher every step (the line segments are divided into thirds and one of them is doubled) and the new sides are three times shorter. The figure's area thus grows exactly by the equilateral triangles glued to each side (so there is the same number of them as of the sides). In the first iteration (when creating the six-pointed star from the original triangle), the area grows by the three equilateral triangles with sides of length  $1/3$  (one third of the original sides' length). Let us denote the area of the original equilateral triangle by  $S_0$ . If we realize that shortening an equilateral triangle's sides three times makes its area decrease nine times, we get

$$S_0 + 3 \cdot \frac{S_0}{9}.$$

for the area of the six-pointed star. Similarly, in the next step we obtain the area of the figure as

$$S_0 + 3 \cdot \frac{S_0}{9} + 4 \cdot 3 \cdot \frac{S_0}{9^2}.$$

Now it is easy to deduce that the area of the resulting snowflake equals the limit

$$\begin{aligned} \lim_{n \rightarrow \infty} \left( S_0 + 3 \cdot \frac{S_0}{9} + 4 \cdot 3 \cdot \frac{S_0}{9^2} + \dots + 4^n \cdot 3 \cdot \frac{S_0}{9^{n+1}} \right) &= \\ S_0 \lim_{n \rightarrow \infty} \left( 1 + \frac{1}{3} + \frac{1}{3} \cdot \frac{4}{9} + \dots + \frac{1}{3} \cdot \left(\frac{4}{9}\right)^n \right) &= \\ S_0 \left[ 1 + \frac{1}{3} \lim_{n \rightarrow \infty} \left( 1 + \frac{4}{9} + \dots + \left(\frac{4}{9}\right)^n \right) \right] &= \\ S_0 \left[ 1 + \frac{1}{3} \lim_{n \rightarrow \infty} \sum_{k=0}^n \left(\frac{4}{9}\right)^k \right] = S_0 \left[ 1 + \frac{1}{3} \sum_{k=0}^{\infty} \left(\frac{4}{9}\right)^k \right] &= \\ S_0 \left[ 1 + \frac{1}{3} \cdot \frac{1}{1-\frac{4}{9}} \right] = \frac{8}{5} S_0. \end{aligned}$$

The snowflake's area is thus equal to  $8/5$  of the area of the original triangle, i. e.

$$\frac{8}{5} S_0 = \frac{8}{5} \cdot \frac{\sqrt{3}}{4} = \frac{2\sqrt{3}}{5}.$$

$k$  is much smaller than 1 (and we can get  $k$  as close to  $q$  as necessary).

On the other hand, the proof of the alternating series test shows that the convergence rate is at least as fast as the convergence of the terms  $a_n$ .

**5.4.8. Power series.** If we consider not a sequence of numbers  $a_n$ , but rather a sequence of functions  $f_n(x)$  sharing the same domain  $A$ , we can use the definition of addition of series "point-wise", thereby obtaining the concept of the *series of functions*

$$S(x) = \sum_{n=0}^{\infty} f_n(x).$$

POWER SERIES

A *power series* is a series of functions given by the expression

$$S(x) = \sum_{n=0}^{\infty} a_n x^n$$

with coefficients  $a_n \in \mathbb{C}$ ,  $n = 0, 1, \dots$

$S(x)$  has the *radius of convergence*  $\rho \geq 0$  if and only if  $S(x)$  converges for every  $x$  satisfying  $|x| < \rho$  and does not converge for  $|x| > \rho$ .

**5.4.9. Properties of power series.** Although a significant part of the proof of the following theorem is postponed until the end of the following chapter, formulation of the basic properties of the power series can be considered now. Notice that the upper limit  $r = \limsup_{n \rightarrow \infty} \sqrt[n]{|a_n|}$  equals the limit  $\lim_{n \rightarrow \infty} \sqrt[n]{|a_n|}$ , whenever this limit exists.

Actually, we should also notice that our argument on the convergence of power series works exactly the same way for complex values of  $z$  and even now, the reader may enjoy a direct simple proof of all the claimed properties in the complex setting in 9.4.2 on page 677 in Chapter 9.

CONVERGENCE AND DIFFERENTIATION

**Theorem.** Let  $S(x) = \sum_{n=0}^{\infty} a_n x^n$  be a power series and let

$$r = \limsup_{n \rightarrow \infty} \sqrt[n]{|a_n|}.$$

Then the radius of convergence of the series  $S$  is  $\rho = r^{-1}$ .

The power series  $S(x)$  converges absolutely on the whole interval of convergence and is continuous on it (including the boundary points, supposing it is convergent there). Moreover, the derivative exists on this interval, and

$$S'(x) = \sum_{n=1}^{\infty} n a_n x^{n-1}.$$

**PROOF.** To verify the absolute convergence of the series, use the root test from theorem 5.4.5(3), for every value of  $x$ .

Let us notice that this snowflake is an example of an infinitely long curve which encloses a finite area.  $\square$

**5.H.3.** Show that the so-called *harmonic series*

$$\sum_{n=1}^{\infty} \frac{1}{n}$$

diverges.

**Solution.** For any natural number  $k$ , the sum of the first  $2^k$  terms of this series is greater than  $k/2$ :

$$\underbrace{1 + \frac{1}{2}}_{> \frac{1}{2}} + \underbrace{\frac{1}{3} + \frac{1}{4}}_{> \frac{1}{4} + \frac{1}{4} = \frac{1}{2}} + \underbrace{\frac{1}{5} + \frac{1}{6} + \frac{1}{7} + \frac{1}{8}}_{> \frac{1}{8} + \frac{1}{8} + \frac{1}{8} + \frac{1}{8} = \frac{1}{2}} + \dots$$

as the sum of the terms from  $2^l + 1$  to  $2^{l+1}$  is always greater than  $2^l$ -times (its number)  $1/2^l$  (the least one of them), which sums to  $1/2$ .  $\square$

**5.H.4.** Determine whether the following series converge, or diverge:

- i)  $\sum_{n=1}^{\infty} \frac{2^n}{n}$
- ii)  $\sum_{n=1}^{\infty} \frac{1}{\sqrt{n}}$
- iii)  $\sum_{n=1}^{\infty} \frac{1}{n \cdot 2^{100000n}}$
- iv)  $\sum_{n=1}^{\infty} \frac{1}{(1+i)^n}$

**Solution.**

i) We will examine the convergence by the ratio test:

$$\lim_{n \rightarrow \infty} \left| \frac{a_{n+1}}{a_n} \right| = \lim_{n \rightarrow \infty} \left| \frac{\frac{2^{n+1}}{n+1}}{\frac{2^n}{n}} \right| = \lim_{n \rightarrow \infty} \frac{2(n+1)}{n} = 2 > 1,$$

so the series diverges.

ii) We will bound the series from below: we know that  $\frac{1}{n} \leq \frac{1}{\sqrt{n}}$  for any natural number  $n$ . Thus the sequence of the partial sums  $s_n$  of the examined series and the sequence of the partial sums  $s'_n$  of the harmonic series satisfy:

$$s_n = \sum_{i=1}^n \frac{1}{\sqrt{i}} \geq \sum_{i=1}^n \frac{1}{i} = s'_n.$$

Since the harmonic series diverges (see the previous exercise), by definition, the sequence of its partial sums  $\{s'_n\}_{n=1}^{\infty}$  diverges as well. Therefore the sequence of its partial sums  $\{s_n\}_{n=1}^{\infty}$  also diverges and so does the examined sequence.

iii) This series is divergent since it is a multiple of the harmonic series.

Calculate (if the limit exists)

$$\lim_{n \rightarrow \infty} \sqrt[n]{|a_n x^n|} = r|x|.$$

Either the series converges absolutely, or it does not converge if this limit is different from 1. It follows that it converges for  $|x| < \rho$  and diverges for  $|x| > \rho$ . If the limit does not exist, use the upper limit in the same way.

The statements about continuity and the derivatives are proved later in a more general context, see 6.3.7–6.3.9.  $\square$

**5.4.10. Remarks.** If the coefficients of the series increase rapidly enough, (for example  $a_n = n^n$ ), then  $r = \infty$ . Then the radius of convergence is zero, and the series converges only at  $x = 0$ .

Here are some examples of convergence of power series (including the boundary points of the corresponding interval): Consider

$$S(x) = \sum_{n=0}^{\infty} x^n, \quad T(x) = \sum_{n=1}^{\infty} \frac{1}{n} x^n.$$

The former example is the *geometric series*, which is already discussed. Its sum is, for every  $x$ ,  $|x| < 1$ ,

$$S(x) = \frac{1}{1-x},$$

while  $|x| > 1$  guarantees that the series diverges. For  $x = 1$ , we obtain the series  $1 + 1 + 1 + \dots$ , which is divergent. For  $x = -1$ , the series is  $1 - 1 + 1 - \dots$ , whose partial sums do not have a limit. The series oscillates.

Theorem 5.4.5(2) shows that the radius of convergence of the series  $T(x)$  is 1 because

$$\lim_{n \rightarrow \infty} \left| \frac{\frac{1}{n+1} x^{n+1}}{\frac{1}{n} x^n} \right| = |x| \lim_{n \rightarrow \infty} \left| \frac{n}{n+1} \right| = |x|.$$

For  $x = 1$ , the series  $1 + \frac{1}{2} + \frac{1}{3} + \dots$ , is divergent: By summing up the  $2^{k-1}$  adjacent terms  $1/2^{k-1}, \dots, 1/(2^k - 1)$  and replacing each of them by  $2^{-k}$  (thus they total up to  $1/2$ ), the partial sums are bounded from below by the sum of these  $1/2$ 's. Since the bound from below diverges to infinity, so does the original series.

On the other hand, the series  $T(-1) = -1 + \frac{1}{2} - \frac{1}{3} + \dots$  converges although of course, it cannot converge absolutely. Of course, this is true since we deal here with an alternating series.

Notice that the convergence of a power series is relatively fast near  $x = 0$ . It is slower near the boundary of the convergence interval.

**5.4.11. Trigonometric functions.** Another important observation is that a power series is a series of numbers for each fixed  $x$  and the individual terms make sense for complex numbers  $x \in \mathbb{C}$ . Thus the domain of convergence of a power series is always a disc in the complex plane  $\mathbb{C}$  centered at the origin.

iv) The examined series is geometric, with common ratio  $\frac{1}{1+i}$ . Such a sequence is convergent if and only if the absolute value of the common ratio is less than one. We know that

$$\left| \frac{1}{1+i} \right| = \left| \frac{1-i}{2} \right| = \left| \frac{1}{2} - \frac{1}{2}i \right| = \sqrt{\frac{1}{4} + \frac{1}{4}} = \frac{\sqrt{2}}{2} < 1,$$

hence the series converges, and we are even able to calculate it:

$$\sum_{n=1}^{\infty} \frac{1}{(1+i)^n} = \frac{1}{1 - \frac{1}{1+i}} = \frac{1+i}{i} = 1-i.$$

□

**5.H.5.** Calculate the series

- (a)  $\sum_{n=1}^{\infty} \left( \frac{1}{\sqrt{n}} - \frac{1}{\sqrt{n+1}} \right)$ ;
- (b)  $\sum_{n=0}^{\infty} \frac{5}{3^n}$ ;
- (c)  $\sum_{n=1}^{\infty} \left( \frac{3}{4^{2n-1}} + \frac{2}{4^{2n}} \right)$ ;
- (d)  $\sum_{n=1}^{\infty} \frac{n}{3^n}$ ;
- (e)  $\sum_{n=0}^{\infty} \frac{1}{(3n+1)(3n+4)}$ .

**Solution.** The case (a). From the definition, the series is equal to

$$\begin{aligned} \sum_{n=1}^{\infty} \left( \frac{1}{\sqrt{n}} - \frac{1}{\sqrt{n+1}} \right) &= \\ \lim_{n \rightarrow \infty} \left( \left( \frac{1}{\sqrt{1}} - \frac{1}{\sqrt{2}} \right) + \left( \frac{1}{\sqrt{2}} - \frac{1}{\sqrt{3}} \right) + \dots + \left( \frac{1}{\sqrt{n}} - \frac{1}{\sqrt{n+1}} \right) \right) &= \\ \lim_{n \rightarrow \infty} \left( 1 + \left( -\frac{1}{\sqrt{2}} + \frac{1}{\sqrt{2}} \right) + \dots + \left( -\frac{1}{\sqrt{n}} + \frac{1}{\sqrt{n}} \right) - \frac{1}{\sqrt{n+1}} \right) &= 1. \end{aligned}$$

The case (b). Apparently, this sequence is a quintuple of the standard geometric series with the common ratio  $q = 1/3$ , hence

$$\sum_{n=0}^{\infty} \frac{5}{3^n} = 5 \sum_{n=0}^{\infty} \left( \frac{1}{3} \right)^n = 5 \cdot \frac{1}{1 - \frac{1}{3}} = \frac{15}{2}.$$

The case (c). We have that (with the substitution  $m = n - 1$ )

$$\begin{aligned} \sum_{n=1}^{\infty} \left( \frac{3}{4^{2n-1}} + \frac{2}{4^{2n}} \right) &= \frac{3}{4} \sum_{n=1}^{\infty} \left( \frac{1}{4^{2n-2}} \right) + \frac{2}{16} \sum_{n=1}^{\infty} \left( \frac{1}{4^{2n-2}} \right) = \\ \left( \frac{3}{4} + \frac{2}{16} \right) \sum_{m=0}^{\infty} \frac{1}{4^{2m}} &= \frac{14}{16} \sum_{m=0}^{\infty} \left( \frac{1}{16} \right)^m = \frac{14}{16} \cdot \frac{1}{1 - \frac{1}{16}} = \frac{14}{15}. \end{aligned}$$

The series of linear combinations was expressed as a linear combination of series (to be more precise, as a sum of series with factoring out the constants), which is a valid modification supposing the obtained series are absolutely convergent.

The case (d). From the partial sum

$$s_n = \frac{1}{3} + \frac{2}{3^2} + \frac{3}{3^3} + \dots + \frac{n}{3^n}, \quad n \in \mathbb{N},$$

we immediately get that

More generally, we can write power functions centered at an arbitrary (complex) point  $x_0$ ,

$$S(x) = \sum_{n=0}^{\infty} a_n (x - x_0)^n,$$

which converge absolutely again on the disc of radius  $\rho$ ,  $\rho^{-1} = \limsup_{n \rightarrow \infty} \sqrt[n]{|a_n|}$ , but this time centered at  $x_0$ .

Earlier we proved explicitly (by a simple application of the ratio test) that the exponential function series converges everywhere. Thus this defines a function for all complex numbers  $x$ .

Its values are the limits of values of (complex) polynomials with real coefficients and each polynomial is completely determined by finitely many of its values. In particular, the values of each series are completely determined on the complex domain by their values at the real input values  $x$ . Therefore, the complex exponential must also satisfy the usual formulae which we have already derived for the real values  $x$ . In particular,  $x \in \mathbb{C}$

$$e^{x+y} = e^x \cdot e^y,$$

see (2) and the theorem 5.4.4(3).

Substitute the values  $x = it$ , where  $i \in \mathbb{C}$  is the imaginary unit,  $t \in \mathbb{R}$  arbitrary.

$$e^{it} = 1 + it - \frac{1}{2}t^2 - i\frac{1}{3!}t^3 + \frac{1}{4!}t^4 + i\frac{1}{5!}t^5 - \dots$$

The conjugate number to  $z = e^{it}$  is the number  $\bar{z} = e^{-it}$ . Hence

$$|z|^2 = z \cdot \bar{z} = e^{it} \cdot e^{-it} = e^0 = 1.$$

All the values  $z = e^{it}$  lie on the unit circle centered at the origin, in the complex plane.

The real and imaginary parts of the points lying on the unit circle are named as the *trigonometric functions*  $\cos \theta$  and  $\sin \theta$ , where  $\theta$  is the corresponding angle.

Differentiating the parametric description of the points of the circle  $t \mapsto e^{it}$ , gives the vectors of “velocities” which are easily computed. Differentiating the real and imaginary parts separately (assuming that the real power series can be differentiated term by term) gives :

$$\begin{aligned} (e^{it})' &= \left( 1 - \frac{1}{2}t^2 + \frac{1}{4!}t^4 \dots \right)' + i \left( t - \frac{1}{3!}t^3 + \frac{1}{5!}t^5 \dots \right)' \\ &= -\left( t - \frac{1}{3!}t^3 + \frac{1}{5!}t^5 \dots \right) + i \left( 1 - \frac{1}{2}t^2 + \frac{1}{4!}t^4 \dots \right) \end{aligned}$$

which means  $(e^{it})' = i \cdot e^{it}$ . So the velocity vectors all have unit length. Hence the entire circle is parametrized if  $t$  is moved through the interval  $[0, 2\pi]$ , where  $2\pi$  stands for the

$$\frac{s_n}{3} = \frac{1}{3^2} + \frac{2}{3^3} + \cdots + \frac{n-1}{3^n} + \frac{n}{3^{n+1}}, \quad n \in \mathbb{N}.$$

Therefore,

$$s_n - \frac{s_n}{3} = \frac{1}{3} + \frac{1}{3^2} + \frac{1}{3^3} + \cdots + \frac{1}{3^n} - \frac{n}{3^{n+1}}, \quad n \in \mathbb{N}.$$

Since  $\lim_{n \rightarrow \infty} \frac{n}{3^{n+1}} = 0$ , we get that

$$\begin{aligned} \sum_{n=1}^{\infty} \frac{n}{3^n} &= \lim_{n \rightarrow \infty} \frac{3}{2} \left( s_n - \frac{s_n}{3} \right) = \frac{3}{2} \lim_{n \rightarrow \infty} \sum_{k=1}^n \frac{1}{3^k} = \\ &= \frac{3}{2} \sum_{k=1}^{\infty} \left( \frac{1}{3} \right)^k = \frac{3}{2} \left( \frac{1}{1-\frac{1}{3}} - 1 \right) = \frac{3}{4}. \end{aligned}$$

The case (e). It suffices to use the form (this is the so-called partial fraction decomposition)

$$\frac{1}{(3n+1)(3n+4)} = \frac{1}{3} \cdot \frac{1}{3n+1} - \frac{1}{3} \cdot \frac{1}{3n+4}, \quad n \in \mathbb{N} \cup \{0\},$$

which gives

$$\begin{aligned} \lim_{n \rightarrow \infty} \frac{1}{3} \left( 1 - \frac{1}{4} + \frac{1}{4} - \frac{1}{7} + \frac{1}{7} - \frac{1}{10} + \cdots + \frac{1}{3n+1} - \frac{1}{3n+4} \right) \\ = \lim_{n \rightarrow \infty} \frac{1}{3} \left( 1 - \frac{1}{3n+4} \right) = \frac{1}{3}. \end{aligned}$$

□

**5.H.6.** Verify that

$$\sum_{n=1}^{\infty} \frac{1}{n^2} < \sum_{n=0}^{\infty} \frac{1}{2^n}.$$

**Solution.** We can immediately see that

$$\begin{aligned} 1 &\leq 1, \quad \frac{1}{2^2} + \frac{1}{3^2} < 2 \cdot \frac{1}{2^2} = \frac{1}{2}, \\ \frac{1}{4^2} + \frac{1}{5^2} + \frac{1}{6^2} + \frac{1}{7^2} &< 4 \cdot \frac{1}{4^2} = \frac{1}{4}, \end{aligned}$$

or, in general:

$$\frac{1}{(2^n)^2} + \cdots + \frac{1}{(2^{n+1}-1)^2} < 2^n \cdot \frac{1}{(2^n)^2} = \frac{1}{2^n}, \quad n \in \mathbb{N}.$$

Hence (by comparing the terms of both of the series) we get the wanted inequality, from which, by the way, it follows that the series  $\sum_{n=1}^{\infty} \frac{1}{n^2}$  converges absolutely.

Eventually, let us specify that

$$\sum_{n=1}^{\infty} \frac{1}{n^2} = \frac{\pi^2}{6} < 2 = \sum_{n=0}^{\infty} \frac{1}{2^n}.$$

□

**5.H.7.** Examine convergence of the series

$$\sum_{n=1}^{\infty} \ln \frac{n+1}{n}.$$

**Solution.** Let us try to add up the terms of this series. We have that

$$\begin{aligned} \sum_{n=1}^{\infty} \ln \frac{n+1}{n} &= \lim_{n \rightarrow \infty} \left( \ln \frac{2}{1} + \ln \frac{3}{2} + \ln \frac{4}{3} + \cdots + \ln \frac{n+1}{n} \right) \\ &= \lim_{n \rightarrow \infty} \ln \frac{2 \cdot 3 \cdot 4 \cdots (n+1)}{1 \cdot 2 \cdot 3 \cdots n} = \lim_{n \rightarrow \infty} \ln(n+1) = +\infty. \end{aligned}$$

Thus the series diverges to  $+\infty$ .

□

length of the circle (a thorough definition of the length of a curve needs integral calculus, which we will develop in the next chapter). In particular, this procedure of parameterizing the circle can be used to define the *number*  $\pi$ , also called Archimedes' constant or the Ludolphian number,<sup>15</sup> half the length of the unit circle in the Euclidean plane  $\mathbb{R}^2$ . It can be found by computing the first positive zero point of the imaginary part of  $e^{it}$ .

For example, use the 10th order approximation  $\cos t \simeq 1 - (1/2)t^2 + (1/24)t^4 - (1/720)t^6 + (1/40320)t^8 - (1/3628800)t^{10}$ . Ask Maple to find the first positive root. The result is  $\pi \simeq 3.14159172323226$ , for which the first 5 decimal points are correct. Compare the result 3.184900868 from the approximation of order 4.

The explicit representation of trigonometric functions in terms of the power series is now apparent:

$$\begin{aligned} \cos t &= \operatorname{Re} e^{it} = 1 - \frac{1}{2}t^2 + \frac{1}{4!}t^4 - \frac{1}{6!}t^6 + \\ &\quad \cdots + (-1)^k \frac{1}{(2k)!}t^{2k} + \cdots \\ \sin t &= \operatorname{Im} e^{it} = t - \frac{1}{3!}t^3 + \frac{1}{5!}t^5 - \frac{1}{7!}t^7 + \\ &\quad \cdots + (-1)^k \frac{1}{(2k+1)!}t^{2k+1} + \cdots \end{aligned}$$

The following diagram illustrates the convergence of the series for the cosine function. It is the graph of the corresponding polynomial of degree 68. Drawing partial sums shows that the approximation near zero is very good. As the order increases, the approximation is better further away from the origin as well.

The well-known formula

$$e^{it} e^{-it} = \sin^2 t + \cos^2 t = 1$$

<sup>15</sup>This number describes the ratio of the circumference to the diameter of an (arbitrary) circle. It was known to the Babylonians and the Greeks in ancient times. The term Ludolphian number is derived from the name of German mathematician Ludolph van Ceulen of the 16th century, who produced 35 digits of the decimal expansion of the number, using the method of inscribed and circumscribed regular polygons, invented by Archimedes.

**5.H.8.** Prove that the series

$$\sum_{n=0}^{\infty} \operatorname{arctg} \frac{n^2+2n+3\sqrt{n}+4}{n+1}; \quad \sum_{n=1}^{\infty} \frac{3^n+1}{n^3+n^2-n}$$

do not converge.

**Solution.** Since

$$\lim_{n \rightarrow \infty} \operatorname{arctg} \frac{n^2+2n+3\sqrt{n}+4}{n+1} = \lim_{n \rightarrow \infty} \operatorname{arctg} \frac{n^2}{n} = \frac{\pi}{2}$$

and

$$\lim_{n \rightarrow \infty} \frac{3^n+1}{n^3+n^2-n} = \lim_{n \rightarrow \infty} \frac{3^n}{n^3} = +\infty,$$

the necessary condition  $\lim_{n \rightarrow \infty} a_n = 0$  for the series  $\sum_{n=n_0}^{\infty} a_n$  to converge does not hold in either case.  $\square$

**5.H.9.** What is the series

$$\sum_{n=2}^{\infty} \frac{1}{\sqrt[n]{\ln n}}?$$

**Solution.** From the inequalities (consider the graph of the natural logarithm)

$$1 \leq \ln n \leq n, \quad n \geq 3, \quad n \in \mathbb{N},$$

it follows that

$$\sqrt[n]{1} \leq \sqrt[n]{\ln n} \leq \sqrt[n]{n}, \quad n \geq 3, \quad n \in \mathbb{N}.$$

By the squeeze theorem,

$$\lim_{n \rightarrow \infty} \sqrt[n]{\ln n} = 1, \quad \text{i. e.} \quad \lim_{n \rightarrow \infty} \frac{1}{\sqrt[n]{\ln n}} = 1.$$

Thus the series does not converge. As its terms are non-negative, it must diverge to  $+\infty$ .  $\square$

**5.H.10.** Determine whether the series

- (a)  $\sum_{n=0}^{\infty} \frac{1}{(n+1) \cdot 3^n}$ ;
  - (b)  $\sum_{n=1}^{\infty} \frac{n^2+1}{n^3}$ ;
  - (c)  $\sum_{n=1}^{\infty} \frac{1}{n-\ln n}$
- converge.

**Solution.** All of the three enlisted series consist of non-negative terms only, so the series is either finite (i. e. converges), or diverges to  $+\infty$ . We have that

- (a)  $\sum_{n=0}^{\infty} \frac{1}{(n+1) \cdot 3^n} \leq \sum_{n=0}^{\infty} \left(\frac{1}{3}\right)^n = \frac{1}{1-\frac{1}{3}} < +\infty$ ;
- (b)  $\sum_{n=1}^{\infty} \frac{n^2+1}{n^3} \geq \sum_{n=1}^{\infty} \frac{n^2}{n^3} = \sum_{n=1}^{\infty} \frac{1}{n} = +\infty$ ;
- (c)  $\sum_{n=1}^{\infty} \frac{1}{n-\ln n} \geq \sum_{n=1}^{\infty} \frac{1}{n} = +\infty$ .

Hence it follows that the series (a) converges; (b) diverges to  $+\infty$ ; (c) diverges to  $+\infty$ .  $\square$

More interesting exercises concerning series can be found at page 356.

is immediate. From the derivative  $(e^{it})' = i e^{it}$  it follows that

$$(\sin t)' = \cos t, \quad (\cos t)' = -\sin t$$

by considering real and imaginary parts. Let  $t_0$  denote the smallest positive number for which  $e^{-it_0} = -e^{it_0}$ .  $t_0$  is the first positive zero point of the function  $\cos t$ . According to the definition of  $\pi$ ,  $t_0 = \frac{1}{2}\pi$ .

Squaring yields  $e^{i2t_0} = e^{-i2t_0} = (e^{-it_0})^2$ . So  $\pi$  is a zero point of the function  $\sin t$ . Of course, for any  $t$ ,

$$e^{i(4kt_0+t)} = (e^{it_0})^{4k} \cdot e^{it} = 1 \cdot e^{it}.$$

Therefore, both trigonometric functions  $\sin$  and  $\cos$  are *periodic*, with period  $2\pi$ . This is their prime period.

Now the usual formulae connecting the trigonometric functions are easily derived. For illustration, we introduce some of them. First, the definition says that

$$(1) \quad \cos t = \frac{1}{2}(e^{it} + e^{-it})$$

$$(2) \quad \sin t = \frac{1}{2i}(e^{it} - e^{-it}).$$

Thus the product of these functions can be expressed as

$$\begin{aligned} \sin t \cos t &= \frac{1}{4i}(e^{it} - e^{-it})(e^{it} + e^{-it}) \\ &= \frac{1}{4i}(e^{i2t} - e^{-i2t}) = \frac{1}{2} \sin 2t. \end{aligned}$$

Further, by utilizing our knowledge of derivatives:

$$\cos 2t = \left(\frac{1}{2} \sin 2t\right)' = (\sin t \cos t)' = \cos^2 t - \sin^2 t.$$

The properties of other trigonometric functions

$$\tan t = \frac{\sin t}{\cos t}, \quad \cot t = (\tan t)^{-1}$$

can easily be derived from their definitions and the formulae for derivatives. The graphs of the functions sine, cosine, tangent, and cotangent are displayed on the diagrams (they are the red one and the green one on the left, and the red one and the green one on the right, respectively):

*Cyclometric functions* are the functions inverse to trigonometric functions. Since the trigonometric functions all have period  $2\pi$ , their inverses can be defined only inside one period, and further, only on the part where the given function is either increasing or decreasing. Two inverse trigonometric functions are

$$\arcsin = \sin^{-1}$$

with domain  $[-1, 1]$  and range  $[-\pi/2, \pi/2]$  and

$$\arccos = \cos^{-1}$$

**I. Power series**

In the previous chapter, we examined whether it makes sense to assign a value to a sum of infinitely many numbers. Now we will turn our attention to the problem what sense the sum of infinitely many functions may have.

**5.I.1.** Determine the radius of convergence of the following power series:

- i)  $\sum_{n=1}^{\infty} \frac{2^n}{n} x^n$
- ii)  $\sum_{n=1}^{\infty} \frac{1}{(1+i)^n} x^n$

**Solution.**

i) From we get that

$$r = \frac{1}{\limsup_{n \rightarrow \infty} \left| \frac{a_{n+1}}{a_n} \right|} = \frac{1}{2}.$$

Thus the power series converges exactly for the real numbers  $x \in (-\frac{1}{2}, \frac{1}{2})$  (alternatively, the complex numbers  $|x| < \frac{1}{2}$ ). Let us notice that the series diverges for  $x = \frac{1}{2}$  (it is harmonic), but on the other hand, it converges for  $x = -\frac{1}{2}$  (alternating harmonic series). To determine the convergence for any  $x$  lying in the complex plane on the circle of radius  $\frac{1}{2}$  is a much harder question which goes beyond our lectures.

ii)

$$r = \limsup_{n \rightarrow \infty} \left| \sqrt[n]{\frac{1}{(1+i)^n}} \right| = \limsup_{n \rightarrow \infty} \left| \frac{1}{1+i} \right| = \frac{\sqrt{2}}{2},$$

**5.I.2.** Determine the radius  $r$  of convergence of the power series

- (a)  $\sum_{n=1}^{\infty} \frac{(-1)^{n+1}}{n \cdot 8^n} x^n;$
- (b)  $\sum_{n=1}^{\infty} (-4n)^n x^n;$
- (c)  $\sum_{n=1}^{\infty} \left(1 + \frac{1}{n}\right)^{n^2} x^n;$
- (d)  $\sum_{n=1}^{\infty} \frac{n^5}{(2+(-1)^n)^n} x^n.$

**Solution.** It holds that

- (a)  $\lim_{n \rightarrow \infty} \sqrt[n]{|a_n|} = \lim_{n \rightarrow \infty} \frac{1}{\sqrt[n]{n \cdot 8}} = \frac{1}{8};$
- (b)  $\lim_{n \rightarrow \infty} \sqrt[n]{|a_n|} = \lim_{n \rightarrow \infty} 4n = +\infty;$
- (c)  $\lim_{n \rightarrow \infty} \sqrt[n]{|a_n|} = \lim_{n \rightarrow \infty} \left(1 + \frac{1}{n}\right)^n = e;$

with domain  $[-1, 1]$  and range  $[0, \pi]$ . See the left-hand illustration..

The remaining functions are (displayed in the diagram on the right)

$$\arctan = \tan^{-1}$$

with domain  $\mathbb{R}$  and range  $(-\pi/2, \pi/2)$ , and finally

$$\operatorname{arccot} = \cot^{-1}$$

with domain  $\mathbb{R}$  and range  $(0, \pi)$ .

The *hyperbolic functions* are also of some importance. Two basic ones are

$$\sinh x = \frac{1}{2}(e^x - e^{-x}), \quad \cosh x = \frac{1}{2}(e^x + e^{-x}).$$

The name indicates that they should have something in common with a hyperbola. From the definition,

$$(\cosh x)^2 - (\sinh x)^2 = 2 \frac{1}{2}(e^x e^{-x}) = 1.$$

The points  $[\cosh t, \sinh t] \in \mathbb{R}^2$  parametrically describe a hyperbola in the plane. For hyperbolic functions, one can easily derive identities similar to the ones for trigonometric functions. By substituting into (1) and (2), one can obtain for example

$$\cosh x = \cos(ix), \quad i \sinh x = \sin(ix).$$

**5.4.12. Notes.** (1) If a power series  $S(x)$  is expressed with the variable  $x$  moved by a constant offset  $x_0$ , we arrive at the function  $T(x) = S(x - x_0)$ . If  $\rho$  is the radius of convergence of  $S$ , then  $T$  will be well-defined on the interval  $(x_0 - \rho, x_0 + \rho)$ . We say that  $T$  is a *power series centered at  $x_0$* .

The power series can be defined in the following way:

$$S(x) = \sum_{n=0}^{\infty} a_n(x - x_0)^n,$$

where  $x_0$  is an arbitrary fixed real number. All of the previous reasonings are still valid. It is only necessary to be aware of the fact that they relate to the point  $x_0$ . Especially, such a power series converges on the interval  $(x_0 - \rho, x_0 + \rho)$ , where  $\rho$  is its radius of convergence.

Further, if a power series  $y = T(x)$  has its values in an interval where a power series  $S(y)$  is well-defined, then the values of the function  $S \circ T$  are also described by a power series which can be obtained by formal substitution of  $y = T(x)$  for  $y$  into  $S(y)$ .

(2) As soon as a power series with a suitable center is available, the coefficients of the power series for inverse functions can be calculated. We do not introduce a list of formulae

$$(d) \limsup_{n \rightarrow \infty} \sqrt[n]{|a_n|} = \limsup_{n \rightarrow \infty} \frac{\sqrt[n]{n^5}}{2+(-1)^n}$$

$$\limsup_{n \rightarrow \infty} \frac{(\sqrt[n]{n})^5}{2+(-1)^n} = 1.$$

Therefore, the radius of convergence is (a)  $r = 8$ , (b)  $r = 0$ , (c)  $r = 1/e$ , (d)  $r = 1$ .  $\square$

**5.I.3.** Calculate the radius  $r$  of convergence of the power series

$$\sum_{n=1}^{\infty} e^{in} \frac{\sqrt[3]{n^3+n} \cdot 3^n}{\sqrt[3]{n^4+2n^3+1} \cdot \pi^n} (x-2)^n.$$

**Solution.** The radius of convergence of any power series does not change if we move its center or alter its coefficients while keeping their absolute values. Therefore, let us determine the radius of convergence of the series

$$\sum_{n=1}^{\infty} \frac{\sqrt[3]{n^3+n} \cdot 3^n}{\sqrt[3]{n^4+2n^3+1} \cdot \pi^n} x^n.$$

Since

$$\lim_{n \rightarrow \infty} \sqrt[n]{n^a} = \left( \lim_{n \rightarrow \infty} \sqrt[n]{n} \right)^a = 1 \quad \text{for } a > 0,$$

we can move to the series

$$\sum_{n=1}^{\infty} \frac{3^n}{\pi^n} x^n$$

with the same radius of convergence  $r = \pi/3$ .  $\square$

**5.I.4.** Give an example of a power series centered at the origin which, on the interval  $(-3, 3)$ , determines the function

$$\frac{1}{x^2-x-12}.$$

**Solution.** As

$$\frac{1}{x^2-x-12} = \frac{1}{(x-4)(x+3)} = \frac{1}{7} \left( \frac{1}{x-4} - \frac{1}{x+3} \right)$$

and

$$\frac{1}{x-4} = -\frac{1}{4} \frac{1}{1-\frac{x}{4}} = -\frac{1}{4} \left( 1 + \frac{x}{4} + \frac{x^2}{4^2} + \dots + \frac{x^n}{4^n} + \dots \right),$$

$$\frac{1}{x+3} = \frac{1}{1-\left(-\frac{x}{3}\right)} = \frac{1}{3} \left( 1 - \frac{x}{3} + \frac{x^2}{3^2} + \dots + \frac{(-x)^n}{3^n} + \dots \right),$$

we get

$$\frac{1}{x^2-x-12} = -\frac{1}{28} \sum_{n=0}^{\infty} \frac{x^n}{4^n} - \frac{1}{21} \sum_{n=0}^{\infty} \frac{(-x)^n}{3^n}$$

$$= \sum_{n=0}^{\infty} \left( \frac{(-1)^{n+1}}{21 \cdot 3^n} - \frac{1}{28 \cdot 4^n} \right) x^n.$$

$\square$

**5.I.5.** Approximate the number  $\sin 1^\circ$  with error less than  $10^{-10}$ .

**Solution.** We know that

$$\sin x = x - \frac{1}{3!} x^3 + \frac{1}{5!} x^5 - \frac{1}{7!} x^7 + \dots$$

$$= \sum_{n=0}^{\infty} \frac{(-1)^n}{(2n+1)!} x^{2n+1}, \quad x \in \mathbb{R}.$$

here. It is easily obtained in Maple, for instance, by the procedure “series”. For illustration, here are two examples:

Begin with

$$e^x = 1 + x + \frac{1}{2}x^2 + \frac{1}{6}x^3 + \frac{1}{24}x^4 + \dots$$

Since  $e^0 = 1$ , we search for a power series centered at  $x = 1$  for the inverse function  $\ln x$ . So assume

$$\ln x = a_0 + a_1(x-1) + a_2(x-1)^2 + a_3(x-1)^3 + a_4(x-1)^4 + \dots$$

Apply the equality  $x = e^{\ln x}$ , regroup the coefficients by the powers of  $x$  and substitute. The result is:

$$x = a_0 + a_1 \left( x + \frac{1}{2}x^2 + \frac{1}{6}x^3 + \frac{1}{24}x^4 + \dots \right)$$

$$+ a_2 \left( x + \frac{1}{2}x^2 + \dots \right)^2 + a_3 \left( x + \frac{1}{2}x^2 + \dots \right)^3 + \dots$$

$$= a_0 + a_1 x + \left( \frac{1}{2}a_1 + a_2 \right) x^2 + \left( \frac{1}{6}a_1 + a_2 + a_3 \right) x^3$$

$$+ \left( \frac{1}{24}a_1 + \left( \frac{1}{4} + \frac{2}{6} \right) a_2 + \frac{3}{2}a_3 + a_4 \right) x^4 + \dots$$

Comparing the coefficients of the corresponding powers on both sides, gives

$$a_0 = 0, \quad a_1 = 1, \quad a_2 = -\frac{1}{2}, \quad a_3 = \frac{1}{3}, \quad a_4 = -\frac{1}{4}, \dots$$

This corresponds to the valid expression (to be verified later):

$$\ln x = \sum_{n=1}^{\infty} \frac{(-1)^{n-1}}{n} (x-1)^n.$$

Similarly, we can begin with the series

$$\sin t = t - \frac{1}{3!}t^3 + \frac{1}{5!}t^5 - \frac{1}{7!}t^7 + \dots$$

and the (unknown so far) power series for its inverse centered at zero (since  $\sin 0 = 0$ )

$$\arcsin t = a_0 + a_1 t + a_2 t^2 + a_3 t^3 + a_4 t^4 + \dots$$

Substitution gives

$$t = a_0 + a_1 \left( t - \frac{1}{3!}t^3 + \frac{1}{5!}t^5 + \dots \right) +$$

$$a_2 \left( t - \frac{1}{3!}t^3 + \frac{1}{5!}t^5 + \dots \right)^2 + \dots$$

$$= a_0 + a_1 t + a_2 t^2 + \left( -\frac{1}{6}a_1 + a_3 \right) t^3 +$$

$$\left( -\frac{2}{6}a_2 + a_4 \right) t^4 + \left( \frac{1}{120}a_1 - \frac{3}{6}a_3 + a_5 \right) t^5 + \dots,$$

hence

$$\arcsin t = t + \frac{1}{6}t^3 + \frac{3}{40}t^5 + \dots$$

(3) Notice that if it is assumed that the function  $e^x$  can be expressed as a power series centered at zero, and that power series can be differentiated term by term, then the differential equation for the coefficients  $a_n$  is easily obtained since  $(x^{n+1})' = (n+1)x^n$ . Therefore, from the condition that

Substituting  $x = \pi/180$  gives us that the partial sums on the right side will approximate  $\sin 1^\circ$ . It remains to determine the sufficient number of terms to add up in order to provably get the error below  $10^{-10}$ . The series

$$\begin{aligned} \frac{\pi}{180} - \frac{1}{3!} \left(\frac{\pi}{180}\right)^3 + \frac{1}{5!} \left(\frac{\pi}{180}\right)^5 - \frac{1}{7!} \left(\frac{\pi}{180}\right)^7 + \cdots \\ = \sum_{n=0}^{\infty} \frac{(-1)^n}{(2n+1)!} \left(\frac{\pi}{180}\right)^{2n+1} \end{aligned}$$

is alternating with the property that the sequence of the absolute values of its terms is decreasing. If we replace any such convergent series with its partial sum, the error we thus make will be less than the absolute value of the first term not included in the partial sum. (We do not give a proof of this theorem.) The error of the approximation

$$\sin 1^\circ \approx \frac{\pi}{180} - \frac{\pi^3}{180^3 \cdot 3!}$$

is thus less than

$$\frac{\pi^5}{180^5 \cdot 5!} < 10^{-10}.$$

□

**5.I.6.** Determine the radius  $r$  of convergence of the power series  $\sum_{n=0}^{\infty} \frac{2^{2n} \cdot n!}{(2n)!} x^n$ . ○

**5.I.7.** Calculate the radius of convergence for  $\sum_{n=1}^{\infty} 2^{\sqrt{n}} x^n$ . ○

**5.I.8.** Without calculation determine the radius of convergence of the power series  $\sum_{n=1}^{\infty} \frac{5}{n \cdot 3^{n-1}} x^{n-1}$ . ○

**5.I.9.** Find the domain of convergence of the power series  $\sum_{n=1}^{\infty} \frac{\sqrt{n+1}}{3^{\sqrt{n}}} x^n$ . ○

**5.I.10.** Determine for which  $x \in \mathbb{R}$  the power series  $\sum_{n=1}^{\infty} \frac{(-3)^n}{\sqrt{n^4 + 2n^3 + 111}} (x - 2)^n$  converges. ○

**5.I.11.** Is the radius of convergence of the power series

$$\sum_{n=0}^{\infty} a_n x^n, \quad \sum_{n=1}^{\infty} \frac{a_{n-1}}{n} x^n$$

common to all sequences  $\{a_n\}_{n=0}^{\infty}$  of real numbers? ○

**5.I.12.** Decide whether the following implications hold:

(a) If the limit  $\lim_{n \rightarrow \infty} \sqrt[3n]{a_n^2}$  exists and is finite, then the power series

$$\sum_{n=1}^{\infty} a_n (x - x_0)^n$$

converges absolutely at at least two distinct points  $x$ .

(b) Conditional convergence of series  $\sum_{n=1}^{\infty} a_n$ ,  $\sum_{n=1}^{\infty} b_n$  implies that the series  $\sum_{n=1}^{\infty} (6a_n - 5b_n)$  converges as well.

(c) If a series  $\sum_{n=0}^{\infty} a_n$  satisfies

the exponential function has its derivative equal to its value at every point,

$$a_{n+1} = \frac{1}{n+1} a_n, \quad a_0 = 1$$

and hence it is clear that  $a_n = \frac{1}{n!}$ .

$$\lim_{n \rightarrow \infty} a_n^2 = 0,$$

then it is convergent.

(d) If a series  $\sum_{n=1}^{\infty} a_n^2$  converges, then the series

$$\sum_{n=1}^{\infty} \frac{a_n}{n}$$

converges absolutely.

**5.I.13.** Approximate  $\cos \frac{\pi}{10}$  with error less than  $10^{-5}$ .

**5.I.14.** For the convergent series

$$\sum_{n=0}^{\infty} \frac{(-1)^n}{\sqrt{n+100}},$$

bound the error of its approximation by the partial sum  $s_{9999}$ .

**5.I.15.** Express the function  $y = e^x$ , defined on the whole real line, as an infinite polynomial whose terms are of the form  $a_n(x-1)^n$ . Then express the function  $y = 2^x$  defined on  $\mathbb{R}$  as an infinite polynomial with terms  $a_n x^n$ .

**5.I.16.** Find the function  $f$  to which, for  $x \in \mathbb{R}$ , the sequence of functions

$$f_n(x) = \frac{n^2 x^3}{n^2 x^2 + 1}, \quad n \in \mathbb{N}.$$

converges. Is this convergence uniform on  $\mathbb{R}$ ?

**5.I.17.** Does the series

$$\sum_{n=1}^{\infty} \frac{n x}{n^4 + x^2}, \quad \text{kde } x \in \mathbb{R},$$

converge uniformly on the real line?

**5.I.18.** Approximate

(a) the cosine of ten degrees with accuracy of at least  $10^{-5}$ ;

(b) the definite integral  $\int_0^{1/2} \frac{dx}{x^4+1}$  with accuracy of at least  $10^{-3}$ .

**5.I.19.** Determine the power series centered at  $x_0 = 0$  of the function

$$f(x) = \int_0^x e^{t^2} dt, \quad x \in \mathbb{R}. \quad \text{input type="radio"/>$$

**5.I.20.** Using the integral test, find the values  $a > 0$  for which the series

$$\sum_{n=1}^{\infty} \frac{1}{n^a}$$

converges.

**5.I.21.** Determine for which  $x \in \mathbb{R}$  the series

$$\sum_{i=1}^{\infty} \frac{1}{2^n \cdot n \cdot \ln(n)} x^{3n}$$

converges.

**5.I.22.** Determine all  $x \in \mathbb{R}$  for which the power series

$$\sum_{i=1}^{\infty} \frac{x^{2n}}{n^2} \text{ is convergent.} \quad \textcircled{\phantom{0}}$$

**5.I.23.** For which  $x \in \mathbb{R}$  does the series

$$\sum_{n=1}^{\infty} \frac{\ln(n!)}{n^x}$$

converge?

**5.I.24.** Determine whether the series

$$\sum_{n=1}^{\infty} (-1)^{n-1} \tan \frac{1}{n\sqrt{n}}$$

converges absolutely, converges conditionally, diverges to  $+\infty$ , diverges to  $-\infty$ , or none of the above. (such a series is sometimes said to be oscillating).

**5.I.25.** Calculate the series

$$\sum_{n=1}^{\infty} \frac{1}{n \cdot 3^n}$$

with the help of an appropriate power series.

**5.I.26.** For  $x \in (-1, 1)$ , add

$$x - 4x^2 + 9x^3 - 16x^4 + \dots \quad \textcircled{\phantom{0}}$$

**5.I.27.** Supposing  $|x| < 1$ , determine the series

(a)  $\sum_{n=1}^{\infty} \frac{1}{2n-1} x^{2n-1};$

(b)  $\sum_{n=1}^{\infty} n^2 x^{n-1}. \quad \textcircled{\phantom{0}}$

**5.I.28.** Calculate

$$\sum_{n=1}^{\infty} \frac{2n-1}{(-2)^{n-1}}$$

using the power series

$$\sum_{n=0}^{\infty} (-1)^n (2n+1) x^{2n}$$

for some  $x \in (-1, 1)$ .

**5.I.29.** For  $x \in \mathbb{R}$ , calculate the series

$$\sum_{n=0}^{\infty} \frac{1}{2^n \cdot n!} x^{3n+1}. \quad \textcircled{\phantom{0}}$$

## J. Additional exercises for the whole chapter

**5.J.1.** Determine a polynomial  $P(x)$  of the least degree possible satisfying the conditions  $P(1) = 1$ ,  $P(2) = 28$ ,  $P(0) = 2$ ,  $P'(0) = 1$ ,  $P'(1) = 9$ .

**5.J.2.** Determine a polynomial  $P(x)$  of the least degree possible satisfying the conditions  $P(0) = 0$ ,  $P(1) = 4$ ,  $P(-1) = -2$ ,  $P'(0) = 1$ ,  $P'(1) = 7$ .

**5.J.3.** Determine a polynomial  $P(x)$  of the least degree possible satisfying the conditions  $P(0) = -1$ ,  $P(1) = -1$ ,  $P'(-1) = 10$ ,  $P'(0) = -1$ ,  $P'(1) = 6$ .

**5.J.4.** From the definition of a limit, prove that

$$\lim_{x \rightarrow 0} (x^3 - 2) = -2.$$

**5.J.5.** From the definition of a limit, determine

$$\lim_{x \rightarrow -1} \frac{(1+x)^2 - 3}{2},$$

i. e. write the  $\delta(\varepsilon)$ -formula as in the previous exercise.

**5.J.6.** From the definition of a limit, show that

$$\lim_{x \rightarrow -\infty} \frac{3(x-2)^4}{2} = +\infty.$$

**5.J.7.** Determine both one-sided limits

$$\lim_{x \rightarrow 0^+} \arctan\left(\frac{1}{x}\right), \quad \lim_{x \rightarrow 0^-} \arctan\left(\frac{1}{x}\right).$$

Knowing the result, decide the existence of the limit

$$\lim_{x \rightarrow 0} \arctan\left(\frac{1}{x}\right).$$

**5.J.8.** Do the following limits exist?

$$\lim_{x \rightarrow 0} \frac{\sin x}{x^3}, \quad \lim_{x \rightarrow 0} \frac{5x^4 + 1}{x}$$

**5.J.9.** Calculate the limit

$$\lim_{x \rightarrow 0} \frac{\tan x - \sin x}{\sin^3 x}.$$

**5.J.10.** Determine

$$\lim_{x \rightarrow \pi/6} \frac{2 \sin^3 x + 7 \sin^2 x + 2 \sin x - 3}{2 \sin^3 x + 3 \sin^2 x - 8 \sin x + 3}.$$

**5.J.11.** For any  $m, n \in \mathbb{N}$ , determine

$$\lim_{x \rightarrow 1} \frac{x^m - 1}{x^n - 1}.$$

5.J.12. Calculate

$$\lim_{x \rightarrow +\infty} (\sqrt{x^2 + x} - x).$$

○

5.J.13. Determine

$$\lim_{x \rightarrow +\infty} (x \sqrt{1 + x^2} - x^2).$$

○

5.J.14. Calculate

$$\lim_{x \rightarrow 0} \frac{\sqrt{2} - \sqrt{1 + \cos x}}{\sin^2 x}.$$

○

5.J.15. Determine

$$\lim_{x \rightarrow 0} \frac{\sin(4x)}{\sqrt{x+1} - 1}.$$

○

5.J.16. Calculate

$$\lim_{x \rightarrow 0^-} \frac{\sqrt{1 + \tan x} - \sqrt{1 - \tan x}}{\sin x}.$$

○

5.J.17. Calculate

$$\lim_{x \rightarrow -\infty} \frac{2^x + \sqrt{1 + x^2} - x^9 - 7x^5 + 44x^2}{3^x + \sqrt[5]{6x^6 + x^2} - 18x^5 - 592x^4}.$$

○

5.J.18. Let  $\lim_{x \rightarrow -\infty} f(x) = 0$ . Is it true that  $\lim_{x \rightarrow -\infty} (f(x) \cdot g(x)) = 0$  for every increasing function  $g : \mathbb{R} \rightarrow \mathbb{R}$ ?

○

5.J.19. Determine the limit

$$\lim_{n \rightarrow \infty} \left( \frac{n}{n+5} \right)^{2n-1}.$$

○

5.J.20. Calculate

$$\lim_{x \rightarrow 0^-} \frac{\sin x - x}{x^3}.$$

○

5.J.21. For  $x > e$ , determine the sign of the derivative of the function

$$f(x) = \arctan\left(\frac{\ln x}{-1 + \ln x}\right).$$

○

5.J.22. Determine all local extrema of the function

$$y = x \ln^2 x$$

defined on the interval  $(0, +\infty)$ .

**5.J.23.** Is there a real number  $a$  such that the function  $f(x) = ax + \sin x$  has a global minimum on the interval  $[0, 2\pi]$  at  $x_0 = 5\pi/4$ ?

**5.J.24.** Find the absolute minimum of the function

$$y = e^x - \ln x, \quad x > 0$$

on its domain.

**5.J.25.** Determine the maximum value of the function

$$y = \sqrt[3]{3x} e^{-x}, \quad x \in \mathbb{R}.$$

**5.J.26.** Find the absolute extrema of the polynomial  $p(x) = x^3 - 3x + 2$  on the interval  $[-3, 2]$ .

**5.J.27.** Let a moving object's position in time be given as follows:

$$s(t) = -(t - 3)^2 + 16, \quad t \in [0, 7],$$

where  $t$  is the time in seconds, and the position  $s$  is measured in meters. Determine

- (a) the initial (i. e. at the time  $t = 0$  s) velocity of the object;
- (b) the time and position at which its velocity is zero;
- (c) its velocity and acceleration at time  $t = 4$  s.

Note. The object's velocity is the derivative of its position and acceleration is the derivative of its velocity.

**5.J.28.** From the definition of a derivative  $f'$  of a function  $f$  at the point  $x_0$ , calculate  $f'$  for  $f(x) = \sqrt{x}$  at any point  $x_0 > 0$ .

**5.J.29.** Determine whether the derivative of the function

$$f(x) = x \arctan\left(\frac{1}{x}\right), \quad x \in \mathbb{R} \setminus \{0\}, \quad f(0) = 0$$

exists at 0.

**5.J.30.** Does the derivative of the function

$$y = \sin\left(\arctan\left(\left|12x^{21} + 11\right| \cdot \frac{e^{\cos(x+2)} - x^3}{-11 - x^{12}}\right)\right) + \sin(\sin(\sin(\sin x))), \quad x \in \mathbb{R}$$

at the point  $x_0 = \pi^3 + 3\pi$  exist?

**5.J.31.** Determine whether the derivative of the function

$$f(x) = (x^2 - 1) \sin\left(\frac{1}{x+1}\right), \quad x \neq -1 (x \in \mathbb{R}), \quad f(-1) = 0$$

at the point  $x_0 = -1$  exists.

**5.J.32.** Give an example of a function  $f : \mathbb{R} \rightarrow \mathbb{R}$  which is continuous on the whole real axis, but does not have derivatives at the points  $x_1 = 5, x_2 = 9$ .

**5.J.33.** Find functions  $f$  and  $g$  which are not differentiable anywhere, yet their composition  $f \circ g$  is differentiable everywhere on the real line.

**5.J.34.** Using basic formulae, calculate the derivative of the function

- (a)  $y = (2 - x^2) \cos x + 2x \sin x, \quad x \in \mathbb{R};$
- (b)  $y = \sin(\sin x), \quad x \in \mathbb{R};$
- (c)  $y = \sin(\ln(x^3 + 2x)), \quad x \in (0, +\infty);$
- (d)  $y = \frac{1+x-x^2}{1-x+x^2}, \quad x \in \mathbb{R}.$

5.J.35. Determine the derivative of the function

(a)  $y = \sqrt{x \sqrt{x \sqrt{x}}}$ ,  $x \in (0, +\infty)$ ;

(b)  $y = \ln \left| \tan \frac{x}{2} \right|$ ,  $x \in \mathbb{R} \setminus \{n\pi; n \in \mathbb{Z}\}$ .

5.J.36. Write down the derivative of the function

$$y = \sin(\sin(\sin x)), \quad x \in \mathbb{R}.$$

5.J.37. For the function

$$f(x) = \arccos\left(\frac{1-x}{\sqrt{2}}\right) + \sqrt[3]{x^3}$$

with maximum possible domain, calculate  $f'$  on the largest subset of  $\mathbb{R}$  where this derivative exists.

5.J.38. At any point  $x \notin \{n\pi; n \in \mathbb{Z}\}$ , determine the first derivative of the function  $y = \sqrt[3]{\sin x}$ .

5.J.39. For  $x \in \mathbb{R}$ , differentiate

$$x\sqrt{1+x^2} + e^x(x^2 - 2x + 2).$$

5.J.40. Calculate  $f'(1)$  if

$$f(x) = (x-1)(x-2)^2(x-3)^3, \quad x \in \mathbb{R}.$$

5.J.41. Determine the derivative of the function

$$y = \sqrt[3]{\frac{1+x^3}{1-x^3}}, \quad |x| \neq 1 (x \in \mathbb{R}).$$

5.J.42. Differentiate (with respect to the real variable  $x$ )

$$x \ln^2(x + \sqrt{1+x^2}) - 2\sqrt{1+x^2} \ln(x + \sqrt{1+x^2}) + 2x$$

at all points where the derivative exists. Simplify the obtained expression.

5.J.43. Determine  $f'$  on a maximal set if  $f(x) = \log_x e$ .

5.J.44. Express the derivative of the product of four functions

$$[f(x)g(x)h(x)k(x)]'$$

as a sum of products of their derivatives and themselves, supposing all of these functions are differentiable.

5.J.45. Determine the derivative of the function

$$y = \frac{x^3(x+1)^2\sqrt[3]{x+2}}{(x+3)^2}$$

for  $x > 0$ .

**5.J.46. The rainbow.** Why is the rainbow circular?

**Solution.** In the exercise called Snell's law we explained what causes a rainbow. It is created by sunlight being refracted while entering a droplet of water. We continue with this problem, examining how the rays behave when going through the droplets. (See the illustration.) The ray dropping onto a droplet's surface at the point  $A$  "splits". Some part of the light reflects (at the angle  $\varphi_i$  from the normal line) and the other part refracts inside the droplet at the marked angle  $\varphi_r$ . The ray, inside the droplet, reflects off the droplet's surface at the point  $B$ . Since  $|OA| = |OB|$ , the angle of reflection equals  $\varphi_r$ . Part of the light refracts out of the droplet. The reflected ray then meets the droplet's surface again at the point  $C$  and refracts towards the observer at the angle  $\varphi_i$  from the normal line. We omit the case of the secondary rainbow arc, which occurs when the ray reflects twice inside the droplet before refracting out of it.

Write  $\alpha := \angle AIC$ . Since  $\angle OAI = \varphi_i$  and  $\angle OAB = \varphi_r$ , it follows that  $\angle BAI = \varphi_i - \varphi_r$ . Then

$$\angle BIA = \pi - (\angle ABI) - (\angle BAI) = \pi - (\pi - \varphi_r) - (\varphi_i - \varphi_r) = 2\varphi_r - \varphi_i$$

and moreover,

$$\alpha = 2 \cdot \angle BIA = 4\varphi_r - 2\varphi_i.$$

By Snell's law,

$$\frac{\sin \varphi_i}{\sin \varphi_r} = n,$$

where  $n$  stands for the refractive index for water (It is assumed that the index of refraction for air is 1). Thus,

$$\varphi_r = \arcsin\left(\frac{\sin \varphi_i}{n}\right)$$

whence it follows that

$$(1) \quad \alpha = 4 \arcsin\left(\frac{\sin \varphi_i}{n}\right) - 2\varphi_i.$$

For the rays leaving the droplet, the value of  $\alpha$  is different. The admissible values of  $\alpha$  are not distributed uniformly. If  $R$  is the droplet's radius and  $y$  is the distance of the point  $A$  from the horizontal plane going through the centre of the droplet, then

$$(2) \quad \sin \varphi_i = \frac{y}{R} \quad \text{for } y \in [0, R].$$

By the huge distance of the Sun from the Earth, it is assumed that the amount of energy coming from the Sun for  $y \in [a - \delta, a + \delta]$  is independent of  $a \in [\delta, R - \delta]$  but depends only on the range of the values of  $y$  for sufficiently small  $\delta > 0$ . Thus it makes sense to analyze the function (see (1) and (2))

$$\alpha(y) = 4 \arcsin\left(\frac{y}{nR}\right) - 2 \arcsin\left(\frac{y}{R}\right), \quad y \in [0, R].$$

Select an appropriate unit of length so that  $R = 1$ . Consider the function

$$\alpha(x) = 4 \arcsin\left(\frac{x}{n}\right) - 2 \arcsin x, \quad x \in [0, 1].$$

The derivative is

$$\alpha'(x) = \frac{4}{n\sqrt{1-\frac{x^2}{n^2}}} - \frac{2}{\sqrt{1-x^2}}, \quad x \in (0, 1)$$

The equation  $\alpha'(x) = 0$  has a unique solution

$$x_0 = \sqrt{\frac{4-n^2}{3}} \in (0, 1), \quad \text{if } n^2 \in (1, 4).$$

Set  $n = 4/3$  (which is approximately the refractive index of water). Further,

$$\alpha'(x) > 0, \quad x \in (0, x_0), \quad \alpha'(x) < 0, \quad x \in (x_0, 1).$$

At the point

$$x_0 = \sqrt{\frac{4-\left(\frac{4}{3}\right)^2}{3}} = \frac{2}{3} \sqrt{\frac{5}{3}} \doteq 0.86,$$

the function  $\alpha$  has a global maximum

$$\alpha(x_0) = 4 \arcsin\left(\frac{\sqrt{5}}{2\sqrt{3}}\right) - 2 \arcsin\left(\frac{2\sqrt{5}}{3\sqrt{3}}\right) \doteq 0.734 \text{ rad} \approx 42^\circ.$$

It follows that the peak of the rainbow cannot be above the level of approximately  $42^\circ$  with regard to the observer. the values

$$\alpha(0.74) \doteq 39.4^\circ, \quad \alpha(0.94) \doteq 39.2^\circ, \quad \alpha(0.8) \doteq 41.2^\circ, \quad \alpha(0.9) \doteq 41.5^\circ.$$

suggest ( $\alpha$  is increasing on the interval  $[0, x_0]$  and decreasing on the interval  $[x_0, 1]$ ) that more than 20 % of the values  $\alpha$  lie in the band from around  $39^\circ$  to around  $42^\circ$ , and that 10 % lie in a band thinner than  $1^\circ$ . Furthermore, for

$$\alpha(0.84) \doteq 41.9^\circ, \quad \alpha(0.88) \doteq 41.9^\circ,$$

the rays for which  $\alpha$  is close to  $42^\circ$  have the greatest intensity. This is an instance of the principle of minimum deviation: the highest concentration of diffused light happens at the rays with minimum deviation since the total angle deviation of the ray equals the angle  $\delta = \pi - \alpha$ .

The droplets from which the rays creating the rainbow for the observer come, lie on the surface of a cone having central angle equal to  $2\alpha(x_0)$ . The part of this cone which is above ground then appears as the rainbow arc to the observer (see the illustration). Thus when the sun is setting, the rainbow has the shape of a semicircle. The rainbow exists only with regard to its observer – it is not anchored in space. The circular shape of the rainbow was examined as early as 1635–1637 by René Descartes.  $\square$

#### 5.J.47. L'Hospital's pulley.

A rope of length  $r$  is tied at one of its ends to the ceiling at a point  $A$ . A small pulley is attached to its other end. A point  $B$  is also on the ceiling at distance  $d$ ,  $d > r$ , from  $A$ . Another rope of length  $l > \sqrt{d^2 + r^2}$ , is tied to  $B$  at one end, passes over the pulley, and has a weight is attached to its other end. Omit the mass and the size of the ropes and the pulley. In what position does the weight stabilize so that the system is in a stationary position? See the illustration.

**Solution.** The system is in stationary position when its potential energy is minimized. This is when the distance between the weight and the ceiling is maximal.

Let  $x$  be the distance between  $A$  and the point  $P$  on the ceiling vertically above the weight and the pulley. Then by the Pythagorean theorem, the distance between the pulley and the ceiling is  $\sqrt{r^2 - x^2}$ . Similarly, the distance between the weight and the pulley is  $l - \sqrt{(d-x)^2 + r^2 - x^2}$ . Hence if  $f(x)$  is the distance between the weight and the ceiling, then

$$f(x) = \sqrt{r^2 - x^2} + l - \sqrt{(d-x)^2 + r^2 - x^2}.$$

The state of the system is fully determined by the value  $x \in [0, r]$  (see the illustration). So it suffices to find the global maximum of the function  $f$  on the interval  $[0, r]$ .

The derivative is

$$f'(x) = \frac{-x}{\sqrt{r^2 - x^2}} - \frac{-(d-x)-x}{\sqrt{(d-x)^2 + r^2 - x^2}} = \frac{-x}{\sqrt{r^2 - x^2}} + \frac{d}{\sqrt{(d-x)^2 + r^2 - x^2}}, \quad x \in (0, r).$$

Square the equation  $f'(x) = 0$  to obtain

$$\frac{x^2}{r^2 - x^2} = \frac{d^2}{(d-x)^2 + r^2 - x^2}.$$

and hence

$$2dx^3 - (2d^2 + r^2)x^2 + d^2r^2 = 0, \quad x \in (0, r).$$

One solution to this equation is  $x = d$ , hence the polynomial on the left side factors into

$$(x - d)(2dx^2 - r^2x - dr^2),$$

or

$$2d(x - d)\left(x - \frac{r^2 + r\sqrt{r^2 + 8d^2}}{4d}\right)\left(x - \frac{r^2 - r\sqrt{r^2 + 8d^2}}{4d}\right),$$

Hence the equation  $f'(x) = 0$  has three solutions. The solution  $x = d$  is outside the interval  $[0, r]$  since  $d > r$ . The solution  $x = x_1 = \frac{r^2 - r\sqrt{r^2 + 8d^2}}{4d}$  is outside the interval  $[0, r]$  since  $x_1 < 0$ . The solution

$$x = x_0 = \frac{r^2 + r\sqrt{r^2 + 8d^2}}{4d}$$

is positive, and furthermore,  $x_0 < \frac{r}{4} + \frac{3r}{4} = r$ , since  $r < d$ . Since  $f'$  is continuous on the interval  $(0, r)$ , it can change sign only at  $x_0$ . From the limits

$$\lim_{x \rightarrow 0^+} f'(x) = \frac{d}{\sqrt{d^2 + r^2}}, \quad \lim_{x \rightarrow r^-} f'(x) = -\infty,$$

it follows that

$$f'(x) > 0, \quad x \in (0, x_0), \quad f'(x) < 0, \quad x \in (x_0, r).$$

Thus the function  $f$  has its global maximum on the interval  $[0, r]$  at  $x_0$ .  $\square$

**5.J.48.** A nameless mail company can only transport parcels whose length does not exceed 108 inches, and for which the sum of the length and the maximal perimeter is at most 165 inches. Find the largest volume a parcel can have to be transported by this company.

**Solution.** Let  $M$  denote the length plus perimeter,  $p$  the perimeter, and  $x$  the parcel's length. Suppose the perimeter  $p$  is constant.

The wanted parcel has a shape such that for any  $t \in (0, x)$ , its cross section has constant perimeter  $p$ . (the maximal one).

The parcel is to have the greatest volume so that the cross section of a given perimeter has the greatest area possible. The largest planar figure of a given perimeter is a disc. Thus the desired parcel has the shape of a cylinder with height equal to  $x$  and radius  $r = p/2\pi$ .

Its volume is

$$V = \pi r^2 x = \frac{p^2 x}{4\pi}.$$

Consequently  $p + x \leq M$  and  $x \leq 108$ . Thus we consider the parcel for which  $p + x = M$ . Its volume is

$$V(x) = \frac{(M-x)^2 x}{4\pi} = \frac{x^3 - 2Mx^2 + M^2 x}{4\pi} \quad \text{where } x \in (0, 108].$$

Having calculated the derivative

$$V'(x) = \frac{3x^2 - 4Mx + M^2}{4\pi} = \frac{3(x-M)(x-\frac{M}{3})}{4\pi}, \quad x \in (0, 108),$$

we find that the function  $V$  is increasing on the interval  $(0, 55] = (0, M/3]$  and decreasing on the interval  $[55, 108] = [M/3, \min\{108, M\}]$ . The greatest volume is thus obtained for  $x = M/3$ , where

$$V\left(\frac{M}{3}\right) = \frac{M^3}{27\pi} \doteq 0.011\,789\,M^3 \approx 0.867\,8\,m^3.$$

If the company also required that the parcel have the shape of a rectangular cuboid (or more generally a right prism of a given number of faces), we can repeat the previous reasoning for a given cross section of area  $S$  without specifying what the cross section looks like. Necessarily  $S = kp^2$  for some  $k > 0$  which is determined by the shape of the cross section. (If we change only the size of the sides of the polygon which is the cross section, then its perimeter will change by the same ratio. However, its area will change by the square of the ratio.) Thus the parcel's volume is the function

$$V(x) = Sx = kp^2 x = k(M-x)^2 x, \quad x \in (0, 108].$$

The constant  $k$  does not affect the point of the global maximum of the function  $V$ , so the maximum is again at the point  $x = M/3$ . For instance, for the largest right prism having a square base, we have  $p = M - x = 2M/3$ , i. e. the length of the square's sides is  $a = M/6$  and the volume is then

$$V = a^2 x = \frac{M^3}{6^2 \cdot 3} \doteq 0.009\,259\,M^3 \approx 0.681\,6\,m^3.$$

For a parcel in the shape of a ball (when  $x$  is the diameter), the condition  $p + x \leq M$  can be expressed as  $\pi x + x \leq M$ , i. e.  $x \leq M/(\pi + 1) < 108$ . Thus for  $x = M/(\pi + 1)$ , the maximal volume is

$$V = \frac{4}{3}\pi \left(\frac{x}{2}\right)^3 = \frac{\pi M^3}{6(\pi+1)^3} \doteq 0.007\,370\,M^3 \approx 0.542\,6\,m^3.$$

Similarly, for a parcel in the shape of a cube (when  $x$  is the length of the cube's edges), the condition  $p + x \leq M$  means  $x \leq M/5 < 108$ . Thus for  $x = M/5$  the maximal volume

$$V = x^3 = \left(\frac{M}{5}\right)^3 = 0.008 M^3 \approx 0.5889 \text{ m}^3.$$

The length of the edges of the cube which has the same volume as the cylinder is

$$a = \frac{M}{\sqrt[3]{3\pi}} \doteq 0.227595 M \approx 0.953849 \text{ m}.$$

Its length and perimeter sum to  $5a \doteq 1.138 M$ . This is more than the company's limit by around 14%.  $\square$

**5.J.49.** A large military area (denoted by MA) has the shape of a square, and has area of  $100 \text{ km}^2$ . It is bounded along its perimeter by a narrow path. From the starting point in one corner of MA, a target point inside MA is situated 5 km along the (boundary) path and then 2 km perpendicularly to it. One can travel along the path at 5 kph, but directly through the MA at 3 kph. At what distance should you travel along the path if you wish to get there as soon as possible?

**Solution.** To travel  $x$  km along the path (where  $x \in [0, 5]$ ),  $x/5$  hours is needed. One way through MA is then

$$\sqrt{2^2 + (5-x)^2} = \sqrt{x^2 - 10x + 29}$$

kilometers long. This takes  $\sqrt{x^2 - 10x + 29}/3$  hours. Altogether, the journey takes

$$f(x) = \frac{1}{5}x + \frac{1}{3}\sqrt{x^2 - 10x + 29}$$

hours. The only zero point of the function

$$f'(x) = \frac{1}{5} + \frac{1}{3} \frac{x-5}{\sqrt{x^2-10x+29}}$$

is  $x = 7/2$ . Since the derivative  $f'$  exists at every point of the interval  $[0, 5]$  and since

$$f\left(\frac{7}{2}\right) = \frac{23}{15} < f(5) = \frac{5}{3} < f(0) = \frac{\sqrt{29}}{3},$$

the function  $f$  has its absolute minimum at the point  $x = 7/2$ . Thus you should go 3.5 km along the path.  $\square$

**5.J.50.** You are in a boat on a lake at distance  $d$  km from the shore. You want to get to a given place on the shore whose straight-line distance is  $\sqrt{d^2 + l^2}$  from you (see the diagram). What path will you take if you want to be there as soon as possible, supposing you can row at  $v_1$  kph and run along the shore at  $v_2$  kph? How long will the journey take?

**Solution.** The optimal strategy is given by first rowing in a straight line to the shore at some point  $[0, x]$  for  $x \in [0, l]$ , and then running along the shore to the target point  $[0, l]$  (see the diagram). So the trajectory consists of two line segments (or only one segment, in the case when  $x = l$ ). The voyage to the point  $[0, x]$  on the shore takes

$$\frac{\sqrt{d^2+x^2}}{v_1} \text{ hours.}$$

The final run takes

$$\frac{l-x}{v_2} \text{ hours.}$$

The total time is given by the function

$$t(x) = \frac{\sqrt{d^2+x^2}}{v_1} + \frac{l-x}{v_2}$$

on the interval  $[0, l]$ . It can be assumed that  $v_1 < v_2$ , for if  $v_1 \geq v_2$ , the optimal strategy is to row straight to the target point, which corresponds to  $x = l$ .

The first derivative is

$$t'(x) = \frac{x}{v_1\sqrt{d^2+x^2}} - \frac{1}{v_2}, \quad x \in (0, l)$$

and the second derivative is

$$t''(x) = \frac{d^2}{v_1\sqrt{(d^2+x^2)^3}}, \quad x \in (0, l).$$

Solve the equation

$$t'(x) = 0, \quad \text{or} \quad \frac{x}{\sqrt{d^2+x^2}} = \frac{v_1}{v_2}.$$

Squaring and rearranging gives

$$x^2 = \left(\frac{v_1}{v_2}\right)^2 (d^2 + x^2).$$

$$x^2 = \frac{\left(\frac{v_1}{v_2}\right)^2 d^2}{1 - \left(\frac{v_1}{v_2}\right)^2}, \quad \text{or} \quad x = x_0 = \frac{v_1 d}{\sqrt{v_2^2 - v_1^2}}$$

If  $x_0 < l$ , then  $t(x)$  has a global minimum at  $x_0$  on the interval  $[0, l]$  since  $\lim_{x \rightarrow 0^+} t'(x) < 0$ ,  $t'(l) > 0$ , and indeed  $t''(x) > 0$  on the same interval.

If  $x_0 \geq l$ , then  $t'(x) \leq 0$  on all of the interval  $[0, l]$  and so the global minimum of  $t(x)$  occurs at  $l$ .

In the former case, the fastest journey (in hours) takes

$$t(x_0) = \frac{\sqrt{d^2 + x_0^2}}{v_1} + \frac{l - x_0}{v_2} = \frac{d \sqrt{v_2^2 - v_1^2}}{v_1 v_2} + \frac{l}{v_2}.$$

In the latter case, the fastest journey takes

$$t(l) = \frac{\sqrt{d^2 + l^2}}{v_1} \text{ hours.}$$

Note. An alternative simpler approach for doing the calculations is to use the variable  $\theta$  instead of the variable  $x$  where  $x = d \tan \theta$ . The fastest journey occurs when  $\sin \theta = v_1/v_2$ . This is a limiting case of Snell's law.

□

**5.J.51.** A company is looking for a rectangular patch of land with sides of lengths  $5a$  and  $b$ . The company wants to enclose it with a fence and then split it into 5 equal parts (each being a rectangle with sides  $a, b$ ) by further fences. For which values of  $a, b$  will the area  $S = 5ab$  of the patch be maximal if the total length of the used fences is 2 400 m?

**Solution.** Reformulate the statement of the problem: Maximize  $5ab$  while satisfying the condition

$$(1) \quad 6b + 10a = 2,400, \quad a, b > 0.$$

The function

$$a \mapsto 5a \frac{2,400 - 10a}{6}$$

defined for  $a \in [0, 240]$  takes its maximal value at the point  $a = 120$ . Hence the result is

$$a = 120 \text{ m}, \quad b = 200 \text{ m.}$$

The value of  $b$  follows immediately from (1). □

**5.J.52.** A rectangle is inscribed into an equilateral triangle with sides of length  $a$  so that one of its sides lies on one of the triangle's sides and the other two of the rectangle's vertices lie on the remaining sides of the triangle. What is the maximum possible area of the rectangle?

**5.J.53.** Determine the dimensions of an (open) swimming pool whose volume is  $32 \text{ m}^3$  and whose bottom has the shape of a square, so that one would use the least amount of paint possible to prime its bottom and its walls. ○

**5.J.54.** Express 28 as a sum of two non-negative numbers such that the sum of the first summand squared and the second summand cubed is as small as possible. ○

**5.J.64.** At time  $t = 0$ , a car left the point  $A = [5, 0]$  at the speed of 4 units per second in the direction  $(-1, 0)$ . At the same time, another car left  $B = [-2, -1]$  at the speed of 2 units per second in the direction  $(0, 1)$ . When will the cars be closest to each other, and what will the distance between them be at that moment?

**5.J.65.** At the time  $t = 0$ , a car left the point  $A = [0, 0]$  at 2 units per second in the direction  $(1, 0)$ . At the same time, another car left the point  $B = [1, -1]$  at 3 units per second in the direction  $(0, 1)$ . When will they be closest to each other and what will the distance be?

**5.J.66.** If a cone has a base of radius  $r$  and height  $h$ , then its surface area (not including the base) is  $\pi r h$  and its volume is  $V = \frac{1}{3}\pi r^2 h$ . Determine the maximum possible volume of a cone with total surface area (including the base)  $3\pi \text{ cm}^2$ .

**5.J.67.** Suppose you own an excess of funds without the possibility of investing outside your own factory. This acts as a regulated market with a nearly unlimited demand and a limited access to some key raw materials, which allows you to produce at most 10 000 products per day. You know that the raw profit  $p$  and the expenses  $e$ , as functions of a variable  $x$  which determines the average number of products per day, satisfy

$$v(x) = 9x, \quad n(x) = x^3 - 6x^2 + 15x, \quad x \in [0, 10].$$

At what production will you profit the most from your factory?

**5.J.68.** Determine

$$\lim_{x \rightarrow 0} \left( \cot x - \frac{1}{x} \right).$$

**Solution.** Notice that

$$\lim_{x \rightarrow 0^+} \cot x = +\infty, \quad \lim_{x \rightarrow 0^+} \frac{1}{x} = +\infty,$$

$$\lim_{x \rightarrow 0^-} \cot x = -\infty, \quad \lim_{x \rightarrow 0^-} \frac{1}{x} = -\infty,$$

we can see that both one-sided limits are of the type  $\infty - \infty$ . Thus we consider the (two-sided) limit.

We write the cotangent function as the ratio of the cosine and the sine and convert the fractions to a common denominator.

$$\lim_{x \rightarrow 0} \left( \cot x - \frac{1}{x} \right) = \lim_{x \rightarrow 0} \frac{x \cos x - \sin x}{x \sin x}.$$

Thus we obtain an expression of the type  $0/0$  for which we get (by l'Hospital's rule)

$$\lim_{x \rightarrow 0} \frac{x \cos x - \sin x}{x \sin x} = \lim_{x \rightarrow 0} \frac{\cos x - x \sin x - \cos x}{\sin x + x \cos x} = \lim_{x \rightarrow 0} \frac{-x \sin x}{\sin x + x \cos x}.$$

By one more use of l'Hospital's rule for the type  $0/0$ , we get

$$\lim_{x \rightarrow 0} \frac{-x \sin x}{\sin x + x \cos x} = \lim_{x \rightarrow 0} \frac{-\sin x - x \cos x}{\cos x + \cos x - x \sin x} = \frac{0 - 0}{1 + 1 - 0} = 0.$$

□

where  $\alpha \in \mathbb{R}$  is arbitrary.

○

5.J.76. By any means, verify that

$$\lim_{x \rightarrow 0} \frac{e^x - 1}{x} = 1.$$

○

5.J.77. By applying the ratio test (also called D'Alembert's criterion; see 5.4.5), determine whether the infinite series

(a)  $\sum_{n=1}^{\infty} \frac{2^n \cdot (n+1)^3}{3^n}$ ;

(b)  $\sum_{n=1}^{\infty} \frac{6^n}{n!}$ ;

(c)  $\sum_{n=1}^{\infty} \frac{n^n}{n^2 \cdot n!}$

converge.

**Solution.** Since  $(a_n \geq 0$  for all  $n$ )

(a)  $\lim_{n \rightarrow \infty} \frac{a_{n+1}}{a_n} = \lim_{n \rightarrow \infty} \frac{2^{n+1} \cdot (n+2)^3 \cdot 3^n}{3^{n+1} \cdot 2^n \cdot (n+1)^3} = \lim_{n \rightarrow \infty} \frac{2(n+2)^3}{3(n+1)^3} = \lim_{n \rightarrow \infty} \frac{2n^3}{3n^3} = \frac{2}{3} < 1$ ;

(b)  $\lim_{n \rightarrow \infty} \frac{a_{n+1}}{a_n} = \lim_{n \rightarrow \infty} \left( \frac{6^{n+1}}{(n+1)!} \cdot \frac{n!}{6^n} \right) = \lim_{n \rightarrow \infty} \frac{6}{n+1} = 0 < 1$ ;

(c)  $\lim_{n \rightarrow \infty} \frac{a_{n+1}}{a_n} = \lim_{n \rightarrow \infty} \left( \frac{(n+1)^{n+1}}{(n+1)^2 \cdot (n+1)!} \cdot \frac{n^2 \cdot n!}{n^n} \right) = \lim_{n \rightarrow \infty} \frac{n^2}{(n+1)^2} \cdot \lim_{n \rightarrow \infty} \frac{(n+1)^n}{n^n} = \lim_{n \rightarrow \infty} \frac{n^2}{n^2} \cdot \lim_{n \rightarrow \infty} \left( 1 + \frac{1}{n} \right)^n = 1 \cdot e > 1$ ,

the series (a) converges; (b) converges; (c) does not converge (it diverges to  $+\infty$ ). □

**5.J.78.** By applying the root test (Cauchy's criterion), determine whether or not the infinite series

- (a)  $\sum_{n=1}^{\infty} \frac{1}{\ln^n(n+1)}$ ;  
 (b)  $\sum_{n=1}^{\infty} \frac{\left(\frac{n+1}{n}\right)^{n^2}}{n^3 \cdot 3^n}$ ;  
 (c)  $\sum_{n=1}^{\infty} \arcsin^n \frac{2n}{2^n}$

converge.

**Solution.** Consider the series with non-negative terms only, where

- (a)  $\lim_{n \rightarrow \infty} \sqrt[n]{a_n} = \lim_{n \rightarrow \infty} \frac{1}{\ln(n+1)} = 0 < 1$ ;  
 (b)  $\lim_{n \rightarrow \infty} \sqrt[n]{a_n} = \lim_{n \rightarrow \infty} \frac{\left(\frac{n+1}{n}\right)^n}{\sqrt[n]{n^3 \cdot 3}} = \frac{\lim_{n \rightarrow \infty} \left(1 + \frac{1}{n}\right)^n}{3 \left(\lim_{n \rightarrow \infty} \sqrt[n]{n}\right)^3} = \frac{e}{3} < 1$ ;  
 (c)  $\lim_{n \rightarrow \infty} \sqrt[n]{a_n} = \lim_{n \rightarrow \infty} \arcsin \frac{2n}{2^n} = \arcsin 0 = 0 < 1$ .

So each of the above series converges. □

**5.J.79.** Determine whether or not the series

- (a)  $\sum_{n=1}^{\infty} (-1)^n \ln\left(1 + \frac{1}{2^n}\right)$ ;  
 (b)  $\sum_{n=1}^{\infty} \frac{(-2)^{n^2}}{n!}$ ;  
 (c)  $\sum_{n=1}^{\infty} \frac{(-3)^n}{(6+(-1)^n)^n}$

converge.

**Solution.** The case (a). By l'Hospital's rule,

$$\lim_{x \rightarrow +\infty} \frac{\ln\left(1 + \frac{1}{2^x}\right)}{\frac{1}{2^x}} = \lim_{x \rightarrow +\infty} \frac{\frac{1}{1+\frac{1}{2^x}} \left(1 + \frac{1}{2^x}\right)'}{\left(\frac{1}{2^x}\right)'} = \lim_{x \rightarrow +\infty} \frac{1}{1 + \frac{1}{2^x}} = 1,$$

hence

$$0 < \ln\left(1 + \frac{1}{2^n}\right) \leq \frac{2}{2^n}$$

for all sufficiently large  $n \in \mathbb{N}$ . However, the series  $\sum_{n=1}^{\infty} \frac{2}{2^n}$  is convergent. So

$$\sum_{n=1}^{\infty} \ln\left(1 + \frac{1}{2^n}\right) < +\infty.$$

The series converges (absolutely).

The case (b). The ratio test gives

$$\lim_{n \rightarrow \infty} \left| \frac{a_{n+1}}{a_n} \right| = \lim_{n \rightarrow \infty} \frac{2^{(n+1)^2} \cdot n!}{(n+1)! \cdot 2^{n^2}} = \lim_{n \rightarrow \infty} \frac{2^{2n+1}}{n+1} = \lim_{n \rightarrow \infty} \frac{2 \cdot 4^n}{n+1} = +\infty.$$

Thus the series does not converge.

The case (c). Use the general version of the root test

$$\limsup_{n \rightarrow \infty} \sqrt[n]{|a_n|} = \limsup_{n \rightarrow \infty} \frac{3}{6+(-1)^n} = \frac{3}{5} < 1.$$

It follows that the series is (absolutely) convergent. □

**5.J.80.** Determine whether or not the following alternating series converge:

- (a)  $\sum_{n=1}^{\infty} (-1)^n \frac{n^2+3n-1}{(3n-2)^2}$ ;  
 (b)  $\sum_{n=1}^{\infty} (-1)^{n-1} \frac{3n^4-3n^3+9n-1}{(5n^3-2) \cdot 4^n}$ .

**Solution.** Case (a). Since

$$\lim_{n \rightarrow \infty} \frac{n^2+3n-1}{(3n-2)^2} = \lim_{n \rightarrow \infty} \frac{n^2}{9n^2} = \frac{1}{9} \neq 0,$$

it follows that the limit

$$\lim_{n \rightarrow \infty} (-1)^n \frac{n^2 + 3n - 1}{(3n - 2)^2}$$

does not exist. Therefore, the series does not converge since a necessary condition for the convergence is not satisfied.

The case (b). When applying the ratio (or root) test, the polynomials in the numerator or in the denominator do not affect the value of the considered limit. Consider the series

$$\sum_{n=1}^{\infty} (-1)^{n-1} \frac{1}{4^n}$$

for which

$$\lim_{n \rightarrow \infty} \left| \frac{a_{n+1}}{a_n} \right| = \frac{1}{4} < 1.$$

This means that the original series is also (absolutely) convergent.  $\square$

**5.J.81.** Does the following series converge?

$$\sum_{n=1}^{\infty} (-1)^{n+1} \arctan \frac{2}{\sqrt{3n}}$$

**Solution.** The sequence  $\{2/\sqrt{3n}\}_{n \in \mathbb{N}}$  is decreasing and the function  $y = \arctan x$  increasing (on the whole real axis). So the sequence  $\{\arctan(2/\sqrt{3n})\}_{n \in \mathbb{N}}$  is decreasing. Thus it is an alternating series such that the sequence of the absolute values of its terms is decreasing. Such an alternating series converges if and only if the sequence of its terms converges to zero (the Leibniz criterion), and this is satisfied:

$$\lim_{n \rightarrow \infty} \arctan \frac{2}{\sqrt{3n}} = \arctan 0 = 0, \text{ i. e. } \lim_{n \rightarrow \infty} \left( (-1)^{n+1} \arctan \frac{2}{\sqrt{3n}} \right) = 0.$$

$\square$

**5.J.82.** Determine whether the series

$$(a) \sum_{n=1}^{\infty} \frac{\sin n}{n^2};$$

$$(b) \sum_{n=1}^{\infty} \frac{\cos(\pi n)}{\sqrt[3]{n^2}}$$

converges absolutely, converges conditionally, or does not converge at all.

**Solution.** The case (a). This series converges absolutely. For instance,

$$\sum_{n=1}^{\infty} \left| \frac{\sin n}{n^2} \right| \leq \sum_{n=1}^{\infty} \frac{1}{n^2} < \sum_{n=0}^{\infty} \frac{1}{2^n} = 2,$$

and the second inequality is already proven.

The case (b).  $\cos(\pi n) = (-1)^n$ ,  $n \in \mathbb{N}$ . So it is an alternating series such that the sequence of the absolute values of its terms is decreasing. Therefore, from the limit

$$\lim_{n \rightarrow \infty} \frac{1}{\sqrt[3]{n^2}} = 0$$

it follows that the series is convergent. On the other hand,

$$\sum_{n=1}^{\infty} \left| \frac{\cos(\pi n)}{\sqrt[3]{n^2}} \right| = \sum_{n=1}^{\infty} \frac{1}{\sqrt[3]{n^2}} \geq \sum_{n=1}^{\infty} \frac{1}{n} = +\infty.$$

The series converges conditionally.  $\square$

**5.J.83.** Calculate the series

$$(a) \sum_{n=1}^{\infty} \left( \frac{1}{\sqrt{n}} - \frac{1}{\sqrt{n+1}} \right);$$

$$(b) \sum_{n=0}^{\infty} \frac{5}{3^n};$$

$$(c) \sum_{n=1}^{\infty} \left( \frac{3}{4^{2n-1}} + \frac{2}{4^{2n}} \right);$$

$$(d) \sum_{n=1}^{\infty} \frac{n}{3^n};$$

$$(e) \sum_{n=0}^{\infty} \frac{1}{(3n+1)(3n+4)}.$$

**Solution.** The case (a). By the definition,

$$\begin{aligned} \sum_{n=1}^{\infty} \left( \frac{1}{\sqrt{n}} - \frac{1}{\sqrt{n+1}} \right) &= \\ \lim_{n \rightarrow \infty} \left( \left( \frac{1}{\sqrt{1}} - \frac{1}{\sqrt{2}} \right) + \left( \frac{1}{\sqrt{2}} - \frac{1}{\sqrt{3}} \right) + \cdots + \left( \frac{1}{\sqrt{n}} - \frac{1}{\sqrt{n+1}} \right) \right) &= \\ \lim_{n \rightarrow \infty} \left( 1 + \left( -\frac{1}{\sqrt{2}} + \frac{1}{\sqrt{2}} \right) + \cdots + \left( -\frac{1}{\sqrt{n}} + \frac{1}{\sqrt{n}} \right) - \frac{1}{\sqrt{n+1}} \right) &= 1. \end{aligned}$$

The case (b). This is a convergent geometric series with the common ratio  $q = 1/3$ , hence

$$\sum_{n=0}^{\infty} \frac{5}{3^n} = 5 \sum_{n=0}^{\infty} \left( \frac{1}{3} \right)^n = 5 \cdot \frac{1}{1-\frac{1}{3}} = \frac{15}{2}.$$

The case (c). By substituting  $m = n - 1$ ,

$$\begin{aligned} \sum_{n=1}^{\infty} \left( \frac{3}{4^{2n-1}} + \frac{2}{4^{2n}} \right) &= \frac{3}{4} \sum_{n=1}^{\infty} \left( \frac{1}{4^{2n-2}} \right) + \frac{2}{16} \sum_{n=1}^{\infty} \left( \frac{1}{4^{2n-2}} \right) = \\ \left( \frac{3}{4} + \frac{2}{16} \right) \sum_{m=0}^{\infty} \frac{1}{4^{2m}} &= \frac{14}{16} \sum_{m=0}^{\infty} \left( \frac{1}{16} \right)^m = \frac{14}{16} \cdot \frac{1}{1-\frac{1}{16}} = \frac{14}{15}. \end{aligned}$$

The series of linear combinations was expressed as a linear combination of a series (to be more precise, as a sum of series factoring out the constants). This is a valid modification supposing the obtained series are absolutely convergent.

The case (d). From the partial sum

$$s_n = \frac{1}{3} + \frac{2}{3^2} + \frac{3}{3^3} + \cdots + \frac{n}{3^n}, \quad n \in \mathbb{N},$$

we obtain

$$\frac{s_n}{3} = \frac{1}{3^2} + \frac{2}{3^3} + \cdots + \frac{n-1}{3^n} + \frac{n}{3^{n+1}}, \quad n \in \mathbb{N}.$$

Thus

$$s_n - \frac{s_n}{3} = \frac{1}{3} + \frac{1}{3^2} + \frac{1}{3^3} + \cdots + \frac{1}{3^n} - \frac{n}{3^{n+1}}, \quad n \in \mathbb{N}.$$

Since  $\lim_{n \rightarrow \infty} \frac{n}{3^{n+1}} = 0$ ,

$$\begin{aligned} \sum_{n=1}^{\infty} \frac{n}{3^n} &= \lim_{n \rightarrow \infty} \frac{3}{2} \left( s_n - \frac{s_n}{3} \right) = \frac{3}{2} \lim_{n \rightarrow \infty} \sum_{k=1}^n \frac{1}{3^k} = \\ \frac{3}{2} \sum_{k=1}^{\infty} \left( \frac{1}{3} \right)^k &= \frac{3}{2} \left( \frac{1}{1-\frac{1}{3}} - 1 \right) = \frac{3}{4}. \end{aligned}$$

The case (e). It suffices to use partial fraction decomposition

$$\frac{1}{(3n+1)(3n+4)} = \frac{1}{3} \cdot \frac{1}{3n+1} - \frac{1}{3} \cdot \frac{1}{3n+4}, \quad n \in \mathbb{N} \cup \{0\},$$

which gives

$$\begin{aligned} \sum_{n=0}^{\infty} \frac{1}{(3n+1)(3n+4)} &= \lim_{n \rightarrow \infty} \frac{1}{3} \left( 1 - \frac{1}{4} + \frac{1}{4} - \frac{1}{7} + \frac{1}{7} - \frac{1}{10} + \cdots + \frac{1}{3n+1} - \frac{1}{3n+4} \right) \\ &= \lim_{n \rightarrow \infty} \frac{1}{3} \left( 1 - \frac{1}{3n+4} \right) = \frac{1}{3}. \end{aligned}$$

□

**5.J.84.** Verify that

$$\sum_{n=1}^{\infty} \frac{1}{n^2} < \sum_{n=0}^{\infty} \frac{1}{2^n}.$$

**Solution.**

$$1 \leq 1, \quad \frac{1}{2^2} + \frac{1}{3^2} < 2 \cdot \frac{1}{2^2} = \frac{1}{2}, \quad \frac{1}{4^2} + \frac{1}{5^2} + \frac{1}{6^2} + \frac{1}{7^2} < 4 \cdot \frac{1}{4^2} = \frac{1}{4},$$

or the general bound

$$\frac{1}{(2^n)^2} + \cdots + \frac{1}{(2^{n+1}-1)^2} < 2^n \cdot \frac{1}{(2^n)^2} = \frac{1}{2^n}, \quad n \in \mathbb{N}.$$

By comparing the terms of both series, we get the desired inequality. It follows that the series  $\sum_{n=1}^{\infty} \frac{1}{n^2}$  is absolutely convergent.

Note that

$$\sum_{n=1}^{\infty} \frac{1}{n^2} = \frac{\pi^2}{6} < 2 = \sum_{n=0}^{\infty} \frac{1}{2^n}.$$

□

**5.J.85.** Examine the convergence of the series

$$\sum_{n=1}^{\infty} \ln \frac{n+1}{n}.$$

**Solution.** Add the terms of this series.

$$\begin{aligned} \sum_{n=1}^{\infty} \ln \frac{n+1}{n} &= \lim_{n \rightarrow \infty} (\ln \frac{2}{1} + \ln \frac{3}{2} + \ln \frac{4}{3} + \cdots + \ln \frac{n+1}{n}) = \\ &= \lim_{n \rightarrow \infty} \ln \frac{2 \cdot 3 \cdot 4 \cdots (n+1)}{1 \cdot 2 \cdot 3 \cdots n} = \lim_{n \rightarrow \infty} \ln (n+1) = +\infty. \end{aligned}$$

Thus the series diverges to  $+\infty$ .

□

**5.J.86.** Prove that the series

$$\sum_{n=0}^{\infty} \arctan \frac{n^2+2n+3\sqrt{n+4}}{n+1}; \quad \sum_{n=1}^{\infty} \frac{3^n+1}{n^3+n^2-n}$$

do not converge.

**Solution.** Since

$$\lim_{n \rightarrow \infty} \arctan \frac{n^2+2n+3\sqrt{n+4}}{n+1} = \lim_{n \rightarrow \infty} \arctan \frac{n^2}{n} = \frac{\pi}{2}$$

and

$$\lim_{n \rightarrow \infty} \frac{3^n+1}{n^3+n^2-n} = \lim_{n \rightarrow \infty} \frac{3^n}{n^3} = +\infty,$$

the necessary condition  $\lim_{n \rightarrow \infty} a_n = 0$  for the series  $\sum_{n=n_0}^{\infty} a_n$  to converge does not hold.

□

**5.J.87.** Determine whether or not the series

$$\sum_{n=2}^{\infty} \frac{1}{\sqrt[n]{\ln n}}?$$

converges.

**Solution.** From the inequalities (consider the graph of the natural logarithm)

$$1 \leq \ln n \leq n, \quad n \geq 3, \quad n \in \mathbb{N}$$

it follows that

$$\sqrt[n]{1} \leq \sqrt[n]{\ln n} \leq \sqrt[n]{n}, \quad n \geq 3, \quad n \in \mathbb{N}.$$

By the squeeze theorem (5.2.12),

$$\lim_{n \rightarrow \infty} \sqrt[n]{\ln n} = 1, \quad \text{i. e.} \quad \lim_{n \rightarrow \infty} \frac{1}{\sqrt[n]{\ln n}} = 1.$$

Thus the series is not convergent. Since all its terms are non-negative, it diverges to  $+\infty$ .

□

**5.J.88.** Determine whether or not the series

(a)  $\sum_{n=0}^{\infty} \frac{1}{(n+1) \cdot 3^n};$

(b)  $\sum_{n=1}^{\infty} \frac{n^2+1}{n^3};$

(c)  $\sum_{n=1}^{\infty} \frac{1}{n - \ln n}$

converges.

**Solution.** All of the three enlisted series consist of non-negative terms only. So the series either converge, or diverge to  $+\infty$ .

(a)  $\sum_{n=0}^{\infty} \frac{1}{(n+1) \cdot 3^n} \leq \sum_{n=0}^{\infty} \left(\frac{1}{3}\right)^n = \frac{1}{1-\frac{1}{3}} < +\infty;$

(b)  $\sum_{n=1}^{\infty} \frac{n^2+1}{n^3} \geq \sum_{n=1}^{\infty} \frac{n^2}{n^3} = \sum_{n=1}^{\infty} \frac{1}{n} = +\infty;$

(c)  $\sum_{n=1}^{\infty} \frac{1}{n-\ln n} \geq \sum_{n=1}^{\infty} \frac{1}{n} = +\infty.$

It follows that (a) converges; (b) diverges to  $+\infty$ ; (c) diverges to  $+\infty$ . □

**5.J.89.** Begin with a square with sides of length  $a > 0$ . Construct a sequence of squares, each of which has as vertices the midpoints of the preceding square. Determine the sum of the areas and the sum of the perimeters of all these (infinitely many) squares. ○

**5.J.90.** Let a sequence of rows of semidisks be given, such that for each  $n \in \mathbb{N}$ , the  $n$ -th row contains  $2^n$  semidisks, each with radius of  $2^{-n}$ . What is the area of an arbitrary figure consisting of all these semidisks, supposing the semicircles do not overlap? ○

**5.J.91.** Solve the equation

$$1 - \tan x + \tan^2 x - \tan^3 x + \tan^4 x - \tan^5 x + \cdots = \frac{\tan 2x}{\tan 2x + 1}.$$

**5.J.92.** Determine

$$\sum_{n=1}^{\infty} \left( \frac{1}{2^{n-1}} + \frac{2}{3^{n-1}} \right).$$

**5.J.93.** Calculate

$$\sum_{n=1}^{\infty} \sqrt[5]{n^2 + 2n + 1}.$$

**5.J.94.** Prove the convergence of the series

$$\sum_{n=1}^{\infty} \frac{3^n + 2^n}{6^n}.$$

and find its value.

**5.J.95.** Calculate the series

(a)  $\sum_{n=1}^{\infty} \frac{2n-1}{2^n};$

(b)  $\sum_{n=0}^{\infty} \frac{n+1}{3^n}.$

**5.J.96.** Sum the series

$$\frac{1}{1 \cdot 3} + \frac{1}{3 \cdot 5} + \frac{1}{5 \cdot 7} + \cdots = \sum_{n=1}^{\infty} \frac{1}{(2n-1)(2n+1)}.$$

**5.J.97.** Using the partial fraction decomposition, calculate

(a)  $\sum_{n=2}^{\infty} \frac{1}{n^2-1};$

(b)  $\sum_{n=1}^{\infty} \frac{1}{n^3+3n^2+2n}$ .

**5.J.98.** Determine the value of the convergent series

$$\sum_{n=0}^{\infty} \frac{1}{4n^2-1}$$

**5.J.99.** Calculate the series

$$\sum_{n=1}^{\infty} \frac{1}{n^2+3n}$$

**5.J.100.** In terms of

$$s := \sum_{n=1}^{\infty} \frac{(-1)^{n-1}}{n} = 1 - \frac{1}{2} + \frac{1}{3} - \frac{1}{4} + \frac{1}{5} - \frac{1}{6} + \frac{1}{7} - \frac{1}{8} + \dots,$$

express the following two series

$$\begin{aligned} & \left(1 - \frac{1}{2} - \frac{1}{4}\right) + \left(\frac{1}{3} - \frac{1}{6} - \frac{1}{8}\right) + \dots; \\ & \left(1 + \frac{1}{3} - \frac{1}{2}\right) + \left(\frac{1}{5} + \frac{1}{7} - \frac{1}{4}\right) + \dots \end{aligned}$$

(both the series contain the same elements as the first one, only in a different order).

**5.J.101.** Determine whether the series

$$\sum_{n=0}^{\infty} \frac{2^n + (-2)^n}{5^n}$$

converges.

**5.J.102.** Prove the following statement: If a series  $\sum_{n=0}^{\infty} a_n$  converges, then  $\lim_{n \rightarrow \infty} \sin(3a_n + \pi) = 0$ .

**5.J.103.** For which  $\alpha \in \mathbb{R}$ ;  $\beta \in \mathbb{Z}$ ;  $\gamma \in \mathbb{R} \setminus \{0\}$  do the series  $\sum_{n=120}^{\infty} \frac{e^{-\alpha n}}{n}$ ;  $\sum_{n=240}^{\infty} \frac{\beta^n \cdot n!}{n^n}$ ;  $\sum_{n=360}^{\infty} \frac{n}{\gamma^n}$  converge?

**5.J.104.** Determine whether the series

$$\sum_{n=21}^{\infty} (-1)^n \frac{n^8 - 5n^6 + 2n}{2^n}$$

converges absolutely, converges conditionally, or does not converge at all.

**5.J.105.** Determine whether or not the limit

$$\lim_{n \rightarrow \infty} \left( \frac{1}{n^2} + \frac{2}{n^2} + \dots + \frac{n-1}{n^2} \right)$$

is finite. Notice that one cannot use the sums

$$\sum_{n=1}^{\infty} \frac{1}{n^2} = \frac{\pi^2}{6}, \quad \sum_{n=2}^{\infty} \frac{n-1}{n^2} = +\infty.$$

**5.J.106.** Find all real numbers  $A \geq 0$  for which the series

$$\sum_{n=1}^{\infty} (-1)^n \ln(1 + A^{2n})$$

is convergent.

**5.J.107.** Recall that the harmonic series diverges.

$$\sum_{n=1}^{\infty} \frac{1}{n} = +\infty.$$

Determine whether or not the series

$$\frac{1}{1} + \cdots + \frac{1}{9} + \frac{1}{11} + \cdots + \frac{1}{19} + \frac{1}{21} + \cdots + \frac{1}{29} + \cdots \\ \cdots + \frac{1}{91} + \cdots + \frac{1}{99} + \frac{1}{111} + \cdots + \frac{1}{119} + \frac{1}{121} + \cdots$$

is also divergent.

**5.J.108.** Give an example of two divergent series  $\sum_{n=1}^{\infty} a_n$ ,  $\sum_{n=1}^{\infty} b_n$  with positive numbers for which the series  $\sum_{n=1}^{\infty} (3a_n - 2b_n)$  converges absolutely.

**5.J.109.** Determine whether the two series

$$\sum_{n=1}^{\infty} (-1)^n \frac{(n!)^2}{(2n)!}; \quad \sum_{n=1}^{\infty} (-1)^n \frac{n^7 - n^4 + n}{n^8 + 2n^6 + n}$$

converge absolutely, converge conditionally, or do not converge at all.

**5.J.110.** Does the series

$$\sum_{n=1}^{\infty} (-1)^{n+1} \frac{\sqrt[3]{n} + \sqrt[5]{n+1}}{n + \sqrt[9]{n}}$$

converge?

**5.J.111.** Find the values of the parameter  $p \in \mathbb{R}$  for which the series

$$\sum_{n=1}^{\infty} (-1)^n \sin^n \frac{p}{n}$$

converges.

**5.J.112.** Determine the maximal subset of  $\mathbb{R}$  where the function

$$y = \operatorname{arctg}(x^{21} + \sin x) \cdot \frac{e^{\cos(\sqrt[5]{x-21} + \cos x)} + x - 256x^3 - 11}{2 + x^{252}}$$

can be defined.

**5.J.113.** Write the maximal domain of the function  $y = \frac{\arccos(\ln x)}{\sqrt{x^2 - 1}}$ .

**5.J.114.** Determine the domain and the range of the function

$$y = \frac{x-1}{2-3x}.$$

Then determine the inverse function.

**5.J.115.** Is the function

(a)  $y = \frac{\cos x}{x^3};$

(b)  $y = \frac{\cos x}{x^3} + 1;$

(c)  $y = \frac{\cos x}{x^4};$

(d)  $y = \frac{\cos x}{x^4} + 1;$

(e)  $y = \sin x + \tan \frac{x}{2};$

(f)  $y = \ln \frac{1+x}{1-x};$

(g)  $y = \sinh x = \frac{e^x - e^{-x}}{2};$

(h)  $y = \cosh x = \frac{e^x + e^{-x}}{2}$

with the maximal domain odd, even, or neither?

**5.J.116.** Is the function

(a)  $y = \frac{\cos x}{x^3};$

(b)  $y = \frac{\cos x}{x^3} + 1;$

(c)  $y = \frac{\cos x}{x^4};$

(d)  $y = \frac{\cos x}{x^4} + 1;$

(e)  $y = \sin x + \tan \frac{x}{2}$ ;

(f)  $y = \ln \frac{1+x}{1-x}$ ;

(g)  $y = \sinh x = \frac{e^x - e^{-x}}{2}$ ;

(h)  $y = \cosh x = \frac{e^x + e^{-x}}{2}$

with the maximal domain even, odd or neither? ○

**5.J.117.** Determine whether the function

(a)  $y = \sin x \cdot \ln |x|$ ;

(b)  $y = \operatorname{arccotg} x$ ;

(c)  $y = x^8 - \sqrt[5]{3}x^6 + 3x^2 - 6$ ;

(d)  $y = \cos(\pi - x)$ ;

(e)  $y = \frac{\tan x + x}{3 + 7 \cos x}$

with the maximal domain is odd or even. ○

**5.J.118.** Is the function

(a)  $y = \ln(\cos x)$ ;

(b)  $y = \tan(3x) + 2 \sin(6x)$

with maximal domain periodic? ○

**5.J.119.** Draw the graphs of the functions  $f(x) = e^{|x|}$ ,  $x \in \mathbb{R}$ ,  $g(x) = \ln|x|$ ,  $x \in \mathbb{R} \setminus \{0\}$ . ○

**5.J.120.** Draw the graph of the function  $y = 2^{-|x|}$ ,  $x \in \mathbb{R}$ . ○

**5.J.121.** The functions

$$\sinh x = \frac{e^x - e^{-x}}{2}, \quad x \in \mathbb{R}; \quad \cosh x = \frac{e^x + e^{-x}}{2}, \quad x \in \mathbb{R};$$

$$\tanh x = \frac{\sinh x}{\cosh x}, \quad x \in \mathbb{R}; \quad \operatorname{coth} x = \frac{\cosh x}{\sinh x}, \quad x \in \mathbb{R} \setminus \{0\}$$

are called hyperbolic functions. Determine the derivatives of these functions on their domains. ○

**5.J.122.** At any point  $x \in \mathbb{R}$ , calculate the derivative of the area hyperbolic sine (denoted  $\operatorname{arsinh}$ ), the function inverse to the hyperbolic sine  $y = \sinh x$  on  $\mathbb{R}$ . ○

**Remark.** Note, that the inverse functions to the hyperbolic functions  $y = \cosh x$ ,  $x \in [0, +\infty)$ ,  $y = \tanh x$ ,  $x \in \mathbb{R}$  and  $y = \operatorname{coth} x$ ,  $x \in (-\infty, 0) \cup (0, +\infty)$  are called area hyperbolic functions ( $y = \operatorname{arsinh} x$  belongs to them, too). They are denoted  $\operatorname{arcosh}$ ,  $\operatorname{artanh}$ ,  $\operatorname{arcoth}$ , respectively and are defined for  $x \in [1, +\infty)$ ,  $x \in (-1, 1)$ , and  $x \in (-\infty, -1) \cup (1, +\infty)$ , respectively. Let us add that

$$(\operatorname{arcosh} x)' = \frac{1}{\sqrt{x^2 - 1}}, \quad x > 1,$$

$$(\operatorname{artanh} x)' = \frac{1}{1 - x^2}, \quad |x| < 1,$$

$$(\operatorname{arcoth} x)' = \frac{1}{1 - x^2}, \quad |x| > 1.$$

**5.J.123.** Calculate the sum of the series:

$$2 + 1 + \frac{2}{2!} + \frac{1}{3!} + \frac{2}{4!} + \frac{1}{5!} + \frac{2}{6!} + \dots$$

Solutions to the exercises

5.A.7.  $P(x) = (-\frac{3}{5} - \frac{4}{5}i)x^2 + (2 + 3i)x - \frac{3}{5} - \frac{14}{5}i$ .

5.A.15. Sought spline differs from the one in 5.A.14 only in the values of the derivatives at the points  $-1$  and  $1$ . Similarly to the previous task, we get that the parts  $S_1$  and  $S_2$  of our spline have the forms  $S_1(x) = ax^3 + bx^2 + 1$  and  $S_2(x) = -ax^3 + bx^2 + 1$ , respectively, where  $a, b, c, d$  are unknown real parameters. Confronting this with the conditions  $S_1(-1) = 0$ ,  $S_1'(-1) = 1$ ,  $S_2(1) = 0$ , and  $S_2'(1) = 1$  yields the system

$$\begin{aligned} -a + b + 1 &= 0, \\ 3a - 2b &= -1, \end{aligned}$$

having the solution  $a = -3$ ,  $b = -4$ . Hence, the wanted spline is the function

$$S(x) = \begin{cases} -3x^3 - 4x^2 + 1 & \text{pro } x \in [-1, 0], \\ 3x^3 - 4x^2 + 1 & \text{pro } x \in [0, 1]. \end{cases}$$

5.A.16.  $3x^2 - 2x - 4$ .

5.A.17.  $(2x^2 - 5)/3$ ; eg.  $(\frac{2}{3}x^2 - \frac{5}{3})^3$ .

5.A.18.  $a = 1, b = -2, c = 0, d = 1$ .

5.A.19.  $x^3 + x^2 - x + 2$ .

5.A.20. Infinitely many.

5.A.21.  $P(x) = x^3 - 2x^2 + 5x - 3; Q(x) = x^3 - 2x^2 + 3x - 3$ .

5.A.22.  $x^5 - 2x^4 - 5x + 2$ .

5.A.23.  $x^2$ .

5.A.24.  $x^3 - 2x + 5; x^3 - x + 6$ .

5.A.25. Infinitely many.

5.A.26. Eg.  $x^2 - 3x + 6$ .

5.A.27.  $S_1(x) = \frac{1}{2}(x+1)^3 - \frac{3}{2}(x+1) + 1, x \in [-1, 0]; S_2(x) = -\frac{1}{2}x^3 + \frac{3}{2}x^2, x \in [0, 1]$ .

5.A.28.  $S_1(x) = \frac{1}{2}(x+1)^3 - \frac{3}{2}(x+1) + 1, x \in [-1, 0]; S_2(x) = -\frac{1}{2}x^3 + \frac{3}{2}x^2, x \in [0, 1]$ .

5.A.29.  $S_1(x) \equiv x; S_2(x) \equiv x$ .

5.A.30.  $S_1(x) \equiv 1; S_2(x) \equiv 1$ .

5.A.31.  $S_i(x) = x + 3, x \in [-3 + i - 1, -3 + i]; i \in \{1, 2\}$ .

5.A.32.  $S_1(x) = 1 - \frac{11}{20}x + \frac{1}{20}x^3; S_2(x) = \frac{1}{2} - \frac{2}{5}(x-1) + \frac{3}{20}(x-1)^2 - \frac{1}{40}(x-1)^3$ .

5.B.2.

$$\sup A = 6, \quad \inf A = -3;$$

$$\sup B = \frac{1}{4}, \quad \inf B = -1;$$

$$\sup C = 9, \quad \inf C = -9.$$

5.B.3. It can easily be shown that

$$\sup A = \frac{3}{2}, \quad \inf A = 0.$$

5.B.4. Clearly

$$\inf \mathbb{N} = 1, \quad \sup \mathcal{M} = 0, \quad \inf \mathcal{J} = 0, \quad \sup \mathcal{J} = 5.$$

5.B.5. We can, for instance, set

$$M := \mathbb{Z} \setminus \mathbb{N}; \quad N := \mathbb{N}.$$

5.B.6. Consider any singleton (one-element set)  $X \subset \mathbb{R}$ .

5.B.7. The set  $C$  must be a singleton. Thus, let us choose  $C = \{0\}$ , for example. Now we can take  $A = (-1, 0), B = (0, 1)$ .

5.C.5. We have

$$\lim_{n \rightarrow \infty} \left( \frac{1}{n^2} + \frac{2}{n^2} + \dots + \frac{n-2}{n^2} + \frac{n-1}{n^2} \right) = \lim_{n \rightarrow \infty} \left( \frac{1+n-1}{n^2} \cdot \frac{n-1}{2} \right) = \frac{1}{2}.$$

5.C.6. It can easily be shown that

$$\lim_{n \rightarrow \infty} \frac{\sqrt{n^3 - 11n^2 + 2} + \sqrt[5]{n^7 - 2n^5 - n^3} - n + \sin^2 n}{2 - \sqrt[3]{5n^4 + 2n^3 + 5}} = -\infty.$$

5.C.7. The limit is equal to 1.

5.C.8. We can, for instance, set

$$x_n := n, \quad y_n := -n + 1, \quad n \in \mathbb{N}.$$

5.C.9. The answer is  $\pm 1$ .

5.C.10. The result is

$$\limsup_{n \rightarrow \infty} a_n = 1, \quad \liminf_{n \rightarrow \infty} a_n = 0.$$

5.C.11. We have

$$\liminf_{n \rightarrow \infty} \left( (-1)^n \left( 1 + \frac{1}{n} \right)^n + \sin \frac{n\pi}{4} \right) = -e - \frac{\sqrt{2}}{2}.$$

5.D.5. The examined function is continuous on the whole  $\mathbb{R}$ .

5.D.6. The function is continuous at the points  $-\pi, 0, \pi$ ; only right-continuous at the point 2; only left-continuous at the point 3; and continuous from neither side at 1.

5.D.7. It is necessary to set  $f(0) := 0$ .

5.D.8. The function is continuous iff  $p = 2$ .

5.D.9. The correct answer is  $a = 4$ .

5.D.10. It holds that

$$\lim_{x \rightarrow 0^+} \frac{\sin^8 x}{x^3} = \lim_{x \rightarrow -\infty} \frac{\sin^8 x}{x^3} = 0.$$

5.D.13. The only solution is  $x = -1$ .

5.D.14. It has even two roots, because  $P(-1) > 0 > P(0) < 0 < P(1)$  and due to 5.2.19 there is one root in  $(-1, 0)$  and one in  $(0, 1)$ .

5.E.4.  $f'(x) = 2x^{\ln x - 1} \cdot \ln x$ .

5.E.5.  $(\sin x)^{1 + \cos x} (\cot^2 x - \ln(\sin x))$ .

5.E.7.  $\frac{\pi}{6} - \frac{2}{\sqrt{3}} \approx 0.003$ .

5.E.8.  $a \approx \frac{\pi}{4} + 0.01$ ;  $b \approx 4.125$ .

5.E.9. a)  $\frac{1}{2} - \frac{\sqrt{3}\pi}{360}$ ; b)  $\frac{\sqrt{2}}{2} + \frac{\sqrt{2}\pi}{360}$ .

5.E.13. (a) 12 ft/s; (b)  $-59, 5 \text{ ft}^2/\text{s}$ ; (c)  $-1 \text{ rad/s}$ .

5.E.14. The slope of the tangent line of the polynomial  $P$  is given by the derivative of the polynomial. Consider  $P(0)$  and  $P(2)$ . Yes, there is.

5.E.15.  $y = \frac{x_0}{p} x - \frac{x_0^2}{2p}$ .

5.E.16.  $y = 2x$ .

5.E.17.  $y = \sqrt[3]{4}(x+1)$ ;  $y = -\frac{\sqrt[3]{2}}{2}(x+1)$ .

5.E.18.  $y - \frac{\ln 5}{2} = \left( \frac{13}{10} - \frac{\ln 5}{4} \right) (x-1)$ ;  $y - \frac{\ln 5}{2} = \frac{20}{5 \ln 5 - 26} (x-1)$ .

5.E.19.  $\left[ \frac{1}{2}, 2\frac{1}{4} \right]$ .

5.E.20.  $t: y = \frac{x}{6} + \frac{8}{3}$ ;  $n: y = -6x + 15$ ;  $\left[ \frac{3}{2}, \sqrt{\left( \frac{3}{2} \right)^2 - 3 \frac{3}{2} + 11} \right]$ .

5.E.21.  $\pi/4$ .

5.E.22.  $y = 2 - x$ ;  $y = x$ .

5.E.23. The inequalities follow, for instance, from the mean value theorem (attributed to Lagrange) applied to the function  $y = \ln(1+t)$ ,  $t \in [0, x]$ .

5.I.6.  $r = +\infty$ .

5.I.7. 1.

5.I.8. 3.

5.I.9.  $[-1, 1]$ .

5.I.10.  $x \in [2 - \frac{1}{3}, 2 + \frac{1}{3}]$ .

5.I.11. It is.

5.I.12.

- (a) True.
- (b) False.
- (c) False.
- (d) True.

5.I.13.  $1 - \frac{\pi^2}{10^2 \cdot 2} + \frac{\pi^4}{10^4 \cdot 4!}$ .

5.I.14. The error lies in the interval  $(0, 1/200)$ .

5.I.15.  $\sum_{n=0}^{\infty} \frac{e}{n!} (x-1)^n$ ;  $\sum_{n=0}^{\infty} \frac{\ln^n 2}{n!} x^n$ .

5.I.16.  $f(x) = x$ ,  $x \in \mathbb{R}$ ; it is.

5.I.17. It does not.

5.I.18. (a)  $1 - \frac{\pi^2}{18^2 \cdot 2!} + \frac{\pi^4}{18^4 \cdot 4!}$ ; (b)  $\frac{1}{2} - \frac{1}{5 \cdot 2^5}$ .

5.I.19.  $\sum_{n=0}^{\infty} \frac{1}{(2n+1)n!} x^{2n+1}$ .

5.I.20.  $a > 1$ .

5.I.21.  $[-\sqrt[3]{2}, \sqrt[3]{2}]$ .

5.I.22. For  $x \in [-1, 1]$ .

5.I.23.  $x > 2$ .

5.I.24. The series is absolutely convergent.

5.I.25.  $\ln(3/2)$ .

5.I.26.  $\frac{x(1-x)}{(1+x)^3}$ .

5.I.27. (a)  $\frac{1}{2} \ln \frac{1+x}{1-x}$ ; (b)  $\frac{1+x}{(1-x)^3}$ .

5.I.28.  $2/9$ .

5.I.29.  $x e^{\frac{x^3}{2}}$ .

5.J.1.  $x^4 + 2x^3 - x^2 + x - 2$ .

5.J.2.  $x^4 + 2x^3 - 2x^2 + x + 2$ .

5.J.3.  $x^4 + 3x^3 - 3x^2 - x - 1$ .

5.J.4. For every  $\varepsilon > 0$ , it suffices to assign to the  $\varepsilon$ -neighborhood of the point  $-2$  the  $\delta$ -neighborhood of the point 0 given by

$$\varepsilon \mapsto \delta, \quad \delta = \varepsilon,$$

and without loss of generality, we can assume that  $\varepsilon \leq 1$ . Since if  $\varepsilon > 1$ , we can set  $\delta = 1$ .

5.J.5. Existence of the limit and the equality

$$\lim_{x \rightarrow -1} \frac{(1+x)^2 - 3}{2} = -\frac{3}{2}$$

follows from the choice  $\delta := \varepsilon$  for  $\varepsilon \in (0, 1)$ .

5.J.6. Since  $-(x-2)^4 < x$  for  $x < 0$ , we get  $3(x-2)^4/2 > -x$  for  $x < 0$ .

5.J.7. As

$$\lim_{x \rightarrow 0^+} \arctan \frac{1}{x} = \frac{\pi}{2}, \quad \lim_{x \rightarrow 0^-} \arctan \frac{1}{x} = -\frac{\pi}{2},$$

the considered limit does not exist.

5.J.8. The former limit equals  $+\infty$ , the latter does not exist.

**5.J.9.** The limit can be determined in many ways. For instance:

$$\begin{aligned}\lim_{x \rightarrow 0} \frac{\tan x - \sin x}{\sin^3 x} &= \lim_{x \rightarrow 0} \left( \frac{\tan x - \sin x}{\sin^3 x} \cdot \frac{\cot x}{\cot x} \right) \\ &= \lim_{x \rightarrow 0} \frac{1 - \cos x}{\cos x \cdot \sin^2 x} = \lim_{x \rightarrow 0} \frac{1 - \cos x}{\cos x (1 - \cos^2 x)} \\ &= \lim_{x \rightarrow 0} \frac{1}{\cos x (1 + \cos x)} = \frac{1}{2}.\end{aligned}$$

**5.J.10.** We have

$$\lim_{x \rightarrow \pi/6} \frac{2 \sin^3 x + 7 \sin^2 x + 2 \sin x - 3}{2 \sin^3 x + 3 \sin^2 x - 8 \sin x + 3} = \lim_{x \rightarrow \pi/6} \frac{\sin x + 1}{\sin x - 1} = -3.$$

**5.J.11.** We have

$$\lim_{x \rightarrow 1} \frac{x^m - 1}{x^n - 1} = \frac{m}{n}.$$

**5.J.12.** After multiplying by the fraction

$$\frac{\sqrt{x^2 + x} + x}{\sqrt{x^2 + x} + x},$$

it follows that

$$\lim_{x \rightarrow +\infty} \left( \sqrt{x^2 + x} - x \right) = \frac{1}{2}.$$

**5.J.13.** We have

$$\lim_{x \rightarrow +\infty} \left( x \sqrt{1 + x^2} - x^2 \right) = \frac{1}{2}.$$

**5.J.14.** We have

$$\lim_{x \rightarrow 0} \frac{\sqrt{2} - \sqrt{1 + \cos x}}{\sin^2 x} = \frac{\sqrt{2}}{8}.$$

**5.J.15.** By extending the given fraction, we obtain

$$\lim_{x \rightarrow 0} \frac{\sin(4x)}{\sqrt{x+1} - 1} = 8.$$

**5.J.16.** We have

$$\lim_{x \rightarrow 0^-} \frac{\sqrt{1 + \tan x} - \sqrt{1 - \tan x}}{\sin x} = 1.$$

**5.J.17.**

$$\lim_{x \rightarrow -\infty} \frac{2^x + \sqrt{1 + x^2} - x^9 - 7x^5 + 44x^2}{3^x + \sqrt[5]{6x^6 + x^2} - 18x^5 - 592x^4} = \frac{7}{18}.$$

**5.J.18.** The statement is false. For example, consider

$$f(x) := \frac{1}{x}, \quad x \in (-\infty, 0); \quad g(x) := x, \quad x \in \mathbb{R}.$$

**5.J.19.**

$$\lim_{n \rightarrow \infty} \left( \frac{n}{n+5} \right)^{2n-1} = e^{-10}.$$

**5.J.20.**  $-\frac{1}{6}$ .

**5.J.21.**  $f'(x) < 0, x > e$ .

**5.J.22.** The function has a local maximum at the point  $x_1 = e^{-2}$ . It has a local minimum at the point  $x_2 = 1$ .

**5.J.23.** No: if  $a = \sqrt{2}/2$ , there is only a local extremum at the point.

**5.J.24.**  $2 = e^{\frac{1}{e}} - \ln \frac{1}{e}$ .

**5.J.25.**  $\frac{1}{\sqrt[3]{e}}$ .

**5.J.26.**  $4 = p(-1) = p(2), -16 = p(-3)$ .

**5.J.27.** (a)  $v(0) = 6$  m/s; (b)  $t = 3$  s,  $s(3) = 16$  m; (c)  $v(4) = -2$  m/s,  $a(4) = -2$  m/s<sup>2</sup>.

$$5.J.28. f'(x_0) = \frac{1}{2\sqrt{x_0}}.$$

5.J.29. It does not because the one-sided derivatives differ (specifically:  $\pi/2$  from the right and  $-\pi/2$  from the left).

5.J.30. It does.

5.J.31. It does not.

$$5.J.32. f(x) := |x - 5| + |x - 9|.$$

5.J.33. Let  $f = g = 1$  at the rational numbers and  $f = g = -1$  at the irrational numbers.

$$5.J.34. (a) x^2 \sin x; (b) \cos(\sin x) \cdot \cos x; (c) \frac{3x^2+2}{x^3+2x} \cos(\ln(x^3+2x)); (d) \frac{2(1-2x)}{(1-x+x^2)^2}.$$

$$5.J.35. (a) \frac{7}{8} x^{-\frac{1}{8}}; (b) \operatorname{cosec} x = \frac{1}{\sin x}.$$

$$5.J.36. \cos x \cdot \cos(\sin x) \cdot \cos(\sin(\sin x)).$$

$$5.J.37. f'(x) = \frac{1}{\sqrt{1+2x-x^2}} + 1, x \in (1 - \sqrt{2}, 1 + \sqrt{2}).$$

$$5.J.38. \frac{\cos x}{3\sqrt[3]{\sin^2 x}}.$$

$$5.J.39. \frac{1+2x^2}{\sqrt{1+x^2}} + x^2 e^x.$$

$$5.J.40. -8.$$

$$5.J.41. \frac{2x^2}{1-x^6} \sqrt[3]{\frac{1+x^3}{1-x^3}}.$$

$$5.J.42. \ln^2(x + \sqrt{1+x^2}), x \in \mathbb{R}.$$

$$5.J.43. f'(x) = -\frac{1}{x} (\log_x e)^2, x > 0, x \neq 1.$$

$$5.J.44. [f(x)g(x)h(x)k(x)]' = f'(x)g(x)h(x)k(x) + f(x)g'(x)h(x)k(x) + f(x)g(x)h'(x)k(x) + f(x)g(x)h(x)k'(x).$$

$$5.J.45. \frac{x^3(x+1)^2 \sqrt[3]{x+2}}{(x+3)^2} \left( \frac{3}{x} + \frac{2}{x+1} + \frac{1}{3(x+2)} - \frac{2}{x+3} \right).$$

5.J.52. The inscribed rectangle has sides of lengths  $x$ ,  $\sqrt{3}/2(a-x)$ , thus its area is  $\sqrt{3}/2(a-x)x$ . The maximum occurs for  $x = a/2$ , hence the greatest possible area is  $(\sqrt{3}/8)a^2$ .

$$5.J.53. 4 \text{ m} \times 4 \text{ m} \times 2 \text{ m}.$$

$$5.J.54. 28 = 24 + 4.$$

$$5.J.55. a = 1.$$

$$5.J.56. 2\sqrt{5}r.$$

5.J.57. It is the square with sides of length  $c$ .

$$5.J.58. h = \frac{4}{3}R, r = \frac{2\sqrt{2}}{3}R.$$

5.J.59. It is the equilateral triangle (with area  $\sqrt{3}p^2/36$ ).

$$5.J.60. [2, -1/2], [-2, -1/2].$$

$$5.J.61. h = 2r.$$

5.J.62. The closest point is  $[1, 1]$ , the distance then  $2\sqrt{2}$ .

5.J.63. The closest point is  $[-1, 1]$ , distance  $3\sqrt{2}$ .

5.J.64.  $t = 1, 5s$ , the distance between will be  $\sqrt{5}$  units.

5.J.65. It will happen at the time  $t = \frac{5}{13} s$ , the distance being  $\frac{\sqrt{13}}{13}$  units.

5.J.66.  $P = \pi r v + \pi r^2 \implies v = \frac{P - \pi r^2}{\pi r} \implies V = \frac{1}{3}r(P - \pi r^2)$ . The extremum is at  $r = \sqrt{\frac{P}{3\pi}}$ , the substitution gives  $V = \frac{2\pi}{3} \text{ cm}^3$ .

5.J.67. At about 3 414 products per day.

5.J.68. Triple use of l'Hospital's rule gives

$$\lim_{x \rightarrow 0^-} \frac{\sin x - x}{x^3} = -\frac{1}{6}.$$

$$5.J.69. 2/\pi.$$

5.J.70.

$$\lim_{x \rightarrow \frac{\pi}{2}^-} \left( \frac{\pi}{2} - x \right) \tan x = 1.$$

5.J.71.

$$\lim_{x \rightarrow +\infty} \left( \left( 3^{\frac{1}{x}} - 2^{\frac{1}{x}} \right) x \right) = \ln \frac{3}{2}.$$

5.J.72.  $1/2$ .

5.J.73. We have

$$\lim_{x \rightarrow +\infty} \left( \cos \frac{2}{x} \right)^{x^2} = e^{-2}.$$

5.J.74. By applying l'Hospital's rule twice, one obtains

$$\lim_{x \rightarrow 0} (1 - \cos x)^{\sin x} = e^0 = 1.$$

5.J.75. In both cases, the result is  $e^\alpha$ .

5.J.76. The limit is easily calculated by l'Hospital's rule, for instance.

5.J.89.  $2a^2$ ;  $4a(2 + \sqrt{2})$ .

5.J.90.  $\pi/2$ .

5.J.91.  $x = \frac{\pi}{6} + k\pi$ ,  $x = \frac{5\pi}{6} + k\pi$ ,  $k \in \mathbb{Z}$ .

5.J.92. 5.

5.J.93.  $+\infty$ .

5.J.94.  $3/2$ .

5.J.95. (a) 3; (b)  $9/4$ .

5.J.96.  $1/2$ .

5.J.97. (a)  $3/4$ ; (b)  $1/4$ .

5.J.98.  $-1/2$ .

5.J.99.  $11/18$ .

5.J.100.  $s/2$ ;  $3s/2$  ( $s = \ln 2$ ).

5.J.101. It does.

5.J.102. It suffices to consider the necessary condition for convergence, namely  $\lim_{n \rightarrow \infty} a_n = 0$ .

5.J.103.  $\alpha > 0$ ;  $\beta \in \{-2, -1, 0, 1, 2\}$ ;  $\gamma \in (-\infty, -1) \cup (1, +\infty)$ .

5.J.104. It is absolutely convergent.

5.J.105. The limit is  $1/2$ .

5.J.106.  $A \in [0, 1)$ .

5.J.107. The value of the given series is finite – the series converges.

5.J.108. For example:  $a_n = n/3$ ,  $b_n = n/2$ ,  $n \in \mathbb{N}$ .

5.J.109. The former series converges absolutely; the latter converges conditionally.

5.J.110. It does.

5.J.111.  $p \in \mathbb{R}$ .

5.J.112.  $\mathbb{R}$ .

5.J.113.  $(1, e]$ .

5.J.114.  $(-\infty, \frac{2}{3}) \cup (\frac{2}{3}, +\infty)$ ;  $(-\infty, -\frac{1}{3}) \cup (-\frac{1}{3}, +\infty)$ ;  $y = \frac{2x+1}{3x+1}$ ,  $x \neq -\frac{1}{3}$ .

5.J.115. (a) yes; (b) no; (c) no; (d) no; (e) yes; (f) yes; (g) yes; (h) no.

5.J.116. (a) no; (b) no; (c) yes; (d) yes; (e) no; (f) no; (g) no; (h) yes.

5.J.117. The functions (a), (e) are odd; the functions (c), (d) are even.

5.J.118. It is periodic. The prime period is (a)  $2\pi$ ; (b)  $\pi/3$ .

5.J.119. The functions  $f$  and  $g$  are even, so it suffices to consider the graphs of the functions  $y = e^x$ ,  $x \in [0, +\infty)$  and  $y = \ln x$ ,  $x \in (0, +\infty)$ .

5.J.120. The given function is even, so to draw its graph, it suffices to know the graph of the function  $y = 2^x$ ,  $x \in (-\infty, 0]$ .

5.J.121.  $(\sinh x)' = \cosh x$ ;  $(\cosh x)' = \sinh x$ ;  $(\tanh x)' = \frac{1}{\cosh^2 x}$ ;  $(\coth x)' = -\frac{1}{\sinh^2 x}$ .

5.J.122.  $\frac{1}{\sqrt{1+x^2}}$ .

**5.J.123.** Consider the series with the expansions of the functions  $\sinh$  and  $\cosh$  into power series. The result is  $\sinh(1) + 2 \cosh(1)$ .

## Differential and integral calculus

*we already have the menagerie, but what shall we do with it?*  
*– we'll learn to control it...*

### A. Derivatives of higher orders

First we'll introduce a convention for denoting the derivatives of higher orders: we'll denote the second derivative of function  $f$  of one variable by  $f''$  or  $f^{(2)}$ , derivatives of third or higher order only by  $f^{(3)}$ ,  $f^{(4)}$ , ...  $f^{(n)}$ . For remembrance, we'll start with a slightly cunning problem using “only” first derivatives.

**6.A.1.** Determine the following derivatives:

- i)  $(x^2 \cdot \sin x)''$ ,
- ii)  $(x^x)''$ ,
- iii)  $\left(\frac{x}{\ln x}\right)^{(3)}$ ,
- iv)  $(x^n)^{(n)}$ ,
- v)  $(\sin x)^{(n)}$ .

**Solution.** (a)  $(x^2 \cdot \sin x)'' = (2x \sin x + x^2 \cos x)'$   
 $= 2 \sin x + 4x \cos x - x^2 \sin x$ .

(b)  $(x^x)'' = [(1 + \ln x)x^x]' = x^{x-1} + x^x(1 + \ln x)^2$ .

(c)  $\left(\frac{x}{\ln x}\right)^{(3)} = \frac{1}{x^2(\ln x)^2} - \frac{6}{x^2(\ln x)^4}$ .

(d)  $(x^n)^{(n)} = [(x^n)']^{(n-1)} = (nx^{n-1})^{(n-1)} = \dots = n!$ .

(e)  $(\sin x)^{(n)} = \operatorname{Re}(i^n \sin x) + \operatorname{Im}(i^n \cos x)$ . □

In the previous chapter, we were working either with an extremely large class of functions (for example, all continuous, all differentiable), or with only particular functions, (for example exponential, trigonometric, polynomial). However we had very few tools. We indicated how to discuss the local behaviour of functions near a given point by linear approximation. We learned how to measure instantaneous changes by differentiation.

Now we derive several results that will allow us to work with functions more easily when modeling real problems. We also deal with the task of summing infinitely many “infinitely small” changes, in particular, how to “integrate”. In the last part of the chapter we come back to series of functions and complete several missing steps in the argumentation so far. We also add useful techniques, how to deal with extra parameters in the functions, and we introduce some further integration concepts briefly.

### 1. Differentiation

**6.1.1. Higher order derivatives.** If the first derivative  $f'(x)$  of a function of one real variable has a derivative  $(f')'(x_0)$  at the point  $x_0$ , we say that the *second derivative* of function  $f$  (or second order derivative) exists. Then we write  $f''(x_0) = (f')'(x_0)$  or  $f^{(2)}(x_0)$ . A function  $f$  is *two times differentiable* on some interval, if it has a second derivative at each of its points. Derivatives of higher orders are defined inductively:

#### $k$ TIMES DIFFERENTIABLE FUNCTIONS

A function  $f$  of one real variable is *differentiable  $k$  times* at the point  $x_0$  for some natural number  $k > 1$ , if it is differentiable  $(k - 1)$  times on some neighbourhood of the point  $x_0$  and its  $(k - 1)$ -st derivative has a derivative at the point  $x_0$ . We write  $f^{(k)}(x)$  for the  $k$ -th derivative of the function  $f(x)$ .

If derivatives of all orders exist on an interval  $A$ , we say the function  $f$  is *smooth* or *infinitely differentiable* on  $A$ .

We use the notation *class of functions*  $C^k(A)$  for functions with continuous  $k$ -th derivative on the interval  $A$ , where  $k$  can attain values  $0, 1, \dots, \infty$ . Often we write only  $C^k$ , if the domain is known from the context. When  $k = 0$ ,  $C^0$  means continuous functions.

**6.A.2.** Differentiate the expression

$$\frac{\sqrt[4]{x-1} \cdot (x+2)^3}{e^x(x+132)^2}$$

of variable  $x > 1$ .

**Solution.** We'll solve this problem using the so called logarithmic differentiation. Let  $f$  be an arbitrary positive function. We know that

$$[\ln f(x)]' = \frac{f'(x)}{f(x)}, \quad \text{tj.} \quad f'(x) = f(x) \cdot [\ln f(x)]',$$

if the derivative  $f'(x)$  exists. The usefulness of this formula is given by the fact that for some functions, it's easier to differentiate their logarithm than themselves. Such is the expression in our problem. We'll obtain

$$\begin{aligned} & \left( \frac{\sqrt[4]{x-1} \cdot (x+2)^3}{e^x(x+132)^2} \right)' \\ &= \frac{\sqrt[4]{x-1} \cdot (x+2)^3}{e^x(x+132)^2} \cdot \left[ \ln \frac{\sqrt[4]{x-1} \cdot (x+2)^3}{e^x(x+132)^2} \right]' \\ &= \frac{\sqrt[4]{x-1} \cdot (x+2)^3}{e^x(x+132)^2} \\ & \quad \cdot \left[ 3 \ln(x+2) + \frac{1}{4} \ln(x-1) - x \ln e - 2 \ln(x+132) \right]' \\ &= \frac{\sqrt[4]{x-1} \cdot (x+2)^3}{e^x(x+132)^2} \left[ \frac{3}{x+2} + \frac{1}{4(x-1)} - 1 - \frac{2}{x+132} \right]. \end{aligned}$$

□

**6.A.3.** Let  $n \in \mathbb{N}$  be arbitrary. Find the  $n$ -th derivative of function

$$y = \ln \frac{1+x}{1-x}, \quad x \in (-1, 1).$$

**Solution.** With respect of the equality

$$\ln \frac{1+x}{1-x} = \ln(1+x) - \ln(1-x), \quad x \in (-1, 1),$$

we'll define an auxiliary function

$$f(x) := \ln(ax+1), \quad x \in (-1, 1), \quad a = \pm 1.$$

For  $x \in (-1, 1)$  we can easily (sequentially) compute

$$\begin{aligned} f'(x) &= \frac{a}{ax+1}, \\ f''(x) &= \frac{-a^2}{(ax+1)^2}, \\ f^{(3)}(x) &= \frac{2a^3}{(ax+1)^3}, \\ f^{(4)}(x) &= \frac{-6a^4}{(ax+1)^4}. \end{aligned}$$

Based on these results we can figure out that

$$(1) \quad f^{(n)}(x) = \frac{(-1)^{n-1} (n-1)! a^n}{(ax+1)^n}, \quad x \in (-1, 1), \quad n \in \mathbb{N}.$$

We'll verify the validity of this formula by mathematical induction. It holds for  $n = 1, 2, 3, 4$ , so it suffices to show that its validity for  $k \in \mathbb{N}$  implies its validity for  $k + 1$ . Because the direct computation yields

We illustrate the concept of higher order derivatives with polynomials. Because the derivative of a polynomial is a polynomial with the degree one less than the original one, then after a finite number of differentiations we obtain the zero polynomial. If  $k$  is the degree of the polynomial, then exactly  $k + 1$  differentiations yields zero. Then derivatives of all orders exist, hence  $f \in C^\infty(\mathbb{R})$ .

In the spline construction, see 5.1.9, we took care that the resulting functions belong to the class  $C^2(\mathbb{R})$ . Their third derivatives are piece-wise constant functions. That is why the splines do not belong to  $C^3(\mathbb{R})$ , even though all their higher order derivatives are zero in all of the inner points of all single intervals in the interpolation. Think this example through in detail!

The next assertion is a combinatorial corollary of Leibniz's rule for differentiation of a product of two functions:

**Lemma.** If two functions  $f$  and  $g$  have derivatives of order  $k$  at the point  $x_0$ , then their product also has a derivative of order  $k$  and the following equality holds:

$$(f \cdot g)^{(k)}(x_0) = \sum_{i=0}^k \binom{k}{i} f^{(i)}(x_0) g^{(k-i)}(x_0).$$

**PROOF.** For  $k = 0$ , the statement is trivial. For  $k = 1$  it is Leibniz's product rule. Suppose equality holds for some  $k$ . Differentiate the right hand side and use Leibniz's rule to obtain the expression

$$\sum_{i=0}^k \binom{k}{i} \left( f^{(i+1)}(x_0) g^{(k-i)}(x_0) + f^{(i)}(x_0) g^{(k-i+1)}(x_0) \right).$$

In this new sum, the sum of orders of the derivatives of products in all summands is  $k + 1$  and the coefficients of  $f^{(j)}(x_0) g^{(k+1-j)}(x_0)$  are the sums of binomial coefficients  $\binom{k}{j-1} + \binom{k}{j} = \binom{k+1}{j}$ . □

**6.1.2. The meaning of second derivative.** We have already

seen that the first derivative of a function is its linear approximation in the neighbourhood of a given point. The sign of a nonzero derivative determines whether the function is increasing or decreasing at the point  $x_0$ . The points where the first derivative is zero are called the *critical points* or *stationary points* of the given function.

If  $x_0$  is a critical point of function  $f$ , there are several possibilities for the behaviour of the function  $f$  in the neighbourhood of  $x_0$ . Consider the behaviour of the function  $f(x) = x^n$  in the neighbourhood of zero for different

$$f^{(k+1)}(x) = \left( \frac{(-1)^{k-1}(k-1)!a^k}{(ax+1)^k} \right)' = \frac{(-1)^{k-1}(k-1)!a^k(-k)a}{(ax+1)^{k+1}} = \frac{(-1)^k k! a^{k+1}}{(ax+1)^{k+1}},$$

(1) holds for all  $n \in \mathbb{N}$ . Then

$$\ln^{(n)}(1+x) = \frac{(-1)^{n-1}(n-1)!}{(x+1)^n}, \quad \ln^{(n)}(1-x) = -\frac{(n-1)!}{(-x+1)^n}, \quad x \in (-1, 1).$$

From here we obtain the result

$$\left( \ln \frac{1+x}{1-x} \right)^{(n)} = (n-1)! \left( \frac{1}{(1-x)^n} - \frac{(-1)^n}{(1+x)^n} \right)$$

pro  $x \in (-1, 1)$  a  $n \in \mathbb{N}$ . □

**6.A.4.** Determine the second derivative of function  $y = \operatorname{tg} x$  on its whole domain, i.e. for  $\cos x \neq 0$ . ○

**6.A.5.** Determine the fifth and the sixth derivative of the polynomial  $p(x) = (3x^2 + 2x + 1) \cdot (2x - 6) \cdot (2x^2 - 5x + 9)$ ,  $x \in \mathbb{R}$ . ○

**6.A.6.** With shortcuts determine the 12th derivative of function

$$y = e^{2x} + \cos x + x^{10} - 5x^7 + 6x^3 - 7x + 3, \quad x \in \mathbb{R}. \quad \text{○}$$

**6.A.7.** Write the 26th derivative of function

$$f(x) = \sin x + x^{23} - x^{18} + 5x^{11} - 3x^8 + e^{2x}, \quad x \in \mathbb{R}. \quad \text{○}$$

**6.A.8.** Let  $f$  be a given function and let  $z$  be a point such that

$$f(z) = 0, \quad f'(z) = 0, \quad f''(z) = 0, \quad f^{(3)}(z) = 1.$$

Which of the following statements:

- (a) the tangent line to the graph of function  $f$  at point  $[z, f(z)]$  is the  $x$  axis;
  - (b) the function  $f$  is not a polynomial of degree two;
  - (c) the function  $f$  is increasing at point  $z$ ;
  - (d) the function  $f$  does not have a strict local minimum at point  $z$ ;
  - (e) the point  $z$  is an inflective point of function  $f$
- are necessarily true? ○

**6.A.9.** Let a movement of a solid (a trajectory of a mass point) be described by function

$$s(t) = -(t-3)^2 + 16, \quad t \in [0, 7]$$

in units m, s. Determine

- (a) the initial (i.e. at time  $t = 0$  s) velocity of the solid;
- (b) the time and location at which the solid has zero velocity;
- (c) the velocity and the acceleration of the solid at time  $t = 4$  s.

Recall that velocity is the derivative of trajectory and acceleration is the derivative of velocity. ○

$n$ . For odd  $n > 0$ ,  $f(x)$  will be increasing on all  $\mathbb{R}$ , while for even  $n$  it will be decreasing for  $x < 0$  and increasing for  $x > 0$ . In the latter case, the function will attain its minimal value among points in the (sufficiently small) neighbourhood of  $x_0 = 0$ .

The same argument applies to the function  $f'$ . If the second derivative is nonzero, its sign determines the behaviour of the first derivative. At the critical point  $x_0$  the derivative  $f'(x)$  is increasing if the second derivative is positive and decreasing if the second derivative is negative. If increasing, it is necessarily negative to the left of the critical point and positive to the right of it. In that case,  $f$  is decreasing to the left of the critical point and increasing to the right of it. So  $f$  attains its minimal value among all points from a (sufficiently small) neighbourhood of  $x_0$  at  $x_0$ .

On the other hand, if the second derivative is negative at  $x_0$ , the first derivative is decreasing. Thus the first derivative is negative to the left of  $x_0$  and positive to the right of it.  $f$  then attains its maximal value at  $x_0$  among all values in a neighbourhood of  $x_0$ .

A function which is differentiable on  $(a, b)$  and continuous on  $[a, b]$  has an absolute maximum and minimum of this interval. Both can be attained only at the boundary of the interval or at a point where the derivative is zero. Thus critical points may be sufficient for finding extremes. Second derivatives help to determine the type of extreme, if nonzero.

For a more precise discussion of the latter phenomena we consider higher order polynomial approximations of the functions. We return to the qualitative study of the behaviour of functions later on.

**6.1.3. Taylor expansion.** As a surprisingly easy use of "Rolle's theorem we derive an extremely important result. It is called the *Taylor expansion with remainder*<sup>1</sup>.

Consider the power series centered at  $a$ ,

$$S(x) = \sum_{n=0}^{\infty} a_n(x-a)^n.$$

Differentiate it repeatedly, to get the power series

$$S^{(k)}(x) = \sum_{n=k}^{\infty} n(n-1)\dots(n-k+1)a_n(x-a)^{n-k}.$$

Put  $x = a$ . Then  $S^{(k)}(a) = k!a_k$ . We can read the last statement as an equation for  $a_k$  and rewrite the original series as

$$S(x) = \sum_{n=0}^{\infty} \frac{1}{k!} S^{(k)}(a)(x-a)^n.$$

(NB. A power series can be differentiated term after term. This is proved later.)

<sup>1</sup>Brook Taylor was an English mathematician (1685-1731) best known for his formalization of the polynomial approximations of functions, recognized by Lagrange as the "main foundation of differential calculus"

**Taylor expansions.** We necessarily need the derivatives of higher orders to determine the Taylor expansion of a given function.

**6.A.10.** Determine the Taylor expansions  $T_x^k$  (of  $k$ -th order at point  $x$ ) of the following functions:

- i)  $T_0^3$  of function  $\sin x$ ,
- ii)  $T_1^3$  of function  $\frac{e^x}{x}$ .

**Solution.** (i) We'll compute the values of the first, second and third derivative of function  $f = \sin$  at point 0:  $f'(0) = \cos(0) = 1$ ,  $f^{(2)}(0) = -\sin(0) = 0$ ,  $f^{(3)}(0) = -\cos(0) = -1$ , also  $f(0) = 0$ . Thus the Taylor expansion of the third order of function  $\sin(x)$  at point 0 is

$$T_0^3(\sin(x)) = x - \frac{1}{6}x^3.$$

(ii) Again  $f(1) = e$ ,

$$\begin{aligned} f'(1) &= \left. \frac{e^x}{x} - \frac{e^x}{x^2} \right|_{x=1} = 0 \\ f^{(2)}(1) &= \left. \frac{e^x}{x} - 2\frac{e^x}{x^2} + \frac{2e^x}{x^3} \right|_{x=1} = e \\ f^{(3)}(1) &= \left. \frac{e^x}{x} - 3\frac{e^x}{x^2} + \frac{6e^x}{x^3} - \frac{6e^x}{x^4} \right|_{x=1} = -2e \end{aligned}$$

Thus we get the Taylor expansion of third order of function  $\frac{e^x}{x}$  at point 1:

$$T_1^3\left(\frac{e^x}{x}\right) = e + \frac{e}{2}(x-1)^2 - \frac{e}{3}(x-1)^3 = e\left(-\frac{x^3}{3} + \frac{3x^2}{2} - 2x + \frac{5}{6}\right).$$

□

**6.A.11.** Determine the Taylor polynomial  $T_0^6$  of function  $\sin$  and using theorem (6.1.3), estimate the error of the polynomial at point  $\pi/4$ .

**Solution.** Analogously to the previous example, we compute

$$T_0^6(\sin(x)) = x - \frac{1}{6}x^3 + \frac{1}{120}x^5.$$

Using the theorem 6.1.3, we then estimate the size of the remainder (error)  $R$ . According to the theorem, there exists  $c \in (0, \frac{\pi}{4})$  such that

$$R(\pi/4) = \left| \frac{-\cos(c)\pi^7}{7!4^7} \right| < \frac{1}{7!} \doteq 0,0002.$$

□

**6.A.12.** Find the Taylor polynomial of third order of function

$$y = \arctg x, \quad x \in \mathbb{R}$$

Suppose  $f$  is a smooth function instead of a power series. We search for a good approximation by polynomials in the neighbourhood of a given point  $a$ .

TAYLOR POLYNOMIAL OF FUNCTION  $f$

For a  $k$  times differentiable (real or complex valued) function  $f$  of one real variable, define its *Taylor polynomial of  $k$ -th degree* centered at  $a$  by the formula

$$T_{k,a}f(x) = f(a) + f'(a)(x-a) + \frac{1}{2}f''(a)(x-a)^2 + \frac{1}{6}f^{(3)}(a)(x-a)^3 + \dots + \frac{1}{k!}f^{(k)}(a)(x-a)^k.$$

The mean value theorem is used to show how good the approximation to  $f$  it is.

TAYLOR EXPANSION WITH A REMAINDER

**Theorem.** Let  $f(x)$  be a function that is  $k$  times differentiable on the interval  $(a, b)$  and continuous on  $[a, b]$ . Then for all  $x \in (a, b)$  there exists a number  $c \in (a, x)$  such that

$$\begin{aligned} f(x) &= f(a) + f'(a)(x-a) + \dots \\ &+ \frac{1}{(k-1)!}f^{(k-1)}(a)(x-a)^{k-1} + \frac{1}{k!}f^{(k)}(c)(x-a)^k \\ &= T_{k-1,a}f(x) + \frac{1}{k!}f^{(k)}(c)(x-a)^k. \end{aligned}$$

**PROOF.** For fixed  $x$  define the remainder  $R$ , by

$$f(x) = T_{k-1,a}f(x) + R.$$

Then  $R = \frac{1}{k!}r(x-a)^k$  for a suitable number  $r$  (dependent on  $x$ ). Consider the function  $F(\xi)$  defined by

$$F(\xi) = \sum_{j=0}^{k-1} \frac{1}{j!}f^{(j)}(\xi)(x-\xi)^j + \frac{1}{k!}r(x-\xi)^k.$$

By the Leibniz rule, its derivative (here  $x$  is considered as a constant parameter) is

$$\begin{aligned} F'(\xi) &= f'(\xi) + \sum_{j=1}^{k-1} \left( \frac{1}{j!}f^{(j+1)}(\xi)(x-\xi)^j - \frac{1}{(j-1)!}f^{(j)}(\xi)(x-\xi)^{j-1} \right) \\ &\quad - \frac{1}{(k-1)!}r(x-\xi)^{k-1} \\ &= \frac{1}{(k-1)!}f^{(k)}(\xi)(x-\xi)^{k-1} - \frac{1}{(k-1)!}r(x-\xi)^{k-1} \\ &= \frac{1}{(k-1)!}(x-\xi)^{k-1}(f^{(k)}(\xi) - r), \end{aligned}$$

because the expressions in the sum cancel each other out sequentially. Now it suffices to notice that  $F(a) = F(x) = f(x)$  (recall that  $x$  is an arbitrarily chosen but fixed number from the interval  $(a, b)$ ). According to Rolle's theorem there

at point  $x_0 = 1$ .

○ exists a number  $c$ ,  $a < c < x$  such that  $F'(c) = 0$ . That is the desired relation. □

**6.A.13.** Determine the Taylor expansion of third order at point  $x_0 = 0$  of function

- (a)  $y = \frac{1}{\cos x}$ ;
- (b)  $y = e^{-\frac{x^2}{2}}$ ;
- (c)  $y = \sin(\sin x)$ ;
- (d)  $y = \operatorname{tg} x$ ;
- (e)  $y = e^x \sin x$

defined in a certain neighbourhood of point  $x_0$ .

$$\ln(1+x) \approx x - \frac{x^2}{2}$$

for  $x \in (-1, 0)$ .

○

**6.A.16.** Write the Taylor polynomial of fourth degree of function  $y = \sin x$ ,  $x \in \mathbb{R}$  centered at the origin. Using this polynomial, approximately compute  $\sin 1^\circ$  and determine the limit

$$\lim_{x \rightarrow 0^+} \frac{x \sin x - x^2}{x^4}.$$

○

**6.A.17.** Determine the Taylor polynomial centered at the origin of degree at least 8 of function  $y = e^{2x}$ ,  $x \in \mathbb{R}$ .

○

**6.A.18.** Express the polynomial  $x^3 - 2x + 5$  as a polynomial in variable  $u = x - 1$ .

○

We'll show some more interesting examples of using the differential calculus. First though, we'll mention the Jensen inequality, which discusses convex and concave functions and which we'll use later.

**6.A.19. Jensen inequality.** For a strictly convex function  $f$  on interval  $I$  and for arbitrary points  $x_1, \dots, x_n \in I$  and real numbers  $c_1, \dots, c_n > 0$  such that  $c_1 + \dots + c_n = 1$ , the inequality

$$f\left(\sum_{i=1}^n c_i x_i\right) \leq \sum_{i=1}^n c_i f(x_i)$$

holds, with equality occurring if and only if  $x_1 = \dots = x_n$ .

**Solution.** Could be proven easily by induction: for  $n = 2$  it is just the definition of the convex function, for the induction

A special case of the last theorem is the mean value theorem, as an approximation by Taylor series of degree zero. See (1).

**6.1.4. Estimations for Taylor expansions.** A simple case of a Taylor expansion is when  $f$  is a polynomial:

$$f(x) = a_n x^n + a_{n-1} x^{n-1} + \dots + a_1 x + a_0, \quad a_n \neq 0.$$

Because the  $(n + 1)$ -th derivative  $f$  is identically zero, the Taylor polynomial of degree  $n$  has zero remainder, therefore for each  $x_0 \in \mathbb{R}$

$$f(x) = f(x_0) + f'(x_0)(x-x_0) + \dots + \frac{1}{n!} f^{(n)}(x_0)(x-x_0)^n.$$

We can compute all the derivatives easily (for example the last term is always of the form  $a_n(x - x_0)^n$ ).

This result is a very special case of error estimation in Taylor expansion with the remainder. We know in advance that the remainder can be estimated by the size of the derivative, and for polynomials this is identically zero for some order onwards.

More generally, the estimation of the size of the  $k$ -th derivative on some interval can be used to estimate the error on the same interval.

Good examples of an expansion of an arbitrary degree are provided by the trigonometric functions  $\sin$  and  $\cos$ . By iterating the differentiation of the function  $\sin x$  we always have either sine or cosine with some signs. The absolute values do not exceed one. Thus we obtain a direct estimation of the speed of convergence of the power series

$$|\sin x - (T_{k,0} \sin)(x)| \leq \frac{|x|^{k+1}}{(k+1)!}.$$

This shows that for  $x$  much smaller than  $k$  the error is small, but for  $x$  comparable with  $k$  or bigger it may be large. In the figure, compare the approximation of the function  $\cos x$  by a Taylor polynomial of degree 68 in paragraph 5.4.11 on the page 337.

As mentioned in the introduction of the discussion of Taylor expansion of functions, if we start with a power series  $f(x)$  centered in  $a$ , then its partial sums coincide with Taylor polynomials  $T_{k,a} f(x)$ . The next statement is one of the simple formulations of the converse implication. This is when the given function  $f(x)$  is actually a power series on some neighbourhood of the given point  $a$ .

step

$$\begin{aligned} f\left(\sum_{i=1}^{k+1} c_i x_i\right) &= f\left(c_1 x_1 + (1 - c_1) \sum_{i=2}^{k+1} \frac{c_i}{1 - c_1} x_i\right) \\ &\leq c_1 f(x_1) + (1 - c_1) f\left(\sum_{i=2}^{k+1} \frac{c_i}{1 - c_1} x_i\right) \\ &\leq c_1 f(x_1) + (1 - c_1) \left(\sum_{i=2}^{k+1} \frac{c_i}{1 - c_1} f(x_i)\right) \\ &= \sum_{i=1}^{k+1} c_i f(x_i), \end{aligned}$$

where we used the inequality first for  $n = 2$  and then  $n = k$ . □

**Remark.**

The Jensen inequality can be also formulated in a more intuitive way: the centroid of mass points placed upon a graph of a strictly convex function lies above this graph.

**6.A.20.** Prove that among all (convex)  $n$ -gons inscribed into a circle, the regular  $n$ -gon has the largest area (for arbitrary  $n \geq 3$ ).

**Solution.** Clearly it suffices to consider the  $n$ -gons inside of which lies the center of the circle. We'll divide each such  $n$ -gon inscribed into a circle with radius  $r$  to  $n$  triangles with areas  $S_i, i \in \{1, \dots, n\}$  according to the figure. With regard to the fact that

$$\sin \frac{\varphi_i}{2} = \frac{x_i}{r}, \quad \cos \frac{\varphi_i}{2} = \frac{h_i}{r}, \quad i \in \{1, \dots, n\},$$

we have

$$S_i = x_i h_i = r^2 \sin \frac{\varphi_i}{2} \cos \frac{\varphi_i}{2} = \frac{1}{2} r^2 \sin \varphi_i, \quad i \in \{1, \dots, n\}.$$

This implies that the area of the hole  $n$ -gon is

$$S = \sum_{i=1}^n S_i = \frac{1}{2} r^2 \sum_{i=1}^n \sin \varphi_i.$$

Thus we want to maximize the sum  $\sum_{i=1}^n \sin \varphi_i$ , while for values  $\varphi_i \in (0, \pi)$  we clearly have

$$(1) \quad \varphi_1 + \dots + \varphi_n = \sum_{i=1}^n \varphi_i = 2\pi.$$

The function  $y = \sin x$  is strictly concave on the interval  $(0, \pi)$ , which means, that the function  $y = -\sin x$  is strictly convex on this interval. Then according to Jensen's inequality for  $c_i = 1/n$  and  $x_i = \varphi_i$ , we have

$$\begin{aligned} -\sin\left(\sum_{i=1}^n \frac{1}{n} \varphi_i\right) &\leq \\ -\sum_{i=1}^n \frac{1}{n} \sin \varphi_i, \quad \text{tj.} \quad \sin\left(\sum_{i=1}^n \frac{1}{n} \varphi_i\right) &\geq \sum_{i=1}^n \frac{1}{n} \sin \varphi_i. \end{aligned}$$

TAYLOR'S THEOREM

**Theorem.** Assume that the function  $f(x)$  is smooth on the interval  $(a - b, a + b)$  and all of its derivatives are bounded uniformly by a constant  $M > 0$ . So

$$|f^{(k)}(x)| \leq M, \quad k = 0, 1, \dots, \quad x \in (a - b, a + b).$$

Then the power series  $S(x) = \sum_{n=0}^{\infty} \frac{1}{k!} f^{(k)}(a)(x - a)^n$  converges on the interval  $(a - b, a + b)$  to  $f(x)$ .

**PROOF.** The proof is identical with the the special case of function  $\sin x$  above. Except that the universal bound by 1 is replaced by  $M$ , and thus the estimate of the remainders are

$$|f(x) - (T_{k,a}f)(x)| \leq \frac{M}{(k+1)!} |x|^{k+1}. \quad \square$$

**6.1.5. Analytic and smooth functions.** If  $f$  is smooth at  $a$ , the formal power series can be written

$$S(x) = \sum_{n=0}^{\infty} \frac{1}{k!} f^{(k)}(a)(x - a)^n.$$

If this power series has a nonzero radius of convergence and simultaneously  $S(x) = f(x)$  on the respective interval, we say that  $f$  is an *analytic function* at  $a$ . A function is analytic on an interval, if it is analytic at its every point.

Not all smooth functions are analytic. It can be proven that for every sequence of numbers  $a_n$  there is a smooth function, whose derivatives of order  $k$  are these numbers  $a_k$ .<sup>2</sup>

To show the essence of the problem, we introduce a function which has all its derivatives vanishing at zero, but is nonzero at every other point. We see later how useful this function is.

Consider the function defined by

$$f(x) = e^{-1/x^2}.$$

It is a well defined smooth function at all points  $x \neq 0$ . Its limit at  $x = 0$  exists, and  $\lim_{x \rightarrow 0} f(x) = 0$ . By defining  $f(0) = 0$ ,  $f$  is a continuous function for all real  $x$ .

By a direct computation based on L'Hôpital's rule we compute the derivative of  $f$  (the first three ones are at the

<sup>2</sup>This is a special case of the *Whitney extension theorem*, which says that there is a smooth function on a Euclidean space with prescribed derivatives in all points of a closed set  $A$  if and only if the Taylor theorem estimates are true for the prescription. In the case of one single point  $A$ , the condition is empty. This is relevant for the Taylor theorem for functions of more than one real variable, as in Chapter 8. Hasler Whitney (1907-1989) was a very influential American mathematician.

Moreover, we know the equality occurs exactly for  $\varphi_1 = \dots = \varphi_n$ . If we express (using (1))

$$S = \frac{r^2 n}{2} \sum_{i=1}^n \frac{1}{n} \sin \varphi_i \leq \frac{r^2 n}{2} \sin \left( \sum_{i=1}^n \frac{1}{n} \varphi_i \right) = \frac{r^2 n}{2} \sin \frac{2\pi}{n},$$

we can see that  $S$  can attain at most the value on the right hand side. But that happens if and only if  $\varphi_1 = \dots = \varphi_n$  (we chose  $x_i = \varphi_i$ ). Hence the regular  $n$ -gon is the one with the maximum area, because it satisfies  $\varphi_1 = \dots = \varphi_n = 2\pi/n$ .  $\square$

**6.A.21. Isoperimetric quotient.** For a closed curve in plane enclosing a planar region, we define its isoperimetric quotient as the number

$$IQ := \frac{S}{\pi \left(\frac{o}{2\pi}\right)^2} = \frac{4\pi S}{o^2},$$

where  $S$  denotes the area of the region and  $o$  its perimeter (i.e. the length of the curve). Hence the isoperimetric quotient determines the ratio of the area of the region and the area of a circle with the same perimeter as the given region. The notation  $IQ$  is therefore not only an English abbreviation for the isoperimetric quotient, but can be also thought of as the “intelligence of the region”, with which it uses its perimeter for attaining as big area as possible. The isoperimetric theorem then states that for every closed curve,  $IQ \leq 1$ , with equality occurring only for a circle, or (“the circle is the smartest”).

Determine  $IQ$  for a regular polygon and a circle and find the sector of a circle, for which its boundary has the largest  $IQ$

**Solution.** First notice that the value of  $IQ$  doesn't change with a change of scale on the axes (same on both). Because when the proportions of the region get  $a$  times bigger (for arbitrary  $a > 0$ ), the perimeter also gets  $a$  times bigger and the area  $a^2$  times (it's a square measure). Hence  $IQ$  doesn't depend on the size of the region, but only on its shape. Thus we can consider a regular  $n$ -gon inscribed into a unit circle. According to the figure,

$$h = \cos \varphi = \cos \frac{\pi}{n}, \quad \frac{x}{2} = \sin \varphi = \sin \frac{\pi}{n},$$

which yields

$$o_n = n \cdot x = 2n \sin \frac{\pi}{n}$$

and

$$S_n = n \cdot \frac{1}{2} hx = n \cos \frac{\pi}{n} \sin \frac{\pi}{n}.$$

Thus for a regular  $n$ -gon, we have

$$IQ = \frac{4\pi n \cos \frac{\pi}{n} \sin \frac{\pi}{n}}{4n^2 \sin^2 \frac{\pi}{n}} = \frac{\pi}{n} \cotg \frac{\pi}{n},$$

which we can verify for example for a square ( $n = 4$ ) with a side of length  $a$ , where

picture, guess which line is which!). It suffices to consider only the right derivative, since the function is even.

$$\begin{aligned} f'(0) &= \lim_{x \rightarrow 0^+} \frac{e^{-1/x^2} - 0}{x} = \lim_{x \rightarrow 0^+} \frac{x^{-1}}{e^{1/x^2}} \\ &= \frac{1}{2} \lim_{x \rightarrow 0^+} \frac{x}{e^{1/x^2}} = 0. \end{aligned}$$

By differentiating  $f(x)$  at an arbitrary point  $x \neq 0$ ,  $f'(x) = e^{-1/x^2} \cdot 2x^{-3}$ . By repeated differentiation of the results, there is always a sum of finitely many terms of the form

$$C \cdot e^{-1/x^2} \cdot x^{-j},$$

where  $C$  is an integer and  $j$  is a natural number.

Next, assume it is already proven that the derivative of order  $k$  of  $f(x)$  exists and vanishes at zero. Compute the limit of the expression  $f^{(k)}(x)/x$  for  $x \rightarrow 0^+$ . This is a finite sum of limits of the expressions  $x^{-j} e^{-1/x^2} = x^{-j} / e^{1/x^2}$ . All these expressions are of type  $\infty/\infty$ , so L'Hôpital's rule can be used repeatedly on them. After several differentiations of both the numerator and denominator (and a similar adjustment as above) there remains the same expression in the denominator, while in the numerator the power is non-negative. Thus the expression necessarily has a zero limit at zero, just as in the case of the first derivative above. The same holds for a finite sum of such expressions. So each derivative  $f^{(k)}(x)$  at zero exists with value zero.

In summary,  $f(x)$  is smooth on the whole of  $\mathbb{R}$ . It is strictly positive everywhere except for  $x = 0$ . All its derivatives at this point are zero.

It cannot be analytic at  $x_0 = 0$ . The limit of the function at the improper points  $\pm\infty$  is 1, while all its derivatives converge quickly to zero.

One of the most important functions in Mathematics and Physics is the *Gaussian function*

$$g(x) = f(x^{-1}) = e^{-x^2}.$$

We see why in Chapter 10 when dealing with probability and statistics.

Replace  $x$  with  $-x^2$  in the power series for the exponential. It follows that  $g$  is an analytic function on the entire  $\mathbb{R}$ . Its derivatives are easily computed. In particular  $g'(0) = 0$  is the only singular point and  $g''(0) = -2$ . Since the limits at  $\pm\infty$  are zero, the number  $g(0) = 1$  is the global maximum of the Gaussian function. Both functions are depicted on the diagram.  $f(x)$  is the solid line, while the Gaussian function is dashed.

$$IQ = \frac{4\pi a^2}{(4a)^2} = \frac{\pi}{4} = \frac{\pi}{4} \cotg \frac{\pi}{4}.$$

Using the limit transition for  $n \rightarrow \infty$  and the limit

$$\lim_{x \rightarrow 0} \frac{\sin x}{x} = 1,$$

we get the isoperimetric quotient for a circle:

$$IQ = \lim_{n \rightarrow \infty} \frac{\pi}{n} \cotg \frac{\pi}{n} = \lim_{n \rightarrow \infty} \frac{\cos \frac{\pi}{n}}{\frac{\sin \frac{\pi}{n}}{\frac{\pi}{n}}} = \frac{\cos 0}{1} = 1.$$

Of course, for a circle with radius  $r$ , we could have also directly computed

$$IQ = \frac{4\pi S}{o^2} = \frac{4\pi(\pi r^2)}{(2\pi r)^2} = 1.$$

For the boundary of a sector of a circle with radius  $r$  and central angle  $\varphi \in (0, 2\pi)$ , we have

$$IQ = \frac{4\pi S}{o^2} = \frac{4\pi \frac{\varphi r^2}{2}}{(2r+r\varphi)^2} = \frac{2\pi\varphi}{(2+\varphi)^2}.$$

Hence we're looking for a maximum of the function

$$f(\varphi) := \frac{2\pi\varphi}{(2+\varphi)^2}, \quad \varphi \in (0, 2\pi).$$

By computing

$$f'(\varphi) = 2\pi \frac{(2+\varphi)^2 - 2\varphi(2+\varphi)}{(2+\varphi)^4} = 2\pi \frac{2-\varphi}{(2+\varphi)^3}, \quad \varphi \in (0, 2\pi)$$

we easily obtain that

$$f'(\varphi) > 0, \quad \varphi \in (0, 2), \quad f'(\varphi) < 0, \quad \varphi \in (2, 2\pi).$$

Hence function  $f$  attains its maximal value for  $\varphi_0 = 2$  and for a central angle  $\varphi_0 = 2$  (radians), we get the largest

$$IQ = \frac{2\pi\varphi_0}{(2+\varphi_0)^2} = \frac{\pi}{4}.$$

For the sake of completeness, for a solid in three-dimensional space (more precisely, for the closed surface which is its boundary), we define

$$IQ := \frac{V}{\frac{4\pi}{3} \left(\frac{S}{4\pi}\right)^{\frac{3}{2}}},$$

where  $V$  is the volume and  $S$  the surface of the solid. Thus we compare the volume of the solid with a given surface with the volume of the ball with the same space. ◻

**6.A.22.** A string of length  $l$  is given. The task is to cut it into

$n$  parts so that it's possible to create boundaries of geometric figures given in advance (for example a square, a triangle, a circle, a halfcircle) with the least sum of areas from the  $n$  smaller strings.

**Solution.** To solve this problem, we'll use the isoperimetric quotient of curves and Jensen's inequality (stated in previous examples). For the geometric figures given in advance, denote the values of their isoperimetric quotients as

$$\frac{1}{\lambda_i} := \frac{4\pi S_i}{o_i^2}, \quad i \in \{1, \dots, n\},$$

where  $S_i$  is the area and  $o_i$  the perimeter of the  $i$ -th figure. We'll also use the denotation

Notice how the function  $f$  touches the  $x$  axis due to the vanishing of all derivatives at zero.

**6.1.6. Useful non-analytic smooth functions.**

The smooth functions are very "elastic" — from a local behaviour around one point we cannot deduce anything at all about the global behavior of such function. On the other hand, analytic functions are completely determined just by derivatives at one point. In particular they are completely determined by their behaviour on an arbitrarily small neighbourhood of a single point from their domain. In this sense, analytic functions are very "rigid".

In particular, the smooth functions allow for joining different constant values on disjoint open intervals in a differentiable way.

Let us look at such functions more closely now. We can modify  $f(x)$  from the previous paragraph in this way:

$$g(x) = \begin{cases} 0 & \text{if } x \leq 0 \\ e^{-1/x^2} & \text{if } x > 0. \end{cases}$$

Again it is a smooth function on all of  $\mathbb{R}$ . By another modification there is another function  $h$ , which is nonzero at all inner points of the interval  $[-a, a]$ ,  $a > 0$  and zero elsewhere.

$$h(x) = \begin{cases} 0 & \text{if } |x| \geq a \\ e^{\frac{1}{x^2 - a^2} + \frac{1}{a^2}} & \text{if } |x| < a. \end{cases}$$

This function is again smooth on all of  $\mathbb{R}$ . The last two functions are in the two figures. On the right, the parameter  $a = 1/2$  is used.

Finally we show how to get smooth analogies of the Heaviside functions. For two fixed real numbers  $a < b$ , define the function  $f(x)$  exploiting the above function  $g$  as follows:

$$f(x) = \frac{g(x-a)}{g(x-a) + g(b-x)}.$$

For all  $x \in \mathbb{R}$  the denominator of the fraction is positive (because  $g$  is non-negative). For each of the three intervals determined by numbers  $a$  and  $b$  at least one of the summands of the denominator is nonzero). Thus the definition yields a smooth function  $f(x)$  on all of  $\mathbb{R}$ . For  $x \leq a$  the numerator of the fraction is zero according to the definition of  $g$ . For  $x \geq b$  the numerator and denominator are equal. In the next two figures there are functions  $f(x)$  with parameters  $a = 1 - \alpha$ ,  $b = 1 + \alpha$ . On the left  $\alpha = 0.8$ , and on the right  $\alpha = 0.4$ .

$$A := \sum_{i=1}^n \lambda_i.$$

Recall that the isoperimetric quotient is given only by the shape of the figure and doesn't depend on its size. In particular, the value  $A$  is constant (it's determined by the shapes of the given figures).

Our task is to minimize the sum  $\sum_{i=1}^n S_i$  with  $\sum_{i=1}^n o_i = l$ . Because

$$S_i = \frac{o_i^2}{4\pi\lambda_i}, \quad i \in \{1, \dots, n\},$$

we need to minimize the expression

$$S := \frac{1}{4\pi} \sum_{i=1}^n \frac{o_i^2}{\lambda_i}.$$

Using Jensen's inequality for the strictly convex function  $y = x^2$  (on the whole real axis), we obtain

$$\left( \sum_{i=1}^n c_i x_i \right)^2 \leq \sum_{i=1}^n c_i x_i^2$$

for  $x_i \in \mathbb{R}$  and  $c_i > 0$  with the property  $c_1 + \dots + c_n = 1$ . Moreover we know that the equality occurs if and only if  $x_1 = \dots = x_n$ . By choosing

$$c_i = \frac{\lambda_i}{A}, \quad x_i = \frac{o_i}{\lambda_i}, \quad i \in \{1, \dots, n\},$$

we then get

$$\left( \sum_{i=1}^n \frac{\lambda_i}{A} \frac{o_i}{\lambda_i} \right)^2 \leq \sum_{i=1}^n \frac{\lambda_i}{A} \left( \frac{o_i}{\lambda_i} \right)^2.$$

By several simplifications, we obtain the inequality

$$\frac{1}{A^2} \left( \sum_{i=1}^n o_i \right)^2 \leq \frac{1}{A} \sum_{i=1}^n \frac{o_i^2}{\lambda_i}$$

and then (notice that  $\sum_{i=1}^n o_i = l$ )

$$\frac{l^2}{A} \leq \sum_{i=1}^n \frac{o_i^2}{\lambda_i},$$

with equality again occurring for

$$(1) \quad x_1 = \dots = x_n, \quad \text{tj.} \quad \frac{o_1}{\lambda_1} = \dots = \frac{o_n}{\lambda_n}.$$

This implies that  $S$  the smallest, if and only if (1) holds. This smallest value of  $S$  is  $l^2/(4\pi A)$ . Now we only need to determine the lengths of the cut parts  $o_i$ . If (1) holds, then clearly  $o_i = k\lambda_i$  for all  $i \in \{1, \dots, n\}$  and certain constant  $k > 0$ . From

$$\sum_{i=1}^n o_i = l \quad \text{and simultaneously} \quad \sum_{i=1}^n o_i = k \sum_{i=1}^n \lambda_i = kA,$$

we can immediately see that  $k = l/A$ , i.e.

$$o_i = \frac{\lambda_i}{A} l, \quad i \in \{1, \dots, n\}.$$

Let's take a look at a specific situation where we are to cut a string of length 1 m into two smaller ones and then create a square and a circle from them so that the sum of their areas is the smallest possible. For a square and a circle (in order), we have (see the example called Isoperimetric quotient)

Finally, we can create a smooth analogue of the characteristic function of any interval  $[c, d]$ .

Write  $f_\varepsilon(x)$  for the latter function  $f(x)$  with parameters  $a = -\varepsilon$ ,  $b = +\varepsilon$ . For the interval  $(c, d)$  with the length  $d - c > 2\varepsilon$  define the function  $h_\varepsilon(x) = f_\varepsilon(x - c) \cdot f_\varepsilon(d - x)$ . This function is identically zero on the intervals  $(-\infty, c - \varepsilon)$  and  $(d + \varepsilon, \infty)$ . It is identically one on the interval  $(c + \varepsilon, d - \varepsilon)$ . Moreover, it is smooth everywhere. Locally it is either constant or monotonic (you should verify the last claim yourself). The smaller the  $\varepsilon > 0$ , the faster  $h_\varepsilon(x)$  jumps from zero to one around the beginning of the interval or back at the end of it.

The diagram shows the choices  $[c, d] = [1, 2]$  and  $\varepsilon = 0.6$ ,  $\varepsilon = 0.3$ .

**6.1.7. Local behaviour of functions.** It is time to return to the behaviour of real functions of one real variable. We have seen that the sign of the first derivative of a differentiable function determines whether it is increasing or decreasing on some neighbourhood of the given point. If the derivative is zero, it does not of itself say much about the behaviour of the function.

We encountered the importance of the second derivative when describing critical points. Now we generalize the discussion of critical points for all orders. First we deal with the local extremes of functions.

In the following we consider real functions with a sufficiently high number of continuous derivatives, without specifically stating this assumption.

The point  $a$  in domain of  $f$  is a *critical point of order  $k$*  if and only if

$$f'(a) = \dots = f^{(k)}(a) = 0, \quad f^{(k+1)}(a) \neq 0.$$

$$\lambda_1 = \frac{4}{\pi}, \quad \lambda_2 = 1, \quad \text{tj.} \quad \Lambda = \lambda_1 + \lambda_2 = \frac{4+\pi}{\pi}.$$

Then the lengths of the respective parts are (in metres)

$$o_1 = \frac{\frac{4}{\pi}}{\frac{4+\pi}{\pi}} \cdot 1 = \frac{4}{4+\pi} \doteq 0,56, \quad o_2 = \frac{1}{\frac{4+\pi}{\pi}} \cdot 1 = \frac{\pi}{4+\pi} \doteq 0,44.$$

The area of a square with perimeter 0,56 m (with a side of length  $a = 0,14$  m) is 0,0196 m<sup>2</sup> and the area of a circle with perimeter 0,44 m (and radius  $r \doteq 0,07$  m) is approximately 0,0154 m<sup>2</sup>. We can verify that (in m<sup>2</sup>)

$$\frac{l^2}{4\pi\Lambda} = \frac{1}{4(4+\pi)} \doteq 0,035 = 0,0196 + 0,0154.$$

**6.A.23.** Expand the function

(a)  $y = \ln \frac{1+x}{1-x}, \quad x \in (-1, 1);$

(b)  $y = e^{x^2} + x^2 e^{-2x}, \quad x \in \mathbb{R}$

into a Taylor series centered at the origin..

**Solution.** If the function can be expressed as a sum of a power series (with a positive radius of convergence) on its domain of convergence, then this series is necessarily the Taylor series of the given function (its sum). This allows us to find the corresponding Taylor series easily.

Case (a). We know that

$$\ln(1+x) = \sum_{n=1}^{\infty} \frac{(-1)^{n+1}}{n} x^n, \quad x \in (-1, 1),$$

i.e. for  $x \in (-1, 1)$  we have

$$\ln(1-x) = \sum_{n=1}^{\infty} \frac{(-1)^{n+1}}{n} (-x)^n = - \sum_{n=1}^{\infty} \frac{1}{n} x^n.$$

In total, for  $x \in (-1, 1)$  we have

$$\begin{aligned} \ln \frac{1+x}{1-x} &= \ln(1+x) - \ln(1-x) = \sum_{n=1}^{\infty} \frac{(-1)^{n+1} + 1}{n} x^n \\ &= \sum_{n=1}^{\infty} \frac{2}{2n-1} x^{2n-1}. \end{aligned}$$

Case (b). Similarly, the well known identity

$$e^x = \sum_{n=0}^{\infty} \frac{1}{n!} x^n, \quad x \in \mathbb{R},$$

implies

$$e^{x^2} = \sum_{n=0}^{\infty} \frac{1}{n!} (x^2)^n = \sum_{n=0}^{\infty} \frac{1}{n!} x^{2n}, \quad x \in \mathbb{R},$$

and

$$x^2 e^{-2x} = x^2 \sum_{n=0}^{\infty} \frac{1}{n!} (-2x)^n = \sum_{n=0}^{\infty} \frac{(-2)^n}{n!} x^{n+2}, \quad x \in \mathbb{R}.$$

Hence

$$e^{x^2} + x^2 e^{-2x} = \sum_{n=0}^{\infty} \frac{x^{2n} + (-2)^n x^{n+2}}{n!}, \quad x \in \mathbb{R}.$$

□

Suppose  $f^{(k+1)}(a) > 0$ . Then this continuous derivative is positive on a certain neighbourhood  $\mathcal{O}(a)$  of the point  $a$  as well. In that case, the Taylor expansion with the remainder gives

$$f(x) = f(a) + \frac{1}{(k+1)!} f^{(k+1)}(c)(x-a)^{k+1}$$

for all  $x$  in  $\mathcal{O}(a)$ . Because of that, the change of values of  $f(x)$  in a neighbourhood of  $a$  is given by the behaviour of  $(x-a)^{k+1}$ . Moreover, if  $k+1$  is an even number, then the values of  $f(x)$  in such a neighbourhood are necessarily larger than the value  $f(a)$ . So  $a$  is a local minimum. But if  $k$  is even then the values on the left are smaller, while those on right are larger than  $f(a)$ . So an extreme does not occur even locally. On the other hand, the graph of the function  $f(x)$  intersects its tangent  $y = f(a)$  at the point  $[a, f(a)]$  in the latter case.

Similarly, if  $f^{(k+1)}(a) < 0$ , then it is a local maximum for odd  $k$ , and there is no extreme for even  $k$ .

**6.1.8. Convex and concave functions.** The differentiable

function  $f$  is *concave* at  $a$ , if its graph lies completely below the tangent at the point  $[a, f(a)]$  in a neighbourhood of  $a$ . That is,

$$f(x) \leq f(a) + f'(a)(x-a).$$

Similarly  $f$  is *convex* at  $a$ , if its graph is above the tangent at the point  $a$ . That is,

$$f(x) \geq f(a) + f'(a)(x-a).$$

A function is convex or concave on an interval, if it has this property at all its points.

Suppose  $f$  has continuous second derivatives in a neighbourhood of  $a$ . The Taylor expansion of second order with the remainder implies

$$f(x) = f(a) + f'(a)(x-a) + \frac{1}{2} f''(c)(x-a)^2.$$

Then the function is convex, whenever  $f''(a) > 0$ , and concave whenever  $f''(a) < 0$ .

If the second derivative is zero, we can use derivatives of higher orders. But we can only make the same conclusion if the first other nonzero derivative after the first derivative is of even order. If the first nonzero derivative is of odd order, the points of the graph of the function on opposite sides of some small neighbourhood of the studied point will lie on opposite sides of the tangent at this point.

**6.A.24.** Determine the Taylor series centered at the origin of function

- (a)  $y = \frac{1}{(1+x)^2}$ ,  $x \in (-1, 1)$ ;  
 (b)  $y = \arctg x$ ,  $x \in (-1, 1)$ .

**Solution.** Case (a). We'll use the formula

$$\frac{1}{1+x} = \sum_{n=0}^{\infty} (-x)^n = \sum_{n=0}^{\infty} (-1)^n x^n, \quad x \in (-1, 1)$$

for the sum of a geometric series. By differentiating it, we obtain for  $x \in (-1, 1)$

$$-\frac{1}{(1+x)^2} = \left( \sum_{n=0}^{\infty} (-1)^n x^n \right)' = \sum_{n=1}^{\infty} (-1)^n n x^{n-1},$$

with  $(x^0)' = 0$ , thus the lower index is  $n = 1$ . We can see that

$$\frac{1}{(1+x)^2} = \sum_{n=1}^{\infty} (-1)^{n+1} n x^{n-1}, \quad x \in (-1, 1).$$

Case (b). We can express the derivative of function  $y = \arctg t$  for  $t \in (-1, 1)$  as

$$(\arctg t)' = \frac{1}{1+t^2} = \sum_{n=0}^{\infty} (-t^2)^n = \sum_{n=0}^{\infty} (-1)^n t^{2n},$$

Because for  $x \in (-1, 1)$  we have

$$\int_0^x (\arctg t)' dt = \arctg x - \arctg 0 = \arctg x$$

and

$$\begin{aligned} \int_0^x \left( \sum_{n=0}^{\infty} (-1)^n t^{2n} \right) dt &= \sum_{n=0}^{\infty} \left( (-1)^n \int_0^x t^{2n} dt \right) \\ &= \sum_{n=0}^{\infty} \frac{(-1)^n}{2n+1} x^{2n+1}, \end{aligned}$$

we already have the result

$$\arctg x = \sum_{n=0}^{\infty} \frac{(-1)^n}{2n+1} x^{2n+1}, \quad x \in (-1, 1).$$

□

**6.A.25.** Find the Taylor series centered at  $x_0 = 0$  of function

$$f(x) = \int_0^x u \cos u^2 du, \quad x \in \mathbb{R}.$$

**Solution.** The equality

$$\cos t = \sum_{n=0}^{\infty} \frac{(-1)^n}{(2n)!} t^{2n}, \quad t \in \mathbb{R}$$

implies

$$u \cos u^2 = u \sum_{n=0}^{\infty} \frac{(-1)^n}{(2n)!} (u^2)^{2n} = \sum_{n=0}^{\infty} \frac{(-1)^n}{(2n)!} u^{4n+1}, \quad u \in \mathbb{R}$$

and then (for  $x \in \mathbb{R}$ )

$$\begin{aligned} f(x) &= \int_0^x u \cos u^2 du = \int_0^x \left( \sum_{n=0}^{\infty} \frac{(-1)^n}{(2n)!} u^{4n+1} \right) du \\ &= \sum_{n=0}^{\infty} \left( \frac{(-1)^n}{(2n)!} \int_0^x u^{4n+1} du \right) = \sum_{n=0}^{\infty} \frac{(-1)^n}{(2n)! (4n+2)} x^{4n+2}. \end{aligned}$$

**6.1.9. Inflection points.** A point  $a$  is called an *inflection point* of a differentiable function  $f$ , if the graph of  $f$  crosses from one side of the tangent in the point  $a$  to the other. The latter discussion on concave and convex functions shows that the inflections can appear only at points with vanishing second derivative.

Suppose  $f$  has continuous third derivatives and write the Taylor expansion of third order with the remainder:

$$f(x) = f(a) + f'(a)(x-a) + \frac{1}{2} f''(a)(x-a)^2 + \frac{1}{6} f'''(c)(x-a)^3.$$

If  $a$  is a zero point of the second derivative such that  $f'''(a) \neq 0$ , then the third derivative is nonzero on some neighbourhood.  $a$  is an inflection point since the second derivative changes the sign at  $a$  and thus the tangent crosses the graph. In that case, the sign of the third derivative determines whether the graph of the function crosses the tangent from the top to the bottom or vice versa.

Moreover, if  $a$  is an isolated zero point of the second derivative and simultaneously an inflection point, then on some small neighbourhood of  $a$  the function is concave on one side and convex on the other. Thus the inflection points are points of the change between concave and convex behaviour of the graph of the function.

**6.1.10. Asymptotes of the graph of the function.** We introduce one more useful utility for understanding/sketching the graph of a function. We consider the *asymptotes*. These are lines in  $\mathbb{R}^2$  whose distance from the graph of  $f(x)$  converges to zero for  $x \rightarrow x_0$ .

Thus, an asymptote at the improper point  $\infty$  is a line  $y = ax + b$ , which satisfies

$$\lim_{x \rightarrow \infty} (f(x) - ax - b) = 0.$$

An *asymptote with a slope*. If such an asymptote exists, it satisfies

$$\lim_{x \rightarrow \infty} (f(x) - ax) = b$$

Consequently the limit

$$\lim_{x \rightarrow \infty} \frac{f(x)}{x} = a$$

also exists.

Conversely, if the last two limits exist, the limit from the definition of the asymptote exists as well, thus these are sufficient conditions too.

The asymptote at the improper point  $-\infty$  is defined similarly.

In this way we find all the lines satisfying the properties of asymptotes with slope. It remains to consider lines perpendicular to the  $x$  axis:

The asymptotes at points  $a \in \mathbb{R}$  are lines  $x = a$  such that the function  $f$  has at least one of the one-sided limits at  $a$  has infinite value. They are called *asymptotes without slope*.

The rational functions have asymptotes at all zero points of the denominator which are zero points of the numerator as well.

□

**6.A.26.** Approximately compute  $\cos \frac{\pi}{10}$  with an error lesser than  $10^{-5}$ . ○

**6.A.27.** Without computing the derivatives, determine the Taylor polynomial of degree 4 centered at  $x_0 = 0$  of function

$$f(x) = \cos x - 2 \sin x - \ln(1+x), \quad x \in (-1, 1).$$

Then decide if the graph of function  $f$  in neighbourhood of the point  $[0, 1]$  is above or below the tangent line. ○

Now we'll state several "classical" problems, in which we'll determine the course of distinct functions. By determining the course we mean

- (a) the domain (it's given) and the range;
- (b) eventual parity and periodicity;
- (c) discontinuities and their kind (including the according one-sided limits);
- (d) points of intersections with the axes  $x, y$ ;
- (e) the intervals where the function is positive and where it's negative;
- (f) the limits  $\lim_{x \rightarrow -\infty} f(x), \lim_{x \rightarrow +\infty} f(x)$ ;
- (g) the first and the second derivative;
- (h) the critical and the so called stationary points, at which the first derivative is zero (eventually the points, at which the first or the second derivative don't exist)
- (i) the intervals of monotonicity;
- (j) strict and nonstrict local and absolute extremes;
- (k) the intervals where the function is convex and where it's concave;
- (l) the points of inflection;
- (m) the horizontal and inclined asymptotes;
- (n) values of the function  $f$  and its derivative  $f'$  at „significant“ points;
- (o) the graph.

**6.A.28.** Determine the range of function

$$f(x) = \frac{e^x - 1}{e^x + 1}, \quad x \in \mathbb{R}.$$

**Solution.** The line  $y = 1$  is clearly an asymptote of function  $f$  at  $+\infty$  and the line  $y = -1$  is an asymptote at  $-\infty$ , because

$$\lim_{x \rightarrow \infty} \frac{e^x - 1}{e^x + 1} = \lim_{x \rightarrow \infty} \frac{e^x}{e^x} = 1, \quad \lim_{x \rightarrow -\infty} \frac{e^x - 1}{e^x + 1} = \frac{0 - 1}{0 + 1} = -1.$$

The inequality

$$f'(x) = \frac{2e^x}{(e^x + 1)^2} > 0, \quad x \in \mathbb{R}$$

We consider a simple illustrative example: Let

$$f(x) = x + \frac{1}{x}.$$

$f$  has two asymptotes  $y = x$  and  $x = 0$ . Indeed, the one-sided limits from the right and left at zero are clearly  $\pm\infty$ , while the limit  $f(x)/x = 1 + 1/x^2$  is of course  $\pm 1$  at the improper points. Finally the limit of  $f(x) - x = 1/x$  is zero at the improper points.

By differentiating,

$$f'(x) = 1 - x^{-2}, \quad f''(x) = 2x^{-3}.$$

The function  $f'(x)$  has two zero points  $\pm 1$ . At  $x = 1$ ,  $f$  has a local minimum. At  $x = -1$ ,  $f$  has a local maximum. The second derivative has no zero points in all its domain  $(-\infty, 0) \cup (0, \infty)$ , so  $f$  has no inflection points.

**6.1.11. Differential of a function.** In practical use of differential calculus, we often work with dependencies between several variables, say  $y$  and  $x$ . The choice of dependent and independent variable is not fixed. The explicit relation  $y = f(x)$  with some function  $f$  is then only one of possible options. Differentiation then expresses that the immediate change of  $y = f(x)$  is proportional to the immediate change of  $x$  with the proportion of  $f'(x) = \frac{df}{dx}(x)$ .

This relation is often written as

$$df(x) = f'(x)dx,$$

where we interpret  $df(x)$  as a linear map  $\mathbb{R} \rightarrow \mathbb{R}$  defined on increments of  $x$  at the given point,  $df(x)(v) = f'(x) \cdot v$ , while  $dx(x)(v) = v$ .

We talk about the *differential of function*  $f$  if the following approximation property is true:

$$\lim_{v \rightarrow 0} \frac{f(x+v) - f(x) - df(x)(v)}{v} = 0.$$

Clearly, the differential is unique if it exists and, indeed,  $df(x) = f'(x)dx$ . Taylor theorem then implies that the differential  $df$  exists if the derivative  $f'$  is bounded. In particular, this happens at the point  $x$  if the first derivative  $f'(x)$  exists and is continuous at  $x$ .

If the quantity  $x$  is expressed by another quantity  $t$ , e.g.  $x = g(t)$  and, moreover,  $g$  has continuous first derivatives

picture!!

then implies that  $f$  is continuous and increasing on  $\mathbb{R}$ . Hence the range is the interval  $(-1, 1)$ .  $\square$

**6.A.29.** Find all intervals on which the function  $y = e^{-x^2}$ ,  $x \in \mathbb{R}$  is concave.  $\circ$

**6.A.30.** Consider function

$$y = \operatorname{arctg} \frac{x-1}{x}, \quad x \neq 0 (x \in \mathbb{R}).$$

Determine intervals on which this function is convex and concave and also all its asymptotes.  $\circ$

**6.A.31.** Find all asymptotes of function

$$(a) y = x e^x;$$

$$(b) y = \frac{(x+3)^3}{(x-2)^3}$$

with maximal domain.  $\circ$

**6.A.32.** Find the asymptotes of function

$$y = 2 \operatorname{arctg} \left| \frac{x}{x^2-1} \right|, \quad x \neq \pm 1 (x \in \mathbb{R}).$$

**6.A.33.** Consider function

$$y = \ln \frac{3e^{2x} + e^x + 10}{e^x + 1}$$

defined for all real  $x$ . Find its asymptotes.  $\circ$

**6.A.34.** Determine the course of the function

$$f(x) = \sqrt[3]{|x|^3 + 1}.$$

**Solution.** The domain is the whole real axis,  $f$  has no discontinuities. For example it suffices to consider that the function  $y = \sqrt[3]{x}$  is continuous at every point  $x \in \mathbb{R}$  (unlike even roots defined only on the nonnegative axis). We can also immediately see that  $f(x) \geq 1$  and  $f(-x) = f(x)$  for all  $x \in \mathbb{R}$ , i.e. the function  $f$  is positive and even. Thus we can obtain the point  $[0, 1]$  as the only intersections of the graph of  $f$  with the axes by substituting  $x = 0$ . The limit behavior of the function can be determined only at  $\pm\infty$  (there are no discontinuities), where we can easily compute

$$(1) \quad \lim_{x \rightarrow \pm\infty} \sqrt[3]{|x|^3 + 1} = \lim_{x \rightarrow \pm\infty} \sqrt[3]{|x|^3} = \lim_{x \rightarrow \pm\infty} |x| = +\infty.$$

Now we'll step up to determining the course of a function by using its derivatives. For  $x > 0$ , we have

$$f(x) = \sqrt[3]{x^3 + 1} = (x^3 + 1)^{\frac{1}{3}},$$

hence

$$(2) \quad f'(x) = \frac{1}{3} (x^3 + 1)^{-\frac{2}{3}} 3x^2 = \frac{x^2}{\sqrt[3]{(x^3 + 1)^2}} > 0, \quad x > 0.$$

again, the chain rule for differentiating the composite functions says that  $f \circ g$  has the differential too and

$$df(t) = d(f \circ g)(t) = \frac{df}{dx}(x) \frac{dx}{dt}(t) dt.$$

Therefore  $df$  can be seen as a linear approximation of the given quantity dependent on the increments of the dependent variable, no matter how this dependence is given.

**6.1.12. The curvature of the graph of a function.** We shall conclude this section with two straightforward applications of differentials. First we discuss curves in the plane and space, starting with the graphs of functions. Then we provide a brief introduction to the numerical procedures for differentiation (jump to 6.1.16 if getting tired with the curvatures).

Imagine the graph of a function as a movement in the plane parametrized by the independent variable  $x$ . The vector  $(1, f'(x)) \in \mathbb{R}^2$  represents the velocity at  $x$  of such a movement. The tangent line through  $[x, f(x)]$  parametrized by this directional vector then represents a linear approximation of the curve. The goal is to discuss how “curved” is the graph at  $x$ . This is a straightforward exercise working with differentials in the setup of elementary plane geometry. It might need some effort to keep the overview.

If  $f''(x) = 0$  and simultaneously  $f'''(x) \neq 0$ , the graph of the function  $f$  intersects its tangent line. In such a case, the tangent line is the best approximation of the curve at the point  $x$  up to the second order as well. We describe this by saying that the graph of  $f$  has *zero curvature* at the point  $x$ .

The nonzero values of the first derivative describe the speed of the growth. Intuitively we expect the second derivative to describe the acceleration, including how “curved” the graph is. As a matter of convention, we want the curvature to be positive if the graph of the function is above its tangent.

The tangent at a fixed point  $P = [x, f(x)]$  is the limit of the secants. The lines passing through the points  $P$  and  $Q = [x + \Delta x, f(x + \Delta x)]$ . To approximate the second derivative, interpolate the points  $P$  and  $Q \neq P$  by the circle  $C_Q$ , whose center is at the intersection of the perpendicular lines to the tangents at  $P$  and  $Q$ .

This implies that  $f$  is increasing on the interval  $(0, +\infty)$ . With respect to its continuity at the origin, it must be increasing on  $[0, +\infty)$ . Because it's an even function, we know that on the interval  $(-\infty, 0]$  it must be decreasing. Thus it has only one local minimum at point  $x_0 = 0$ , which is also a (strict) global minimum. Because a nonconstant continuous function maps an interval to an interval, the range of  $f$  is exactly  $[1, +\infty)$  (consider  $f(x_0) = 1$  and (1)). Notice that thanks to the even parity of the function, we didn't have to compute the derivative  $f'$  on the negative half-axis, which can though be easily determined by substituting  $|x|^3 = (-x)^3 = -x^3$ , yielding

$$f'(x) = \frac{1}{3} (-x^3 + 1)^{-\frac{2}{3}} (-3x^2) = -\frac{x^2}{\sqrt[3]{(-x^3+1)^2}} < 0, \quad x < 0.$$

When computing  $f'(0)$ , we can proceed according to the definition or we can use the limits

$$\lim_{x \rightarrow 0^+} \frac{x^2}{\sqrt[3]{(x^3+1)^2}} = 0 = \lim_{x \rightarrow 0^-} -\frac{x^2}{\sqrt[3]{(-x^3+1)^2}}$$

determine the one-sided derivatives and then  $f'(0) = 0$ . In fact, we didn't even have to compute the first derivative on the positive half-axis either. To obtain that  $f$  is increasing on  $(0, +\infty)$ , we only needed to realize that both functions  $y = \sqrt[3]{x}$  and  $y = x^3 + 1$  are increasing on  $\mathbb{R}$  and a composition of increasing functions is again an increasing function.

For  $x > 0$ , we can easily compute the second derivative using (2)

$$f''(x) = \frac{2x\sqrt[3]{(x^3+1)^2} - \frac{2}{3}x^2\sqrt[3]{(x^3+1)^{-1}}(3x^2)}{\sqrt[3]{(x^3+1)^4}},$$

i.e. after a simplification we have

$$(3) \quad f''(x) = \frac{2x}{\sqrt[3]{(x^3+1)^5}} > 0, \quad x > 0.$$

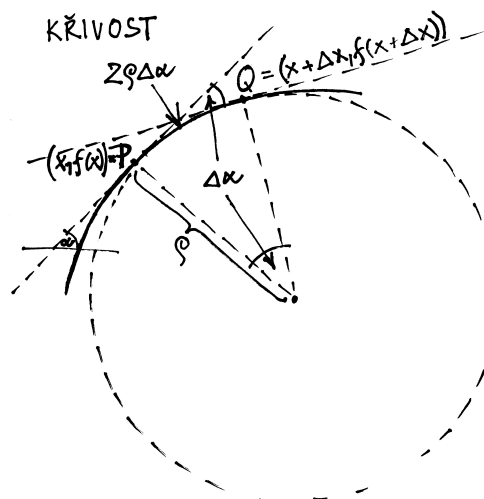

Similarly we can compute  $f''(x)$

$$\begin{aligned} &= -\frac{2x\sqrt[3]{(-x^3+1)^2} - \frac{2}{3}x^2\sqrt[3]{(-x^3+1)^{-1}}(-3x^2)}{\sqrt[3]{(-x^3+1)^4}} \\ &= -\frac{2x}{\sqrt[3]{(-x^3+1)^5}} > 0, \end{aligned}$$

for  $x > 0$  and then  $f''(0) = 0$ . Next, we can use a limit transition:

$$\lim_{x \rightarrow 0^+} \frac{2x}{\sqrt[3]{(x^3+1)^5}} = 0 = \lim_{x \rightarrow 0^-} -\frac{2x}{\sqrt[3]{(-x^3+1)^5}}.$$

According to the inequality (3),  $f$  is strictly convex on the interval  $(0, +\infty)$ . Also  $f$  must be strictly convex on  $(-\infty, 0)$ .

It can be seen from the figure that if the angle between the tangent at the fixed point  $P$  and the  $x$  axis is  $\alpha$  and the angle between the tangent at the chosen point  $Q$  and the  $x$  axis is  $\alpha + \Delta\alpha$ , then the angle of the latter perpendicular lines is  $\Delta\alpha$  as well.

improve a bit the picture - should only  $\rho\Delta\alpha$  a perhaps make the measured arc thicker.

Denote the radius of the circle by  $\rho$ . Then the length of the arc between points  $P$  and  $Q$  is  $\rho\Delta\alpha$ . As  $Q$  approaches the fixed point  $P$ , the length  $\rho\Delta\alpha$  of the arc approaches the length  $\Delta s$  of the curve between  $P$  and  $Q$ , that is, the graph of the function  $f(x)$ . At the same time the circle approaches some circle  $C_P$ . Thus we arrive at the basic relation for the expected radius  $\rho$  of the circle  $C_P$  in terms of the linear approximations of the quantities:

$$\rho = \lim_{\Delta\alpha \rightarrow 0} \frac{\Delta s}{\Delta\alpha} = \frac{ds}{d\alpha}.$$

Notice that the quantity on the right hand side is well defined (independently of its rather intuitive justification).

Define the *curvature* of the graph of the function  $f$  at the point  $P$  as the number  $1/\rho$ . Zero curvature then corresponds to an infinite radius  $\rho$ .

For computing the radius  $\rho$  in terms of  $f$  we need to express the length of the arc  $s$  by the change of the angle  $\alpha$  and express the derivative of this function by the derivative of  $f$ .

Notice that for an increasing angle  $\alpha$  the length of the arc can either increase or decrease, depending on whether the circle  $C_Q$  has its center above or below the graph of the function  $f$ . The sign of  $\rho$  then reflects whether the function is concave or convex. There is also the special case when the center "runs off" to infinity in the limit. Instead of a circle there is the tangent line.

There is no direct tool to compute the derivative  $\frac{ds}{d\alpha}$ . However,  $\text{tg } \alpha = \frac{df}{dx}$ . By differentiating this equality with respect to  $x$  we obtain (using the chain rule for differentials)

$$\frac{1}{(\cos \alpha)^2} \frac{d\alpha}{dx} = f''.$$

On the left hand side we can substitute

$$\frac{1}{(\cos \alpha)^2} = 1 + (\text{tg } \alpha)^2 = 1 + (f')^2$$

To obtain this conclusion though, we again didn't have to compute the second derivative for  $x < 0$ , it sufficed to use the even parity of the function. In total, we obtained that  $f$  is convex on its whole domain (it doesn't have any inflection points).

To be able to plot the graph of the function, we still need to find the asymptotes (we leave the computation of values of the function at certain points to the reader). Since  $f$  is continuous on  $\mathbb{R}$ , it can't have any horizontal asymptotes. A line  $y = ax + b$  is an inclined asymptote for  $x \rightarrow \infty$  if and only if both (proper) limits

$$\lim_{x \rightarrow \infty} \frac{f(x)}{x} = a, \quad \lim_{x \rightarrow \infty} (f(x) - ax) = b.$$

exist. Analogous statement holds for  $x \rightarrow -\infty$ . Hence the limits

$$\begin{aligned} \lim_{x \rightarrow \infty} \frac{f(x)}{x} &= \lim_{x \rightarrow \infty} \frac{\sqrt[3]{x^3+1}}{x} = \lim_{x \rightarrow \infty} \frac{\sqrt[3]{x^3}}{x} = 1, \\ \lim_{x \rightarrow \infty} (f(x) - 1 \cdot x) &= \lim_{x \rightarrow \infty} (\sqrt[3]{x^3+1} - x) = \\ \lim_{x \rightarrow \infty} \left( \left[ \sqrt[3]{x^3+1} - x \right] \frac{\sqrt[3]{(x^3+1)^2+x\sqrt[3]{x^3+1}+x^2}}{\sqrt[3]{(x^3+1)^2+x\sqrt[3]{x^3+1}+x^2}} \right) &= \\ \lim_{x \rightarrow \infty} \frac{x^3+1-x^3}{\sqrt[3]{(x^3+1)^2+x\sqrt[3]{x^3+1}+x^2}} &= \lim_{x \rightarrow \infty} \frac{1}{3x^2} = 0 \end{aligned}$$

imply that the line  $y = x$  is an asymptote at  $+\infty$ . If we again consider the fact that  $f$  is even, we'll immediately obtain the line  $y = -x$  as an asymptote at  $-\infty$ .  $\square$

**6.A.35.** Determine the course of the function

$$f(x) = \frac{\cos x}{\cos 2x}.$$

**Solution.** The domain consists of exactly those  $x \in \mathbb{R}$ , for which  $\cos 2x \neq 0$ . The equality  $\cos 2x = 0$  is satisfied exactly for

$$2x = \frac{\pi}{2} + k\pi, \quad k \in \mathbb{Z}, \quad \text{tj.} \quad x = \frac{\pi}{4} + \frac{k\pi}{2}, \quad k \in \mathbb{Z}.$$

Hence the domain is

$$\mathbb{R} \setminus \left\{ \frac{\pi}{4} + \frac{k\pi}{2}; k \in \mathbb{Z} \right\}.$$

Clearly we have

$$f(-x) = \frac{\cos(-x)}{\cos(-2x)} = \frac{\cos x}{\cos 2x} = f(x)$$

for all  $x$  in the domain, thus  $f$  (with its domain symmetric with respect to the origin) is an even function, which was implied by the even parity of the function  $y = \cos x$ . Moreover, because cosine is periodic with a period of  $2\pi$  (i.e.  $y = \cos 2x$  has a period of  $\pi$ ), it suffices to consider the function  $f$  for

$$\begin{aligned} x \in \mathcal{D} := [0, \pi] \setminus \left\{ \frac{\pi}{4} + \frac{k\pi}{2}; k \in \mathbb{Z} \right\} = \\ \left[ 0, \frac{\pi}{4} \right) \cup \left( \frac{\pi}{4}, \frac{3\pi}{4} \right) \cup \left( \frac{3\pi}{4}, \pi \right], \end{aligned}$$

which implies (see the rule for differentiating inverse functions)

$$\frac{dx}{d\alpha} = \frac{1 + (\text{tg } \alpha)^2}{f''} = \frac{1 + (f')^2}{f''}.$$

Now, we are almost finished, because the increment of the length of arc  $s$  dependent on  $x$  is given by the formula

$$\frac{ds}{dx} = (1 + (f')^2)^{1/2}.$$

Thus, by the chain rule,

$$\rho = \frac{ds}{d\alpha} = \frac{ds}{dx} \frac{dx}{d\alpha} = \frac{(1 + (f')^2)^{3/2}}{f''}.$$

The result explains the relation between the curvature and the second derivative. The numerator of the fraction is always positive. It equals the third power of the length of the tangent vector of the given curve. The sign of the curvature is therefore given only by the sign of the second derivative, which confirms the ideas about concave and convex points of functions.

If the second derivative is zero, the curvature  $1/\rho$  is also zero. If  $f''$  is large, then the radius  $\rho$  is small, thus the curvature is large as well.

The circle, by which curvature is defined is called the *osculating circle*.

Compute the curvature of simple functions yourself and use osculating circles while sketching their graphs. The computation at the critical points of the function  $f$  is easiest. The radius of the osculating circle is the reciprocal value of the second derivative with the corresponding sign.

**6.1.13. Vector differential calculus.** As mentioned already in the introduction to chapter five, most considerations related to differentiation are based on the fact that the functions are defined on real numbers and that their values can be added and multiplied by real numbers. That is why functions  $f : \mathbb{R} \rightarrow V$  need to have values in a vector space  $V$ . We call them *vector functions of one real variable* or more briefly *vector functions*.

To end this section, we digress to consider functions with values in the plane or in space. Thus,  $f : \mathbb{R} \rightarrow \mathbb{R}^2$  and  $f : \mathbb{R} \rightarrow \mathbb{R}^3$ . We consider (parametrized) curves in plane and space. We could work with values in  $\mathbb{R}^n$  for any finite dimension  $n$ .

For simplification, we work with the fixed standard bases  $e_i$  in  $\mathbb{R}^2$  and  $\mathbb{R}^3$ . So curves are given by pairs or triples of real functions of one real variable, respectively. The vector function  $r$  in plane or space, respectively, is given by

$$r(t) = x(t)e_1 + y(t)e_2, \quad r(t) = x(t)e_1 + y(t)e_2 + z(t)e_3.$$

The derivative of such a vector function is a vector, which approximates the map  $r$  by a linear map of the real line to the plane or to the space.

In the plane it is

$$\frac{dr}{dt}(t) = r'(t) = x'(t)e_1 + y'(t)e_2$$

and similarly in space.

since the course of the function on its whole domain can be derived using its even parity and periodicity with a period of  $2\pi$ .

Hence we'll only be concerned with the discontinuities  $x_1 = \pi/4$  and  $x_2 = 3\pi/4$ . We'll determine the corresponding one-sided limits

$$\begin{aligned} \lim_{x \rightarrow \frac{\pi}{4}^-} \frac{\cos x}{\cos 2x} &= +\infty, & \lim_{x \rightarrow \frac{\pi}{4}^+} \frac{\cos x}{\cos 2x} &= -\infty, \\ \lim_{x \rightarrow \frac{3\pi}{4}^-} \frac{\cos x}{\cos 2x} &= +\infty, & \lim_{x \rightarrow \frac{3\pi}{4}^+} \frac{\cos x}{\cos 2x} &= -\infty. \end{aligned}$$

If we have a respect to the continuity of  $f$  on the interval  $(\pi/4, 3\pi/4)$ , we can see that  $f$  attains all real values on this interval. Hence the range of  $f$  is the whole  $\mathbb{R}$ . We also found out that the discontinuities are of the second kind, where at least one of the one-sided limits is improper (or doesn't exist). By that, we simultaneously proved that the lines  $x = \pi/4$  and  $x = 3\pi/4$  are horizontal asymptotes. If we'd want to formulate the previous results without a restriction to the  $[0, \pi]$ , we can say that at all points

$$\hat{x}_k = \frac{\pi}{4} + \frac{k\pi}{2}, \quad k \in \mathbb{Z}$$

$f$  has a discontinuity of the second kind and every line

$$x = \frac{\pi}{4} + \frac{k\pi}{2}, \quad k \in \mathbb{Z}$$

is a horizontal asymptote. Also the periodicity of  $f$  implies that no other asymptotes exist. In particular, it cannot have any inclined asymptotes, nor can the (improper) limits  $\lim_{x \rightarrow +\infty} f(x)$ ,  $\lim_{x \rightarrow -\infty} f(x)$  exist. Now we'll find the points of intersection with the axes. The point of intersection  $[0, 1]$  with the  $y$  axis can be found by computing  $f(0) = 1$ . When looking for the points of intersection with the  $x$  axis, we consider the equation  $\cos x = 0$ ,  $x \in \mathcal{D}$  with the only solution being  $x = \pi/2$ . Then we can easily obtain the intervals  $[0, \pi/4)$ ,  $(\pi/2, 3\pi/4)$ , on which  $f$  is positive, and the intervals  $(\pi/4, \pi/2)$ ,  $(3\pi/4, \pi]$ , where it's negative.

Now we'll step up to computing the derivative

$$\begin{aligned} f'(x) &= \frac{-\sin x \cos 2x - 2 \cos x (-\sin 2x)}{\cos^2 2x} \\ &= \frac{-\sin x (\cos^2 x - \sin^2 x) + 2 \cos x (2 \sin x \cos x)}{\cos^2 2x} \\ &= \frac{\sin^3 x + 3 \cos^2 x \sin x}{\cos^2 2x} \\ &= \frac{(\sin^2 x + \cos^2 x + 2 \cos^2 x) \sin x}{\cos^2 2x} \\ &= \frac{(2 \cos^2 x + 1) \sin x}{\cos^2 2x}, \quad x \in \mathcal{D}. \end{aligned}$$

The differential of a vector function in this context is:

$$dr = \left( \frac{dx}{dt} e_1 + \frac{dy}{dt} e_2 + \frac{dz}{dt} e_3 \right) dt$$

where the expression on the right hand side is understood as "selecting" an increment of the scalar independent variable  $t$  and mapping it linearly by multiplying the vector of the three derivative components. Thus the corresponding increment of the vector quantity  $r$  is obtained (of course, only two components in the plane).

The notation  $r(t)$  is a convenient way to describe curves in space. For example  $r(t) = (a \cos t, a \sin t, bt)$  or  $r(t) = a \cos t e_1 + a \sin t e_2 + b e_3$  for fixed constants  $a, b$  describes a circular helix. Here the parameter  $t$  is related to a suitable angle measured around the  $z$ -axis. The derivative of  $r(t)$  at  $t = t_0$ , determines the direction of the tangent line at  $r(t_0)$ . In Newtonian mechanics, the parameter  $t$  can stand for time, measured in suitable units. In this case the derivative of  $r(t)$  at time  $t = t_0$ , gives the velocity vector at the same time. The second derivative then represents the acceleration vector at the same time.

**6.1.14. Differentiating composite maps.** In linear algebra and geometry there are very useful special maps called forms. They have one or more vectors as their arguments and they are linear in each of their arguments. In this way we defined the length of the vectors (the dot product is a symmetric bilinear form) or the volume of a parallelepiped (this is an  $n$ -linear antisymmetric form, where  $n$  is the dimension of the space), see for example the paragraphs 2.3.22 a 4.1.22.

Of course, we insert vectors  $r(t)$  dependent on a parameter as the arguments of these operations. By a straightforward usage of the Leibniz rule for differentiation of a product of functions, the following is verified:

**Theorem.** (1) If  $r(t) : \mathbb{R} \rightarrow \mathbb{R}^n$  is a differentiable vector and  $\Psi : \mathbb{R}^n \rightarrow \mathbb{R}^m$  is a linear map, then the derivative of the map  $\Psi \circ r$  satisfies

$$\frac{d(\Psi \circ r)}{dt} = \Psi \circ \frac{dr}{dt}.$$

(2) Let there be differentiable vectors  $r_1, \dots, r_k : \mathbb{R} \rightarrow \mathbb{R}^n$  and a  $k$ -linear form  $\Phi : \mathbb{R}^n \times \dots \times \mathbb{R}^n$  on the space  $\mathbb{R}^n$ . Then the derivative of the composed map

$$\varphi(t) = \Phi(r_1(t), \dots, r_k(t))$$

satisfies the (generalized) Leibniz rule

$$\frac{d\varphi}{dt} = \Phi\left(\frac{dr_1}{dt}, r_2, \dots, r_k\right) + \dots + \Phi\left(r_1, \dots, r_{k-1}, \frac{dr_k}{dt}\right).$$

(3) The previous statement remains valid even if  $\Phi$  also has values in the vector space, and is linear in all its  $k$  arguments.

**PROOF.** (1) The linear maps are given by a constant matrix of scalars  $A = (a_{ij})$  so that

$$\Psi \circ r(t) = \left( \sum_{i=1}^n a_{1i} r_i(t), \dots, \sum_{i=1}^n a_{mi} r_i(t) \right).$$

The points at which  $f'(x) = 0$  are clearly the solutions of the equation  $\sin x = 0, x \in \mathcal{D}$ , i.e. the derivative is zero at points  $x_3 = 0, x_4 = \pi$ . The inequalities

$2 \cos^2 x + 1 \geq \cos^2 2x > 0, \sin x > 0, x \in \mathcal{D} \cap (0, \pi)$  imply that  $f$  is increasing at every inner point of the set  $\mathcal{D}$ , thus  $f$  is increasing on every subinterval of  $\mathcal{D}$ . The even parity of  $f$  then implies that it's decreasing at every point  $x \in (-\pi, 0), x \neq -3\pi/4, x \neq -\pi/4$ . Hence the function has strict local extremes exactly at the points

$$\tilde{x}_k = k\pi, \quad k \in \mathbb{Z}.$$

With respect to periodicity of  $f$ , we uniquely describe these extremes by stating that for  $x_3 = \tilde{x}_0 = 0$ , we get a local minimum (recall the value of the function  $f(0) = 1$ ) and for  $x_4 = \tilde{x}_1 = \pi$ , a local maximum with the value  $f(\pi) = -1$ .

Let's compute the second derivative

$$\begin{aligned} f''(x) &= \frac{[4 \cos x (-\sin x) \sin x + (2 \cos^2 x + 1) \cos x] \cos^2 2x}{\cos^4 2x} \\ &= \frac{4 \cos 2x (-\sin 2x) (2 \cos^2 x + 1) \sin x}{\cos^4 2x} = \dots \\ &= \frac{[10 \sin^2 x \cos^2 x + 2 \cos^4 x + \cos^2 x + 4 \sin^4 x + 7 \sin^2 x] \cos x}{\cos^3 2x}, \end{aligned}$$

$x \in \mathcal{D}$ . Note that after a few simplifications, we can also express

$$f''(x) = \frac{(3 + 4 \cos^2 x \sin^2 x + 8 \sin^2 x) \cos x}{\cos^3 2x}, \quad x \in \mathcal{D}$$

or

$$f''(x) = \frac{(11 - 4 \cos^4 x - 4 \cos^2 x) \cos x}{\cos^3 2x}, \quad x \in \mathcal{D}.$$

Since

$$10 \sin^2 x \cos^2 x + 2 \cos^4 x + \cos^2 x + 4 \sin^4 x + 7 \sin^2 x > 0, \quad x \in \mathbb{R},$$

or

$$3 + 4 \cos^2 x \sin^2 x + 8 \sin^2 x = 11 - 4 \cos^4 x - 4 \cos^2 x \geq 3, \quad x \in \mathbb{R}$$

respectively, we have  $f''(x) = 0$  for certain  $x \in \mathcal{D}$  if and only if  $\cos x = 0$ . But that's satisfied only by  $x_5 = \pi/2 \in \mathcal{D}$ . It's clear that  $f''$  changes its sign at this point, i.e. it's a point of inflection. No other points of inflection exist (the second derivative  $f''$  is continuous on  $\mathcal{D}$ ). Other changes of the sign of  $f''$  occur at zero points of the denominator, which we have already determined as discontinuities  $x_1 = \pi/4$  and  $x_2 = 3\pi/4$ . Hence the sign changes exactly at points  $x_1, x_2, x_5$ , thus the inequality

Carry out the differentiation separately for individual coordinates of the result. However, the derivative acts linearly with respect to scalar linear combinations, see Theorem 5.3.4. That is why the derivative is obtained simply by evaluating the original linear map  $\Psi$  on the derivative  $r'(t)$ .

(2) The second statement is obtained analogously. Write out the evaluation of the  $k$ -linear form on the vectors  $r_1, \dots, r_k$  in the coordinates in this way:

$$\Phi(r_1(t), \dots, r_k(t)) = \sum_{i_1, \dots, i_k=1}^n B_{i_1 \dots i_k} \cdot (r_1)_{i_1}(t) \dots (r_k)_{i_k}(t),$$

where the scalars  $B_{i_1 \dots i_k}$  are given as the value  $\Phi(e_{i_1}, \dots, e_{i_k})$  of the given form on the chosen  $k$ -tuple of base vectors for every choice of indices. The rule for differentiating a product of scalar functions then yields the statement.

(3) If  $\Phi$  has vector values, it is given by finitely many components and the previous result can be used for each of them  $\square$

In the Euclidean space  $\mathbb{R}^3$ , the scalar product assigns a scalar to two vectors, There is also the vector product, which assigns the vector  $u \times v \in \mathbb{R}^3$  to vectors  $u$  and  $v$ , see 4.1.24. This vector  $u \times v$  is orthogonal to both vectors  $u$  and  $v$ , its length equals the area of the parallelogram determined by  $u$  and  $v$  (in this order) and the orientation is such that the triple  $u, v, u \times v$  is a positively oriented basis.

The previous ideas immediately imply:

**Corollary.** Consider the vectors  $u(t)$  and  $v(t)$  in the space  $\mathbb{R}^3$ . The derivatives of their scalar product  $\langle u(t), v(t) \rangle$  and their vector product  $u(t) \times v(t)$  satisfy

$$\begin{aligned} (1) \quad & \frac{d}{dt} \langle u(t), v(t) \rangle = \langle u'(t), v(t) \rangle + \langle u(t), v'(t) \rangle \\ (2) \quad & \frac{d}{dt} (u(t) \times v(t)) = u'(t) \times v(t) + u(t) \times v'(t) \end{aligned}$$

**6.1.15. The curvature of curves.** We develop far more powerful tools for studying curves in a more systematic way than when we discussed the curvature of the graphs of functions. We proceed in dimension three. Plane curves are a special case in which the third component is the constant zero.

Let  $r(t)$  be a curve in the Euclidean space  $\mathbb{R}^3$ . For theoretical purposes, it is convenient to choose arc length  $s$  as a parameter. Since  $dr^2 = dx^2 + dy^2 + dz^2 = ds^2$ , it follows that  $|\frac{dr}{ds}| = 1$ , so that the tangent vector has unit length. When  $s$  is the parameter, the notation  $'$  is used for differentiation.

So  $\langle r'(s), r'(s) \rangle = 1$  for all  $s$ . The curve  $r(s)$  is parametrized by the length  $s$ . By another differentiation of this unit vector  $r'(s)$ , the vector  $r''(s)$ , for which (using the symmetry of the dot product)

$$0 = \frac{d}{ds} \langle r'(s), r'(s) \rangle = 2 \langle r''(s), r'(s) \rangle.$$

Thus the vector  $r''(s)$  is always orthogonal to the vector  $r'(s)$ .

$$f''(x) > 0 \quad \text{pro} \quad x \rightarrow 0^+$$

implies that  $f$  is convex on the interval  $[0, \pi/4)$ , concave on  $(\pi/4, \pi/2]$ , convex on  $[\pi/2, 3\pi/4)$  and concave on  $(3\pi/4, \pi]$ . The convexity and concavity of  $f$  on other subintervals is given by its periodicity and a simple observation: if a function is even and convex on an interval  $(a, b)$ , where  $0 \leq a < b$ , then it's also convex on  $(-b, -a)$ .

All that's left is computing the derivative (to estimate the speed of the growth of the function) at the point of inflection, yielding  $f'(\pi/2) = 1$ . Based on all previous results, it's now easy to plot the graph of function  $f$ .  $\square$

**6.A.36.** Determine the course of the function

$$\frac{x}{\ln(x)},$$

and plot its graph.

**Solution.** i) First we'll determine the domain of the function:  $\mathbb{R}^+ \setminus \{1\}$ .

ii) We'll find the intervals of monotonicity of the function: first we'll find zero points of the derivative:

$$f'(x) = \frac{\ln(x) - 1}{\ln^2(x)} = 0$$

The root of this equation is  $e$ . Next we can see that  $f'(x)$  is negative on both intervals  $(0, 1)$  and  $(1, e)$ , hence  $f(x)$  is decreasing on both intervals  $(0, 1)$  and  $(1, e)$ . Additionally,  $f'(x)$  is positive on the interval  $(e, \infty)$ , thus  $f(x)$  is increasing here. That means the function  $f$  has the only extreme at point  $e$ , being the minimum. (we can also decide this using the sign of the second derivative of the function  $f$  at point  $e$ , because  $f^{(2)}(e) > 0$ ).

iii) We'll find the points of inflection:

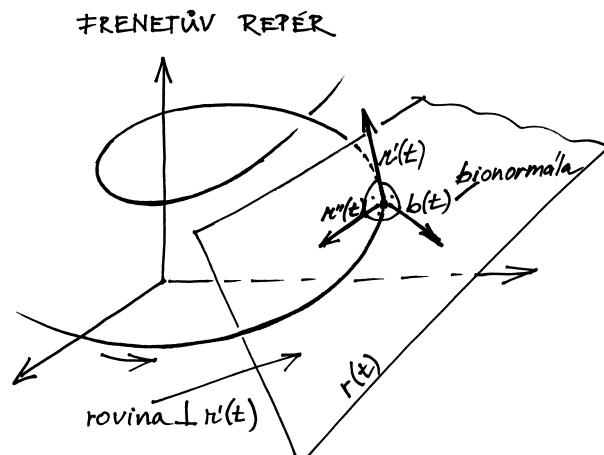

$$f^{(2)}(x) = \frac{\ln(x) - 2}{x \ln^3(x)} = 0$$

The root of this equation is  $e^2$ , so it must be a point of inflection (it cannot be an extreme with regard to the previous point).

iv) The asymptotes. The line  $x = 1$  is an asymptote of the function. Next, let's look for asymptotes with a finite slope  $k$ :

$$k = \lim_{x \rightarrow \infty} \frac{\frac{x}{\ln(x)}}{x} = \lim_{x \rightarrow \infty} \frac{1}{\ln(x)} = 0.$$

This corresponds to the idea that after the choice of a parametrization with a derivative of constant length, the second derivative in the direction of the movement vanishes. The second derivative lies in the plane orthogonal to the tangent vector.

If the second derivative is nonzero, the normed vector

$$n(s) = \frac{1}{\|r''(s)\|} r''(s)$$

is the (principal) *normal of the curve*  $r(s)$ . The scalar function  $\kappa(s)$  satisfying (at the points where  $r''(s) \neq 0$ )

$$r''(s) = \kappa(s)n(s)$$

is called *the curvature of the curve*  $r(s)$ . At the zero points of the second derivative  $\kappa(s)$  is defined as 0.

At the nonzero points of the curvature, the unit vector  $b(s) = r'(s) \times n(s)$  is well defined and is called the *binormal of the curve*  $r(s)$ . By direct computation

$$\begin{aligned} 0 &= \frac{d}{ds} \langle b(s), r'(s) \rangle = \langle b'(s), r'(s) \rangle + \langle b(s), r''(s) \rangle \\ &= \langle b'(s), r'(s) \rangle + \kappa(s) \langle b(s), n(s) \rangle = \langle b'(s), r'(s) \rangle, \end{aligned}$$

which shows that the derivative of the binormal is orthogonal to  $r'(s)$ .  $b'(s)$  is also orthogonal to  $b(s)$  (for the same reason as with  $r'$  above). Therefore it is a multiple of the principal normal  $n(s)$ . We write

$$b'(s) = -\tau(s)n(s).$$

The scalar function  $\tau(s)$  is called the *torsion of the curve*  $r(s)$ .

In the case of plane curves, the definitions of binormal and torsion do not make sense.

We have not yet computed the rate of change of the principal normal, which can be written as  $n(s) = b(s) \times r'(s)$ :

$$\begin{aligned} n'(s) &= b'(s) \times r'(s) + \kappa(s)b(s) \times n(s) \\ &= -\tau(s)n(s) \times r'(s) + \kappa(s)(-r'(s)) \\ &= \tau(s)b(s) - \kappa(s)r'(s). \end{aligned}$$

Successively, for all points with nonzero second derivative of the curve  $r(s)$  parametrized by the arc length, there is derived the important basis  $(r'(s), n(s), b(s))$ , called *the Frenet frame* in the classical literature. At the same time, this

If the asymptote exists, its slope must be 0. Let's continue the computation

$$\lim_{x \rightarrow \infty} \frac{x}{\ln(x)} - 0 \cdot x = \lim_{x \rightarrow \infty} \ln(x) = \infty,$$

and because the limit isn't finite, an asymptote with a finite slope doesn't exist.

The course of the function:

Now move from determining the course of functions onto other subjects connected to derivatives of functions. First we'll demonstrate the concept of curvature and the osculating circle on an ellipse

**6.A.37.** Determine the curvature of the ellipse  $x^2 + 2y^2 = 2$  at its vertices (4.C.9). Also determine the equations of the circles of osculation at these vertices.

**Solution.** Because the ellipse is already in the basic form at the given coordinates (there are no mixed or linear terms), the given basis is already a polar basis. Its axes are the coordinate axes  $x$  and  $y$ , its vertices are the points  $[\sqrt{2}, 0]$ ,  $[-\sqrt{2}, 0]$ ,  $[0, 1]$  and  $[0, -1]$ . Let's first compute the curvature at vertice  $[0, 1]$ . If we consider the coordinate  $y$  as a function of the coordinate  $x$  (determined uniquely in a neighbourhood of  $[0, 1]$ ), then differentiating the equation of the ellipse with respect to the variable  $x$  yields  $2x + 4yy' = 0$ , hence  $y' = -\frac{x}{2y}$  ( $y'$  denotes the derivative of function  $y(x)$  with respect to the variable  $x$ ; in fact it's nothing else than expressing the derivative of a function given implicitly, see ??). Differentiating this

basis is used in order to express the derivatives of its components in the form of the *Frenet-Serret formulas*

$$\begin{aligned} \frac{dr'}{ds}(s) &= \kappa(s)n(s), & \frac{dn}{ds}(s) &= \tau(s)b(s) - \kappa(s)r'(s) \\ \frac{db}{ds}(s) &= -\tau(s)n(s). \end{aligned}$$

The following theorem tells how crucial the curvature and torsion are. Notice that if the curve  $r(s)$  lies in one plane, then the torsion is identically zero. In fact, the converse is true as well. We shall not provide the proofs here.

**Theorem.** Two curves in a space parametrized by the length of their arc can be mapped to each other by an Euclidean transformation if and only if their curvature functions and torsion functions coincide except for a constant shift of the parameter. Moreover, for every choice of smooth functions  $\kappa$  a  $\tau$  there exists a smooth curve with these parameters.

By a straightforward computation we can check that the curvature of the graph of the function  $y = f(x)$  in plane and the curvature  $\kappa$  of this curve defined in this paragraph coincide. Indeed, comparing the differentials of the length of the arc for the graph of a function (as a curve with coordinates  $x(t), y(t) = f(x(t))$ ):

$$dt = (1 + (f_x)^2)^{1/2} dx, \quad dx = (1 + (f_x)^2)^{-1/2} dt$$

(here we write  $f_x = \frac{df}{dx}$ ) we obtain the following equality for the unit tangent vector of the graph of a curve

$$\square \quad r'(s) = (x'(s), y'(s)) = ((1 + (f_x)^2)^{-1/2}, f_x(1 + (f_x)^2)^{-1/2}).$$

A messy, but very similar computation for the second derivative and its length leads to

$$\kappa^2 = \|r''\|^2 = \left(\frac{d^2 f}{dx^2}\right)^2 (1 + (f_x)^2)^{-3}$$

as expected. If we write  $r = (x, y)$ ,  $y' = f_x x'$ ,  $x' = (1 + f_x^2)^{-1/2}$ , then

$$\begin{aligned} x'' &= -\frac{1}{2}(x')^3 2f_x f_{xx} x' = -(x')^4 f_x f_{xx} \\ y'' &= f_{xx}(x')^2 + f_x x'' = f_{xx}(x')^2 - f_{xx} f_x^2 (x')^4. \end{aligned}$$

Hence

$$\begin{aligned} (x'')^2 + (y'')^2 &= f_{xx}^2 (x')^8 (f_x + (1 + f_x^2)^2 + f_x^4 \\ &\quad - 2f_x^2(1 + f_x^2)) \\ &= f_{xx}^2 (1 + f_x^2)^{-4} (f_x^2 + 1) \\ &= f_{xx}^2 (1 + f_x^2)^{-3}. \end{aligned}$$

**6.1.16. The numerical derivatives.** In the begining of this textbook we discussed how to describe the values in a sequence if its immediate differences are known, (c.f. paragraphs 1.1.5, 1.2.1). Before proceeding the same way with the derivatives we clarify the connections between derivatives and differences. The key to this is the Taylor expansion with remainder.

equation with respect to  $x$  than yields  $y'' = -\frac{1}{2}(\frac{1}{y} - \frac{xy'}{y^2})$ . At point  $[1, 0]$ , we obtain  $y' = 0$  and  $y'' = -\frac{1}{2}$  (we'd receive the same results if we explicitly expressed  $y = \frac{1}{2}\sqrt{2-x^2}$  from the equation of the ellipse and performed differentiation; the computation would be only a little more complicated, as the reader can surely verify). According to 6.1.12, the radius of the osculation circle will be

$$\frac{(1 + (y')^2)^{\frac{3}{2}}}{(y'')^2} = -2,$$

or 2, respectively, and the sign tells us the circle will be “below” the graph of the function. The ideas in 6.1.12 and 6.1.15 imply that its center will be in the direction opposite to the normal line of this curve, i.e. on the  $y$  axis (the function  $y$  as a function of variable  $x$  has a derivative at point  $[0, 1]$ , thus the tangent line to its graph at this point will be parallel to the  $x$  axis, and because the normal is perpendicular to the tangent, it must be the  $y$  axis at this point). The radius is 2, so the center will be at point  $[0, 1 - 2] = [0, -1]$ . In total, the equation of the osculation circle of the ellipse  $x^2 + 2y^2 = 2$  at point  $[0, 1]$  will be  $x^2 + (y + 1)^2 = 4$ . Analogously, we can determine the equation of the osculation circle at point  $[0, -1]$ :  $x^2 + (y - 1)^2 = 4$ . The curvatures of the ellipse (as a curve) at these points then equal  $\frac{1}{2}$  (the absolute value of the curvature of the graph of the function).

For determining the osculation circle at point  $[\sqrt{2}, 0]$ , we'll consider the equation of the ellipse as a formula for the variable  $x$  depending on the variable  $y$ , i.e.  $x$  as a function of  $y$  (in a neighbourhood of point  $[\sqrt{2}, 0]$ , the variable  $y$  as a function of  $x$  isn't determined uniquely, so we cannot use the previous procedure - technically it would end up by dividing by zero). Sequentially, we obtain:  $2xx' + 4y = 0$ , thus  $x' = -2\frac{y}{x}$ , and  $x'' = -2(\frac{1}{x} - \frac{yx'}{x^2})$ . Hence at point  $[\sqrt{2}, 0]$ , we have  $x' = 0$  and  $x'' = -\sqrt{2}$  and the radius of the circle of osculation is  $\rho = -\frac{1}{\sqrt{2}} = \frac{\sqrt{2}}{2}$  according to 6.1.12. The normal line is heading to  $-\infty$  along the  $x$  axis at point  $[\sqrt{2}, 0]$ , thus the center of the osculation circle will be on the  $x$  axis on the other side at distance  $\frac{\sqrt{2}}{2}$ , hence at the point  $[\sqrt{2} - \frac{\sqrt{2}}{2}, 0] = [\frac{\sqrt{2}}{2}, 0]$ . In total, the equation of the circle of osculation at vertice  $[\sqrt{2}, 0]$  will be  $(x - \frac{\sqrt{2}}{2})^2 + y^2 = \frac{1}{2}$ . The curvature at both of these vertices equals  $\sqrt{2}$ .

Suppose that for some (sufficiently) differentiable function  $f(x)$  defined on the interval  $[a, b]$ , the values  $f_i = f(x_i)$  at the points  $x_0 = a, x_1, x_2, \dots, x_n = b$ , are given while  $x_i - x_{i-1} = h$  for some constant  $h > 0$  and all indices  $i = 1, \dots, n$ . Write the Taylor expansion of function  $f$  in the form

$$f(x_i \pm h) = f_i \pm hf'(x_i) + \frac{h^2}{2}f''(x_i) \pm \frac{h^3}{3!}f^{(3)}(x_i) + \dots$$

Suppose the expansion is terminated at the term containing  $h^k$  which is of order  $k$  in  $h$ . Then the actual error is bounded by

$$\frac{h^{k+1}}{(k+1)!}|f^{(k+1)}(x)|$$

on the interval  $[x_i - h, x_i + h]$ . If the  $(k+1)^{th}$  derivative  $f$  is continuous, it can be approximated by a constant. Then for small  $h$ , the error of the approximation by the Taylor polynomial of order  $k$  acts like  $h^{k+1}$  except for a constant multiple. Such an estimation is called an *asymptotic estimation*.

#### ASYMPTOTIC ESTIMATES

**Definition.** The expression  $G(h)$  is asymptotically equal to  $F(h)$  for  $h \rightarrow 0$ . Write  $G(h) = O(F(h))$ , if the finite limit

$$\lim_{h \rightarrow 0} \frac{G(h)}{F(h)} = a \in \mathbb{R}$$

exists.

Similarly, compare the expressions for  $h \rightarrow \infty$  and use the same notation.

Denote the values of the derivatives of  $f(x)$  at the points  $x_i$  as  $f_i^{(j)}$ . Write the Taylor expansion as:

$$f_{i \pm 1} = f_i \pm f_i' h + \frac{f_i''}{2} h^2 \pm \frac{f_i'''}{6} h^3 + \dots$$

Considering combinations of the two expansions and  $f_i$  itself, we can express the derivative  $f_i'$  as follows

$$\begin{aligned} \frac{f_{i+1} - f_{i-1}}{2h} &= f_i' + \frac{h^2}{3!} f_i^{(3)} + \dots \\ \frac{f_{i+1} - f_i}{h} &= f_i' + \frac{h}{2!} f_i'' + \dots \\ \frac{f_i - f_{i-1}}{h} &= f_i' - \frac{h}{2!} f_i'' + \dots \end{aligned}$$

This suggests a basic numerical approximation for derivatives:

#### CENTRAL, FORWARD, AND BACKWARD DIFFERENCES

The *central difference* is defined as  $f_i' = \frac{f_{i+1} - f_{i-1}}{2h}$ , the *forward difference* is  $f_i' = \frac{f_{i+1} - f_i}{h}$ , and the *backward difference* is  $f_i' = \frac{f_i - f_{i-1}}{h}$ .

If we use the Taylor expansions with remainder of the appropriate order, we obtain an expression of the error of the

**6.A.38. Remark.** The vertices of an ellipse (more generally the vertices of a closed smooth curve in plane) can be defined as the points at which the function of curvature has an extreme. The ellipse having four vertices isn't a coincidence. The so called "Four vertices theorem" states that a closed curve of the class  $C^3$  has at least four vertices. (A curve of the class  $C^3$  is locally given parametrically by points  $[f(t), g(t)] \in \mathbb{R}^2$ ,  $t \in (a, b) \subset \mathbb{R}$ , where  $f$  and  $g$  are functions of the class  $C^3(\mathbb{R})$ .) Thus the curvature of the ellipse at its any point is between its curvatures at its vertices, i.e. between  $\frac{1}{2}$  and  $\sqrt{2}$ .

**B. Integration**

We start with an example testing the understanding the concept of Riemannian integration.

**6.B.1.** Let  $y = |x|$  on the interval  $I = [-1, 1]$  and let

$$\Xi_n = \left(-1, -\frac{n-1}{n}, \dots, -\frac{1}{n}, 0, \frac{1}{n}, \dots, \frac{n-1}{n}, 1\right)$$

be a partition of the interval  $I$  for arbitrary  $n \in \mathbb{N}$ . Determine  $S_{\Xi_n, \text{sup}}$  and  $S_{\Xi_n, \text{inf}}$  (the upper and lower Riemann sum corresponding to the given partition).

Based on this result decide if the function  $y = |x|$  on  $[-1, 1]$  is integrable (in Riemann sense). ○

And now some easy examples that everyone should handle.

**6.B.2.** Using integration "by heart", express

- (a)  $\int e^{-x} dx$ ,  $x \in \mathbb{R}$ ;
- (b)  $\int \frac{1}{\sqrt{4-x^2}} dx$ ,  $x \in (-2, 2)$ ;
- (c)  $\int \frac{1}{x^2+3} dx$ ,  $x \in \mathbb{R}$ ;
- (d)  $\int \frac{3x^2+1}{x^3+x+2} dx$ ,  $x \neq -1$ .

**Solution.** We can easily obtain

approximation by the central difference in the form

$$\frac{1}{3!}h^2(f^{(3)}(x_i + \xi h) - f^{(3)}(x_i - \eta h)).$$

Here,  $0 \leq \xi, \eta \leq 1$  are the values from the remainder expression of  $f_{i+1}$  and  $f_{i-1}$ , respectively. The error of the second derivative in the other two cases is obtained similarly. Thus, under the assumption of bounded derivatives of third or second order, the asymptotic estimates are computed.

**Theorem.** *The asymptotic estimate of the error of the central difference is  $O(h^2)$ . The errors of the backward and forward differences are  $O(h)$ .*

Surprisingly, the central difference is one order better than the other two. But of course, the constants in the asymptotic estimates are important, too. In the case of the central difference, the bound on the third derivative appears, while in the two other cases second derivatives show up instead.

We proceed the same way when approximating the second derivative. To compute  $f''(x_i)$  from a suitable combination of the Taylor polynomials, we cancel both the first derivative and the value at  $x_i$ . The simplest combination cancels all the odd derivatives as well:

$$\frac{f_{i+1} - 2f_i + f_{i-1}}{h^2} = f_i^{(2)} + \frac{h^2}{12}f^{(4)}(x_i) + \dots$$

This is called the *second order difference*. Just as in the central first order difference, the asymptotic estimate of the error is

$$f_i^{(2)} = \frac{f_{i+1} - 2f_i + f_{i-1}}{h^2} + O(h^2).$$

Notice that the actual bound depends on the fourth derivative of  $f$ .

**2. Integration**

**6.2.1. Indefinite integral.** Now, we reverse the procedure

of differentiation. We want to reconstruct the actual values of a function using its immediate changes. If we consider the given function  $f(x)$  as the (say continuous) derivative of an unknown function  $F(x)$ , then at the level of differentials we can write

$$dF = f(x) dx.$$

We call the function  $F$  the *primitive function* or the *indefinite integral* of the function  $f$ . Traditionally we write

$$F(x) = \int f(x) dx.$$

**Lemma.** *The primitive function  $F(x)$  to the function  $f(x)$  is determined uniquely on each interval  $[a, b]$  up to an additive constant.*

**PROOF.** The statement follows immediately from Lagrange's mean value theorem, see 5.3.9. Indeed, if  $F'(x) = G'(x) = f(x)$  on the whole interval  $[a, b]$ , then the derivative of the function  $(F - G)(x)$  vanishes at all points  $c$  of the interval  $[a, b]$ . The mean value theorem implies that for all points  $x$  in this interval,

$$F(x) - G(x) = F(a) - G(a) + 0 \cdot (x - a).$$

- (a)  $\int e^{-x} dx = -\int -e^{-x} dx = -e^{-x} + C$ ;  
 (b)  $\int \frac{1}{\sqrt{4-x^2}} dx = \int \frac{\frac{1}{2}}{\sqrt{1-(\frac{x}{2})^2}} dx = \arcsin \frac{x}{2} + C$ ;  
 (c)  $\int \frac{1}{x^2+3} dx = \frac{1}{3} \int \frac{1}{\frac{x^2}{3}+1} dx = \frac{1}{\sqrt{3}} \int \frac{\frac{1}{\sqrt{3}}}{1+(\frac{x}{\sqrt{3}})^2} dx = \frac{1}{\sqrt{3}} \operatorname{arctg} \frac{x}{\sqrt{3}} + C$ ;  
 (d)  $\int \frac{3x^2+3}{x^3+3x+2} dx = \ln |x^3 + 3x + 2| + C$ ,  
 where we used the formula  $\int \frac{f'(x)}{f(x)} dx = \ln |f(x)| + C$ .

Thus the difference of the values of the functions  $F$  and  $G$  is constant on the interval  $[a, b]$ .  $\square$

The previous lemma supports another notation for the indefinite integral:

$$F(x) = \int f(x) dx + C$$

with an unknown constant  $C$ .

**6.B.3.** Compute the indefinite integral

$$\int \left( 7x + 4e^{\frac{2x}{3}} - \frac{1}{2x} + 9 \sin 5x + 2 \cos \frac{x}{2} - \frac{3}{\cos^2 x} + \frac{1}{3-x} \right) dx$$

for  $x \neq 3, x \neq \frac{\pi}{2} + k\pi, k \in \mathbb{Z}$ .

**Solution.** Only by combining the earlier derived formulas, we obtain

$$\int \left( 7x + 4e^{\frac{2x}{3}} - \frac{1}{2x} + 9 \sin 5x + 2 \cos \frac{x}{2} - \frac{3}{\cos^2 x} + \frac{1}{3-x} \right) dx = \frac{7x^2}{2} + 6e^{\frac{2x}{3}} + \frac{1}{2x \ln 2} - \frac{9}{5} \cos 5x + 4 \sin \frac{x}{2} - 3 \operatorname{tg} x - \ln |3-x| + C.$$

**6.2.2. Newton integral.** We consider the value of a real function  $f(x)$  as an immediate increment of the region bounded by the graph of the function  $f$  and the  $x$  axis and try to find the area of this region between boundary values  $a$  and  $b$  of some interval. We relate this idea with the indefinite integral.

Suppose we are given a real function  $f$  and its indefinite integral  $F(x)$ , i.e.  $F'(x) = f(x)$  on the interval  $[a, b]$ .

Divide the interval  $[a, b]$  into  $n$  parts by choosing the points

$$a = x_0 < x_1 < \dots < x_n = b.$$

Approximate the values of the derivatives at the points  $x_i$  by the forward differences. That is, by the expressions

$$f(x_i) = F'(x_i) \simeq \frac{F(x_{i+1}) - F(x_i)}{x_{i+1} - x_i}.$$

Finally the sum over all the intervals of our partition yields the approximation of the area:

$$\begin{aligned} \sum_{i=0}^{n-1} f(x_i)(x_{i+1} - x_i) &\simeq \sum_{i=0}^{n-1} \frac{F(x_{i+1}) - F(x_i)}{x_{i+1} - x_i} (x_{i+1} - x_i) \\ &= \sum_{i=0}^{n-1} (F(x_{i+1}) - F(x_i)) = F(b) - F(a). \end{aligned}$$

Therefore we expect that for “nice enough” functions  $f(x)$ , the area of the region bounded by the graph of the function and the  $x$  axis (including the signs) can be calculated as a difference of the values of the primitive function at the boundary points of the interval. This procedure is called the *Newton integration*.<sup>3</sup>

For expressing the following integrals, we'll use the method of integration by parts (see 6.2.3).

**6.B.4.** Compute  $\int x \cos x dx, x \in \mathbb{R}$  and  $\int \ln x dx, x > 0$ ;

**Solution.**

$$\begin{aligned} \int \ln x dx &= \left| \begin{array}{ll} u = \ln x & u' = \frac{1}{x} \\ v' = 1 & v = x \end{array} \right| \\ &= x \ln x - \int 1 dx = x \ln x - x + C. \end{aligned}$$

$$\begin{aligned} \int x \cos x dx &= \left| \begin{array}{ll} u = x & u' = 1 \\ v' = \cos x & v = \sin x \end{array} \right| \\ &= x \sin x - \int \sin x dx = x \sin x + \cos x + C. \end{aligned}$$

**6.B.5.** Using integration by parts, compute

- (a)  $\int (x^2 + 1) e^{-x} dx, x \in \mathbb{R}$ ,  
 (b)  $\int (2x - 1) \ln x dx, x > 0$ ,  
 (c)  $\int \operatorname{arctg} x dx, x \in \mathbb{R}$ ,  
 (d)  $\int e^x \sin(\beta x) dx, x, \beta \in \mathbb{R}$ ,

<sup>3</sup>Isaac Newton (1642-1726) was a phenomenal English physicist and mathematician. The principles of integration and differentiation were formulated independently by him and Gottfried Leibniz in the late 17th century. It took nearly another two centuries before Bernhard Riemann introduced the completely rigorous modern version of the integration process.

**Solution.** First emphasise that by integration by parts, we can compute every integral in the form of

$$\begin{aligned} \int P(x) a^{bx} dx, \quad \int P(x) \sin(bx) dx, \quad \int P(x) \cos(bx) dx, \\ \int P(x) \log_a^n x dx, \quad \int x^b \log_a^n(kx) dx, \\ \int P(x) \arcsin(bx) dx, \quad \int P(x) \arccos(bx) dx, \\ \int P(x) \operatorname{arctg}(bx) dx, \quad \int P(x) \operatorname{arccotg}(bx) dx, \\ \int a^{bx} \sin(cx) dx, \quad \int a^{bx} \cos(cx) dx, \end{aligned}$$

where  $P$  is an arbitrary polynomial and

$$a \in (0, 1) \cup (1, +\infty), \quad b, c \in \mathbb{R} \setminus \{0\}, \quad n \in \mathbb{N}, \quad k > 0.$$

Thus we know that

(a)

$$\begin{aligned} \int (x^2 + 1) e^{-x} dx = \\ \left| \begin{array}{l} F(x) = x^2 + 1 \\ G'(x) = e^{-x} \end{array} \right| \left| \begin{array}{l} F'(x) = 2x \\ G(x) = -e^{-x} \end{array} \right| = \\ -(x^2 + 1) e^{-x} + \int 2x e^{-x} dx = \\ \left| \begin{array}{l} F(x) = 2x \\ G'(x) = e^{-x} \end{array} \right| \left| \begin{array}{l} F'(x) = 2 \\ G(x) = -e^{-x} \end{array} \right| = \\ -(x^2 + 1) e^{-x} - 2x e^{-x} + \int 2 e^{-x} dx = \\ -(x^2 + 1) e^{-x} - 2x e^{-x} - 2 e^{-x} + C = \\ -e^{-x} (x^2 + 2x + 3) + C; \end{aligned}$$

(b)

$$\begin{aligned} \int (2x - 1) \ln x dx = \\ \left| \begin{array}{l} F(x) = \ln x \\ G'(x) = 2x - 1 \end{array} \right| \left| \begin{array}{l} F'(x) = 1/x \\ G(x) = x^2 - x \end{array} \right| = \\ (x^2 - x) \ln x - \int \frac{x^2 - x}{x} dx = \\ (x^2 - x) \ln x + \int 1 - x dx = (x^2 - x) \ln x + x - \frac{x^2}{2} + C; \end{aligned}$$

(c)

$$\begin{aligned} \int \operatorname{arctg} x dx = \left| \begin{array}{l} F(x) = \operatorname{arctg} x \\ G'(x) = 1 \end{array} \right| \left| \begin{array}{l} F'(x) = \frac{1}{1+x^2} \\ G(x) = x \end{array} \right| = \\ x \operatorname{arctg} x - \int \frac{x}{1+x^2} dx = x \operatorname{arctg} x - \frac{1}{2} \int \frac{2x}{1+x^2} dx = \\ x \operatorname{arctg} x - \frac{1}{2} \ln(1+x^2) + C; \end{aligned}$$

(d)

$$\begin{aligned} \int e^x \sin(\beta x) dx = \\ \left| \begin{array}{l} F(x) = e^x \\ G'(x) = \sin(\beta x) \end{array} \right| \left| \begin{array}{l} F'(x) = e^x \\ G(x) = -\frac{1}{\beta} \cos \beta x \end{array} \right| = \\ -\frac{1}{\beta} e^x \cos(\beta x) + \frac{1}{\beta} \int e^x \cos(\beta x) dx = \\ \left| \begin{array}{l} F(x) = e^x \\ G'(x) = \cos(\beta x) \end{array} \right| \left| \begin{array}{l} F'(x) = e^x \\ G(x) = \frac{1}{\beta} \sin(\beta x) \end{array} \right| = \\ -\frac{1}{\beta} e^x \cos(\beta x) + \frac{1}{\beta^2} e^x \sin(\beta x) - \frac{1}{\beta^2} \int e^x \sin(\beta x) dx, \end{aligned}$$

which implies

$$\int e^x \sin x dx = \frac{1}{1+\beta^2} e^x (\sin(\beta x) - \beta \cos(\beta x)) + C.$$

### NEWTON INTEGRAL

If  $F$  is the primitive function to the function  $f$  on the interval  $[a, b]$ , then we write

$$\int_a^b f(x) dx = [F(x)]_a^b = F(b) - F(a)$$

and call it the *Newton (definite) integral* with the bounds  $a$  and  $b$ .

We prove later that for all continuous functions  $f \in C^0(a, b)$  the Newton integral exists and computes the area as expected. This is one of the fascinating theorems in elementary calculus. Before going into this, we discuss how to compute these integrals.

The primitive functions are well defined for complex functions  $f$ , where the real and the imaginary part of the indefinite integrals are real primitive functions to the real and the imaginary parts of  $f$ . Thus, with no loss of generality, we work only with real functions in sequel.

**6.2.3. Integration “by heart”.** We show several procedures for computing the Newton integral. We exploit the knowledge of differentiation, and look for primitive functions.

The easiest case is the one where the given function is known as a derivative. To learn such cases, it suffices to read the tables for function derivatives in the menagerie the other way round. Hence:

□

For expressing the following integrals, it's convenient to use the substitution method (see 6.2.5).

**6.B.6.** Using a suitable substitution, determine

- (a)  $\int \sqrt{2x-5} \, dx, x > \frac{5}{2};$
- (b)  $\int \frac{(7+\ln x)^7}{x} \, dx, x > 0;$
- (c)  $\int \frac{\cos x}{(1+\sin x)^2} \, dx, x \neq \frac{(3+4k)\pi}{2}, k \in \mathbb{Z};$
- (d)  $\int \frac{\cos x}{\sqrt{1+\sin^2 x}} \, dx, x \in \mathbb{R}.$

**Solution.** We have

(a)

$$\begin{aligned} \int \sqrt{2x-5} \, dx &= \left| \begin{array}{l} t = 2x - 5 \\ dt = 2 \, dx \end{array} \right| = \frac{1}{2} \int \sqrt{t} \, dt \\ &= \frac{1}{3} t^{\frac{3}{2}} + C = \frac{1}{3} \sqrt{(2x-5)^3} + C; \end{aligned}$$

(b)

$$\begin{aligned} \int \frac{(7+\ln x)^7}{x} \, dx &= \left| \begin{array}{l} t = 7 + \ln x \\ dt = \frac{1}{x} \, dx \end{array} \right| = \int t^7 \, dt = \frac{t^8}{8} + C \\ &= \frac{(7+\ln x)^8}{8} + C; \end{aligned}$$

(c)

$$\begin{aligned} \int \frac{\cos x}{(1+\sin x)^2} \, dx &= \left| \begin{array}{l} t = 1 + \sin x \\ dt = \cos x \, dx \end{array} \right| = \int \frac{dt}{t^2} \\ &= -\frac{1}{t} + C = -\frac{1}{1+\sin x} + C; \end{aligned}$$

(d)

$$\begin{aligned} \int \frac{\cos x}{\sqrt{1+\sin^2 x}} \, dx &= \left| \begin{array}{l} t = \sin x \\ dt = \cos x \, dx \end{array} \right| = \int \frac{1}{\sqrt{1+t^2}} \, dt \\ &= \left| \begin{array}{l} u = t + \sqrt{1+t^2} > 0 \\ du = \left(1 + \frac{t}{\sqrt{1+t^2}}\right) dt \\ \frac{du}{t + \sqrt{1+t^2}} = \frac{1}{\sqrt{1+t^2}} dt \end{array} \right| = \int \frac{1}{u} \, du = \ln u + C = \\ &= \ln(t + \sqrt{1+t^2}) + C \\ &= \ln(\sin x + \sqrt{1+\sin^2 x}) + C. \end{aligned}$$

**6.B.7.** Determine the integrals

- a)  $\int \frac{dx}{\sin^2(x) - \cos^2(x)},$
- b)  $\int x^2 \sqrt{2x+1} \, dx.$

INTEGRATION TABLE

For arbitrary nonzero  $a, b \in \mathbb{R}$  and  $n \in \mathbb{Z}, n \neq -1$ :

$$\begin{aligned} \int a \, dx &= ax + C \\ \int ax^n \, dx &= \frac{a}{n+1} x^{n+1} + C \\ \int e^{ax} \, dx &= \frac{1}{a} e^{ax} + C \\ \int \frac{a}{x} \, dx &= a \ln x + C \\ \int a \cos(bx) \, dx &= \frac{a}{b} \sin(bx) + C \\ \int a \sin(bx) \, dx &= -\frac{a}{b} \cos(bx) + C \\ \int a \cos(bx) \sin^n(bx) \, dx &= \frac{a}{b(n+1)} \sin^{n+1}(bx) + C \\ \int a \sin(bx) \cos^n(bx) \, dx &= -\frac{a}{b(n+1)} \cos^{n+1}(bx) + C \\ \int a \operatorname{tg}(bx) \, dx &= -\frac{a}{b} \ln(\cos(bx)) + C \\ \int \frac{a}{a^2+x^2} \, dx &= \operatorname{arctg}\left(\frac{x}{a}\right) + C \\ \int \frac{-1}{\sqrt{a^2-x^2}} \, dx &= \arccos\left(\frac{x}{a}\right) + C \\ \int \frac{1}{\sqrt{a^2-x^2}} \, dx &= \arcsin\left(\frac{x}{a}\right) + C. \end{aligned}$$

In all the above formulae, it is necessary to clarify the domain on which the indefinite integral is well defined. We leave this to the reader.

Further rules can be added by observations of suitable structure of the given functions. For example,

$$\int \frac{f'(x)}{f(x)} \, dx = \ln|f(x)| + C$$

for all continuously differentiable functions  $f$  on intervals where they are nonzero.

Of course, the rules for differentiating a sum of differentiable functions and constant multiples of differentiable functions yield analogous rules for the indefinite integral. So the sum of two indefinite integral is the indefinite integral of the sum of the integrated functions, up to the freedom in the chosen constant, etc.

□

**6.2.4. Integration by parts.** The Leibniz rule for derivatives,  $(F \cdot G)'(t) = F'(t)G(t) + F(t)G'(t)$ , can be interpreted in the realm of the primitive functions. This observation leads to the following very useful practical procedure. It also has theoretical consequences.

**Solution.** For computing the first integral, we'll choose the substitution  $t = \operatorname{tg} x$ , which can be often used with an advantage.

$$\begin{aligned} & \int \frac{dx}{\sin^2(x) - \cos^2(x)} \\ &= \left. \begin{array}{l} \text{substitution } t = \operatorname{tg} x \\ dt = \frac{1}{\cos^2 x} dx = (1 + \operatorname{tg}^2(x)) dx = (1 + t^2) dx \\ \sin^2(x) = \frac{\operatorname{tg}^2(x)}{1 + \operatorname{tg}^2(x)} = \frac{t^2}{1 + t^2} \\ \cos^2(x) = \frac{1}{1 + \operatorname{tg}^2(x)} = \frac{1}{1 + t^2} \end{array} \right| \\ &= \int \frac{1}{t^2 - 1} dt = \frac{1}{2} \int \frac{1}{t - 1} - \frac{1}{2} \int \frac{1}{t + 1} \\ &= \frac{1}{2} \ln \left( \frac{\operatorname{tg}(x) - 1}{\operatorname{tg} + 1} \right) + C \end{aligned}$$

Now we'll compute the second integral:

$$\begin{aligned} & \int x^2 \sqrt{2x + 1} dx \\ &= \left| \begin{array}{ll} u = x^2 & u = 2x \\ v' = \sqrt{2x + 1} & v = \frac{1}{3}(2x + 1) \end{array} \right| \\ &= \frac{1}{3} x^2 (2x + 1)^{\frac{3}{2}} - \frac{4}{3} \int x^2 \sqrt{2x + 1} dx - \frac{2}{9} (2x + 1)^{\frac{3}{2}} + C, \end{aligned}$$

which can be thought of as an equation, when the variable is the integral. By putting it on one side,

$$\begin{aligned} & \int x^2 \sqrt{2x + 1} dx \\ &= \frac{1}{7} x^2 (2x + 1)^{\frac{3}{2}} - \frac{2}{7} \int x \sqrt{2x + 1} \\ & \left| \begin{array}{ll} u = x & u' = 1 \\ v' = \sqrt{2x + 1} & v = \frac{1}{3} \sqrt{2x + 1} \end{array} \right| \\ &= \frac{1}{7} x^2 (2x + 1)^{\frac{3}{2}} - \frac{2}{7} \left( \frac{1}{3} x \sqrt{2x + 1} - \frac{1}{3} \int (2x + 1)^{\frac{3}{2}} dx \right) \\ &= \frac{1}{7} x^2 (2x + 1)^{\frac{3}{2}} - \frac{2}{21} x \sqrt{2x + 1} + \frac{2}{105} (2x + 1)^{\frac{5}{2}} \\ &= \frac{1}{7} x^2 (2x + 1)^{\frac{3}{2}} - \frac{2}{35} x (2x + 1)^{\frac{3}{2}} + \frac{2}{105} (2x + 1)^{\frac{5}{2}} + C \end{aligned}$$

**6.B.8.** Using the basic formulas, compute

- (a)  $\int \frac{1}{\sqrt[3]{x}} dx, x \neq 0;$
- (b)  $\int \operatorname{tg}^2 x dx, x \neq \frac{\pi}{2} + k\pi, k \in \mathbb{Z};$
- (c)  $\int \frac{\cos x}{1 + \sin x} dx, x \neq -\frac{\pi}{2} + 2k\pi, k \in \mathbb{Z};$
- (d)  $\int 6 \sin 5x + \cos \frac{x}{2} + 2e^{\frac{2x}{3}} dx, x \in \mathbb{R}.$

**Solution.** Case (a). We can immediately determine

$$\int \frac{1}{\sqrt[3]{x}} dx = \int x^{-1/3} dx = \frac{x^{2/3}}{2/3} + C = \frac{3}{2} \sqrt[3]{x^2} + C,$$

where the notation in which we add  $C \in \mathbb{R}$  has to be understood in a way that we can get all primitive functions exactly by a constant translation of an arbitrary primitive function.

INTEGRATION BY PARTS

The formula for computing the integral on the left hand side

$$\int F(x)G'(x) dx = F(x) \cdot G(x) - \int F'(x)G(x) dx + C$$

is called *integration by parts*.

The above formula is useful if we can compute  $G$  and at the same time compute the integral on the right hand side.

The principle is best shown on an example. Compute

$$I = \int x \sin x dx.$$

In this case the choice  $F(x) = x, G'(x) = \sin x$  will help. Then  $G(x) = -\cos x$  and therefore

$$I = x(-\cos x) - \int -\cos x dx = -x \cos x + \sin x + C.$$

Some integrals can be dealt with by inserting the factor 1, so that  $G'(x) = 1$ :

$$\begin{aligned} \int \ln x dx &= \int 1 \cdot \ln x dx \\ &= x \ln x - \int \frac{1}{x} dx = x \ln x - x + C. \end{aligned}$$

**6.2.5. Integration by substitution.** Another useful procedure is derived from the chain rule for differentiating composite functions. If

$$F'(y) = f(y), \quad y = \varphi(x),$$

where  $\varphi$  is a differentiable function with nonzero derivative, then

$$\frac{dF(\varphi(x))}{dx} = F'(y) \cdot \varphi'(x)$$

and thus  $F(y) + C = \int f(y) dy$  can be computed as

$$F(\varphi(x)) + C = \int f(\varphi(x))\varphi'(x) dx.$$

By substituting  $x = \varphi^{-1}(y)$ , we obtain the originally desired primitive function. This is often written as follows:

INTEGRATION BY SUBSTITUTION

If  $\varphi(x)$  is differentiable with a nowhere vanishing derivative, then

$$F(y) = \int f(y) dy = \int f(\varphi(x))\varphi'(x) dx = F(\varphi(x)).$$

We talk about substituting the variable  $y$  by  $y = \varphi(x)$ .

On the level of differentials, the substitution can be easily understood in a way that (linearized) increments of the variable  $y$  and  $x$  are in mutual relation formally described by

$$dy = \varphi'(x) dx,$$

which corresponds the relation between the integrated quantities

$$f(y) dy = f(\varphi(x))\varphi'(x) dx.$$

But that's only true on an interval. In other words, the value  $C$  is generally distinct for  $x < 0$  and for  $x > 0$ . Thus we should consider the values  $C_1$  and  $C_2$ . For the sake of simplicity though, we'll use the notation without indices and stating the corresponding intervals. Furthermore, we'll help ourselves by letting  $aC = C$  for  $a \in \mathbb{R} \setminus \{0\}$  and  $C + b = C$  for  $b \in \mathbb{R}$ , based on the fact that

$$\{C; C \in \mathbb{R}\} = \{aC; C \in \mathbb{R}\} = \{C + b; C \in \mathbb{R}\} = \mathbb{R}.$$

We could then obtain an entirely correct expression for example by substitutions  $\hat{C} = aC$ ,  $\tilde{C} = C + b$ . These simplifications will prove their usefulness when computing more complicated problems, because they make the procedures and the simplifications more lucid.

Case (b). Sequential simplifications of the integrated function lead to

$$\int \operatorname{tg}^2 x \, dx = \int \frac{\sin^2 x}{\cos^2 x} \, dx = \int \frac{1 - \cos^2 x}{\cos^2 x} \, dx = \int \frac{1}{\cos^2 x} \, dx - \int 1 \, dx = \operatorname{tg} x - x + C,$$

where we helped ourselves by the knowledge of the derivative

$$(\operatorname{tg} x)' = \frac{1}{\cos^2 x}, \quad x \neq \frac{\pi}{2} + k\pi, \quad k \in \mathbb{Z}.$$

Case (c). It suffices to realize that this is a special case of the formula

$$\int \frac{f'(x)}{f(x)} \, dx = \ln |f(x)| + C,$$

which can be verified directly by differentiation

$$(\ln |f(x)| + C)' = (\ln |\pm f(x)|)' + (C)' = \frac{[\pm f(x)]'}{\pm f(x)} = \frac{\pm f'(x)}{\pm f(x)} = \frac{f'(x)}{f(x)}.$$

Hence

$$\int \frac{\cos x}{1 + \sin x} \, dx = \ln(1 + \sin x) + C.$$

Case (d). Because the integral of a sum is the sum of integrals (if the separate integrals are sensible) and a nonzero constant can be factored out of the integral at any time, we have

$$\int 6 \sin 5x + \cos \frac{x}{2} + 2e^{\frac{2x}{3}} \, dx = -\frac{6}{5} \cos 5x + 2 \sin \frac{x}{2} + 3e^{\frac{2x}{3}} + C.$$

### 6.B.9. Determine

- (a)  $\int \frac{x}{\cos^2 x} \, dx$ ,  $x \neq \frac{\pi}{2} + k\pi$ ,  $k \in \mathbb{Z}$ ;
- (b)  $\int x^2 e^{-3x} \, dx$ ,  $x \in \mathbb{R}$ ;
- (c)  $\int \cos^2 x \, dx$ ,  $x \in \mathbb{R}$ .

**Solution.** Case (a). Using integration by parts, we obtain

As an illustration, we verify the last but one integral in the list in 6.2.3 using this method. To compute

$$I = \int \frac{1}{\sqrt{1-x^2}} \, dx.$$

Choose the substitution  $x = \sin t$ . Then  $dx = \cos t \, dt$ . So

$$\begin{aligned} I &= \int \frac{1}{\sqrt{1-\sin^2 t}} \cos t \, dt = \int \frac{1}{\sqrt{\cos^2 t}} \cos t \, dt \\ &= \int dt = t + C. \end{aligned}$$

By substitution  $t = \arcsin x$  into the result,  $I = \arcsin x + C$ .

While substituting, the actual existence of the inverse function to  $y = \varphi(x)$  is required. To evaluate a definite Newton integral, it is needed to correctly recalculate the bounds of integration. Problems with the domains of the inverse functions can sometimes be avoided by dividing the integration into several intervals. We return to this point later.

### 6.2.6. Integration by reduction to recurrences.

Often the use of substitutions and integrating by parts leads to recurrent relations, from which desired integrals can be evaluated. We illustrate by an example. Integrating by parts, to evaluate

$$\begin{aligned} I_m &= \int \cos^m x \, dx = \int \cos^{m-1} x \cos x \, dx \\ &= \cos^{m-1} x \sin x - (m-1) \int \cos^{m-2} x (-\sin x) \sin x \, dx \\ &= \cos^{m-1} x \sin x + (m-1) \int \cos^{m-2} x \sin^2 x \, dx. \end{aligned}$$

Using the formula  $\sin^2 x = 1 - \cos^2 x$ ,

$$mI_m = \cos^{m-1} x \sin x + (m-1)I_{m-2}$$

The initial values are

$$I_0 = x, \quad I_1 = \sin x.$$

Integrals in which the integrated function depends on expressions of the form  $(x^2 + 1)$  can be reduced to these types of integrals using the substitution  $x = \operatorname{tg} t$ . For example, to compute

$$J_k = \int \frac{dx}{(x^2 + 1)^k}$$

the latter substitution yields (notice that  $dx = \cos^{-2} t \, dt$ )

$$J_k = \int \frac{dt}{\cos^2 t \left( \frac{\sin^2 t}{\cos^2 t} + 1 \right)^k} = \int \cos^{2k-2} t \, dt.$$

□ For  $k = 2$ , the result is

$$J_2 = \frac{1}{2} (\cos t \sin t + t) = \frac{1}{2} \left( \frac{\operatorname{tg} t}{1 + \operatorname{tg}^2 t} + t \right).$$

After the reverse substitution  $t = \operatorname{arctg} x$

$$J_2 = \frac{1}{2} \left( \frac{x}{1+x^2} + \operatorname{arctg} x \right) + C.$$

When evaluating definite integrals, we can compute the whole recurrence after evaluating with the given bounds. For

$$\int \frac{x}{\cos^2 x} dx = \left| \begin{array}{l} F(x) = x \\ G'(x) = \frac{1}{\cos^2 x} \end{array} \right| \left| \begin{array}{l} F'(x) = 1 \\ G(x) = \operatorname{tg} x \end{array} \right| = x \operatorname{tg} x - \int \operatorname{tg} x dx = x \operatorname{tg} x + \int \frac{-\sin x}{\cos x} dx = x \operatorname{tg} x + \ln |\cos x| + C.$$

Case (b). This time we are clearly integrating a product of two functions. By applying the method of integration by parts, we reduce the integral to another integral in a way that we differentiate one function and integrate the second. We can integrate both of them (we can differentiate all elementary functions). Thus we must decide which of the two variants of the method we'll use (whether we'll integrate the function  $y = x^2$ , or  $y = e^{-3x}$ ). Notice that we can use integration by parts repeatedly and that the  $n$ -th derivative of a polynomial of degree  $n \in \mathbb{N}$  is a constant polynomial. That gives us a way to compute

$$\int x^2 e^{-3x} dx = \left| \begin{array}{l} F(x) = x^2 \\ G'(x) = e^{-3x} \end{array} \right| \left| \begin{array}{l} F'(x) = 2x \\ G(x) = -\frac{1}{3} e^{-3x} \end{array} \right| = -\frac{1}{3} x^2 e^{-3x} + \frac{2}{3} \int x e^{-3x} dx$$

and furthermore

$$\int x e^{-3x} dx = \left| \begin{array}{l} F(x) = x \\ G'(x) = e^{-3x} \end{array} \right| \left| \begin{array}{l} F'(x) = 1 \\ G(x) = -\frac{1}{3} e^{-3x} \end{array} \right| = -\frac{1}{3} x e^{-3x} + \frac{1}{3} \int e^{-3x} dx = -\frac{1}{3} x e^{-3x} - \frac{1}{9} e^{-3x} + C.$$

In total, we have

$$\int x^2 e^{-3x} dx = -\frac{1}{3} x^2 e^{-3x} - \frac{2}{9} x e^{-3x} - \frac{2}{27} e^{-3x} + C = -\frac{1}{3} e^{-3x} \left( x^2 + \frac{2}{3} x + \frac{2}{9} \right) + C.$$

Note that a repeated use of integration by parts within the scope of computing one integral is common (just like when computing limits by the l'Hospital rule).

Case (c). Again we apply integration by parts using

$$\begin{aligned} \int \cos^2 x dx &= \int \cos x \cdot \cos x dx = \\ &= \left| \begin{array}{l} F(x) = \cos x \\ G'(x) = \cos x \end{array} \right| \left| \begin{array}{l} F'(x) = -\sin x \\ G(x) = \sin x \end{array} \right| = \\ \cos x \cdot \sin x + \int \sin^2 x dx &= \cos x \cdot \sin x + \int 1 - \cos^2 x dx = \\ \cos x \cdot \sin x + \int 1 dx - \int \cos^2 x dx &= \\ \cos x \cdot \sin x + x - \int \cos^2 x dx. \end{aligned}$$

Although the return to the given integral might make the reader cast some doubts on it, the equality

$$\int \cos^2 x dx = \cos x \cdot \sin x + x - \int \cos^2 x dx$$

implies

$$2 \int \cos^2 x dx = \cos x \cdot \sin x + x + C,$$

i.e.

$$(1) \quad \int \cos^2 x dx = \frac{1}{2} (x + \sin x \cdot \cos x) + C.$$

It suffices to remember that we put  $C/2 = C$  and that the indefinite integral (as an infinite set) can be represented by one specific function and its translations.

example while integrating over the interval  $[0, 2\pi]$ , the integrals have these values:

$$I_0 = \int_0^{2\pi} dx = [x]_0^{2\pi} = 2\pi$$

$$I_1 = \int_0^{2\pi} \cos x dx = [\sin x]_0^{2\pi} = 0$$

$$I_m = \int_0^{2\pi} \cos^m x dx = \begin{cases} 0 & \text{for even } m \\ \frac{m-1}{m} I_{m-2} & \text{for odd } m \end{cases}.$$

Thus for even  $m = 2n$ , the result is

$$\int_0^{2\pi} \cos^{2n} x dx = \frac{(2n-1)(2n-3)\dots 3 \cdot 1}{2n(2n-2)\dots 2} 2\pi.$$

For odd  $m$  it is zero (as could be guessed from the graph of the function  $\cos x$ ).

**6.2.7. Integration of rational functions.** The next goal is the integration of the quotients of two polynomials  $f(x)/g(x)$ . There are several simplifications to start with.

If the degree of the polynomial  $f$  in the numerator is greater or equal to the degree of the polynomial  $g$  in the denominator, carry out the division with remainder (see the paragraph 5.1.2). This reduces the integration to a sum of two integrals.

The division provides

$$f = q \cdot g + h, \quad \frac{f}{g} = q + \frac{h}{g}.$$

Thus,  $\int f(x)/g(x) dx = \int q dx + \int h(x)/g(x) dx$  where the first integral is easy and the second one is again an expression of the type  $h(x)/g(x)$ , but with degree of  $g(x)$  strictly larger than the degree of  $h(x)$  (such functions are called *proper rational functions*).

Thus we can assume that the degree of  $g$  is strictly larger than the degree of  $f$ . We introduce the procedure to integrate proper rational functions by a simple example.

Observe that we can integrate  $(a+x)^{-n}$ ,  $n > 1$ , and

$$\int \frac{1}{a+x} dx = \ln |a+x| + C.$$

Summing such simple fractions yields more complicated ones:

$$\frac{-2}{x+1} + \frac{6}{x+2} = \frac{4x+2}{x^2+3x+2}$$

which can be integrated directly:

$$\int \frac{4x+2}{x^2+3x+2} dx = -2 \ln |x+1| + 6 \ln |x+2| + C.$$

This suggests looking for a procedure to express proper rational functions as a sum of simple ones. In the example, it is straightforward to compute the unknown coefficients  $A$  and  $B$ , once the roots of the denominator are known:

$$\frac{4x+2}{x^2+3x+2} = \frac{4x+2}{(x+1)(x+2)} = \frac{A}{x+1} + \frac{B}{x+2}.$$

We emphasise that usually suitable simplifications or substitutions lead to the result faster than integration by parts. For example, by using the identity

$$\cos^2 x = \frac{1}{2} (1 + \cos 2x), \quad x \in \mathbb{R}$$

we easily obtain

$$\begin{aligned} \int \cos^2 x \, dx &= \int \frac{1}{2} dx + \int \frac{1}{2} \cos 2x \, dx = \frac{x}{2} + \frac{\sin 2x}{4} + C = \\ &= \frac{x}{2} + \frac{2 \sin x \cos x}{4} + C = \frac{1}{2} (x + \sin x \cdot \cos x) + C. \end{aligned}$$

### 6.B.10. Integrate

- (a)  $\int \cos^5 x \cdot \sin x \, dx, x \in \mathbb{R};$   
 (b)  $\int \cos^5 x \cdot \sin^2 x \, dx, x \in \mathbb{R};$   
 (c)  $\int \frac{\sin^4 x}{\cos^4 x} \, dx, x \in (-\frac{\pi}{2}, \frac{\pi}{2});$   
 (d)  $\frac{1-\sqrt{x}+\sqrt{x}}{\sqrt{x^5+x}} \, dx, x > 0.$

**Solution.** Case (a). This is a simple problem for the so called first substitution method, whose essence is writing the integral in the form of

$$(1) \quad \int f(\varphi(x)) \varphi'(x) \, dx$$

for certain functions  $f$  and  $\varphi$ . Using the substitution  $y = \varphi(x)$ , (we also substitute  $dy = \varphi'(x) \, dx$ , which we get by differentiating  $y = \varphi(x)$ ), such integral can be reduced to the integral  $\int f(y) \, dy$ . By substituting  $y = \cos x$ , where  $dy = -\sin x \, dx$ , we then obtain

$$\begin{aligned} \int \cos^5 x \cdot \sin x \, dx &= -\int \cos^5 x (-\sin x) \, dx = \\ &= -\int y^5 \, dy = \\ &= -\frac{y^6}{6} + C = -\frac{\cos^6 x}{6} + C. \end{aligned}$$

Case (b). Using the equality

$$\begin{aligned} \int \cos^5 x \cdot \sin^2 x \, dx &= \int (\cos^2 x)^2 \sin^2 x \cdot \cos x \, dx = \\ &= \int (1 - \sin^2 x)^2 \sin^2 x \cdot \cos x \, dx \end{aligned}$$

we're tempted to use the substitution  $t = \sin x$ , which yields

$$\begin{aligned} \int \cos^5 x \cdot \sin^2 x \, dx &= \left| \begin{array}{l} t = \sin x \\ dt = \cos x \, dx \end{array} \right| = \\ &= \int (1 - t^2)^2 t^2 \, dt = \\ &= \int t^6 - 2t^4 + t^2 \, dt = \frac{t^7}{7} - 2\frac{t^5}{5} + \frac{t^3}{3} + C = \\ &= \frac{\sin^7 x}{7} - \frac{2\sin^5 x}{5} + \frac{\sin^3 x}{3} + C. \end{aligned}$$

Case (c). Because both sine and cosine are contained in an even power, we cannot proceed as in the previous problem. Let's try to use the so called second substitution method, which means a reduction of  $\int f(y) \, dy$  to the form (1) for  $y = \varphi(x)$ . A situation in which we replace a simple expression by a more complicated one might seem surprising. But don't forget that this more complicated integral might have

Multiply both sides by the polynomial  $x^2+3x+2$  from the denominator and compare coefficients of the individual powers of  $x$  in the resulting polynomials:

$$4x+2 = A(x+2)+B(x+1) \implies 2A+B = 2, A+B = 4.$$

This procedure is called *decomposition into partial fractions*.

This is a purely algebraic procedure based on properties of polynomials.

Without loss of generality, suppose that the denominator  $g(x)$  and the numerator  $f(x)$  do not share any real or complex roots and that  $g(x)$  has exactly  $n$  distinct real roots  $a_1, \dots, a_n$ .

Then the points  $a_1, \dots, a_n$  are all the discontinuities of the function  $f(x)/g(x)$ .  $\square$

Split the expression  $\frac{f(x)}{g(x)}$  according to the factors of the denominator. Thus, assume  $g(x)$  is the product

$$g(x) = p(x)q(x)$$

of two coprime polynomials. By the Bezout identity (see 12.2.9 on the page 869), which is a corollary of the polynomial division with a remainder, there exist polynomials  $a(x)$  and  $b(x)$  of degrees strictly less than the degree of  $g$  such that

$$a(x)p(x) + b(x)q(x) = 1.$$

Multiplying this equality by the quotient  $f(x)/g(x)$ , gives

$$\frac{f(x)}{g(x)} = \frac{a(x)}{q(x)} + \frac{b(x)}{p(x)}.$$

Thus, we may restrict our attention to cases where the denominator  $g(x)$  cannot be decomposed further into two coprime polynomials.

Suppose that the polynomial  $g(x)$  has only real roots. Then there is a unique decomposition into factors  $(x - a_i)^{n_i}$ , where  $n_i$  are the multiplicities of the roots  $a_i, i = 1, \dots, k$ . By a sequential use of the latter procedure with coprime polynomials  $p(x)$  and  $q(x)$ , we obtain a representation of  $f(x)/g(x)$  as a sum of fractions of the form

$$\frac{f(x)}{g(x)} = \frac{r_1(x)}{(x - a_1)^{n_1}} + \dots + \frac{r_k(x)}{(x - a_k)^{n_j}},$$

where the degrees of the polynomials  $r_i(x)$  are strictly smaller than the degrees of the denominators. Finally, each can be represented as a sum

$$\frac{r(x)}{(x - a)^n} = \frac{A_1}{x - a} + \frac{A_2}{(x - a)^2} + \dots + \frac{A_n}{(x - a)^n}.$$

Indeed, we multiply the equation by  $(x - a)^n$  and start comparing the coefficients from the highest powers of the polynomial  $r(x)$  and compute sequentially  $A_1, A_2, \dots$  after expanding all the products. This can be done faster by suitable additions and subtractions, starting by the highest orders. For example,

$$\frac{5x - 16}{(x - 2)^2} = 5 \frac{x - 2}{(x - 2)^2} - 6 \frac{1}{(x - 2)^2} = \frac{5}{x - 2} + \frac{6}{(x - 2)^2}.$$

Finally, we have to handle the case, where there are not enough real roots. There always exists a factorization of  $g(x)$  into linear factors with complex roots (see the fundamental theorem of Algebra in 12.2.8 on page 867). The non-real

such a form that we may just be able to compute it. We want to determine the primitive function of function  $f(x) = \operatorname{tg}^4 x$ . Thus it's sensible to consider the substitution  $u = \operatorname{tg} x$ . We obtain

$$\int \frac{\sin^4 x}{\cos^4 x} dx = \left| \begin{array}{l} x = \operatorname{arctg} u \\ dx = \frac{du}{1+u^2} \end{array} \right| = \int \frac{u^4}{1+u^2} du = \int u^2 - 1 + \frac{1}{u^2+1} du = \frac{u^3}{3} - u + \operatorname{arctg} u + C = \frac{\operatorname{tg}^3 x}{3} - \operatorname{tg} x + \operatorname{arctg}(\operatorname{tg} x) + C = \frac{\operatorname{tg}^3 x}{3} - \operatorname{tg} x + x + C.$$

Case (d). We have

$$\int \frac{1-\sqrt[3]{x}+\sqrt{x}}{\sqrt[5]{x^5+x}} dx = \left| \begin{array}{l} z^6 = x \\ 6z^5 dz = dx \end{array} \right| = \int \frac{1-z^2+z^3}{z^5+z^6} 6z^5 dz = 6 \int \frac{1-z^2+z^3}{1+z} dz = 6 \int z^2 - 2z + 2 - \frac{1}{z+1} dz = 6 \left( \frac{z^3}{3} - z^2 + 2z - \ln|z+1| \right) + C = 2\sqrt{x} - 6\sqrt[3]{x} + 12\sqrt[6]{x} - 6 \ln(\sqrt[6]{x} + 1) + C,$$

where we again easily determined by substitution (for  $z \neq -1$ )

$$\int \frac{dz}{z+1} = \left| \begin{array}{l} v = z+1 \\ dv = dz \end{array} \right| = \int \frac{dv}{v} = \ln|v| + C = \ln|z+1| + C.$$

□

**6.B.11.** By combining integration by parts and the substitution method, determine

- (a)  $\int x^3 e^{-x^2} dx, x \in \mathbb{R};$
- (b)  $\int x \arcsin x^2 dx, x \in (-1, 1).$

**Solution.** Case (a). The substitution method leads to the integral

$$\int x^3 e^{-x^2} dx = \left| \begin{array}{l} t = -x^2 \\ dt = -2x dx \end{array} \right| = \frac{1}{2} \int t e^t dt,$$

which can be easily computed by integrating by parts, yielding

$$\frac{1}{2} \int t e^t dt = \left| \begin{array}{l} F(t) = t \\ G'(t) = e^t \end{array} \right| \left| \begin{array}{l} F'(t) = 1 \\ G(t) = e^t \end{array} \right| = \frac{1}{2} t e^t - \frac{1}{2} \int e^t dt = \frac{1}{2} t e^t - \frac{1}{2} e^t + C = -\frac{1}{2} e^{-x^2} (x^2 + 1) + C.$$

Case (b). Similarly, we obtain

$$\int x \arcsin x^2 dx = \left| \begin{array}{l} t = x^2 \\ dt = 2x dx \end{array} \right| = \frac{1}{2} \int \arcsin t dt = \left| \begin{array}{l} F(t) = \arcsin t \\ G'(t) = 1 \end{array} \right| \left| \begin{array}{l} F'(t) = \frac{1}{\sqrt{1-t^2}} \\ G(t) = t \end{array} \right| = \frac{1}{2} t \arcsin t - \frac{1}{2} \int \frac{t}{\sqrt{1-t^2}} dt = \left| \begin{array}{l} u = 1-t^2 \\ du = -2t dt \end{array} \right| = \frac{1}{2} t \arcsin t + \frac{1}{4} \int \frac{du}{\sqrt{u}} = \frac{1}{2} t \arcsin t + \frac{1}{2} \sqrt{u} + C = \frac{1}{2} t \arcsin t + \frac{1}{2} \sqrt{1-t^2} + C = \frac{1}{2} x^2 \arcsin x^2 + \frac{1}{2} \sqrt{1-x^4} + C.$$

roots always appear in conjugated pairs, since  $\overline{g(z)} = g(\bar{z})$  for a polynomial with real coefficients.

Repeating the above procedure for ratios of complex polynomials gives the same result, but with complex coefficients. If we insist in having real expressions only, we may collect the conjugate pairs together and get quadratic factors expressed as sums of squares  $(x-a)^2 + b^2$  and their powers. The procedure works well and guarantees that it is possible to find summands in the form of

$$\frac{Bx + C}{((x-a)^2 + b^2)^n}.$$

As in the real roots case, there is always a corresponding decomposition into partial fractions of the form

$$\frac{A_1 x + B_1}{(x-a)^2 + b^2} + \dots + \frac{A_n x + B_n}{((x-a)^2 + b^2)^n}$$

in the case of a power  $((x-a)^2 + b^2)^n$  of such quadratic (irreducible) factor as well.

The factorization of the polynomials and the further computations might be quite time consuming. The reader could prefer to experiment with computer algebra software instead. This works well in Maple by calling the procedure `convert(h, parfrac, x)` that decomposes the expression  $h$  rationally dependent on the variable  $x$  into partial fractions.

The important point is that we can already integrate all of the above partial fractions. The last mentioned ones lead to integrals discussed in example 6.2.6.

In summary, the rational functions  $f(x)/g(x)$  can be integrated easily, if the corresponding decomposition of the polynomial in the denominator  $g(x)$  is known. The reality is not that simple when computing (definite) Newton integrals. Although we find the primitive functions, the problematic points are the discontinuities of rational functions, in whose neighbourhood these functions are unbounded. We return to this problem later (see paragraph 6.2.16 below).

**6.2.8. Riemann integral.** We return to the idea of defining the integral as a tool for computing the area of the region bounded by the graph of a function and the  $x$  axis. This is our next goal. We prove that for all continuous functions on a closed bounded interval, this definition yields the same result as the Newton integral.

Consider a real function  $f$  defined on the interval  $[a, b]$ . Choose a partition of this interval along with the choice of representatives  $\xi_i$  of the respective parts, i.e.  $a = x_0 < x_1 < \dots < x_n = b$  and  $\xi_i \in [x_{i-1}, x_i], i = 1, \dots, n$ . The number  $\delta = \min_i \{x_i - x_{i-1}\}$  is called the *norm of the partition*. Define the *Riemann sum* corresponding to the chosen partition along with the chosen representatives  $\Xi = (x_0, \dots, x_n; \xi_1, \dots, \xi_n)$  as

$$S_\Xi = \sum_{i=1}^n f(\xi_i) \cdot (x_i - x_{i-1}).$$

6.B.12. Compute the integral

$$\int \sqrt{1-x^2} dx, \quad x \in (-1, 1)$$

in two different ways.

**Solution.** Integration by parts yields

$$\begin{aligned} \int \sqrt{1-x^2} dx &= \left| \begin{array}{l} F(x) = \sqrt{1-x^2} \\ G'(x) = 1 \end{array} \right| \left| \begin{array}{l} F'(x) = \frac{-x}{\sqrt{1-x^2}} \\ G(x) = x \end{array} \right| = \\ &= x\sqrt{1-x^2} + \int \frac{x^2}{\sqrt{1-x^2}} dx = x\sqrt{1-x^2} - \int \frac{1-x^2-1}{\sqrt{1-x^2}} dx = \\ &= x\sqrt{1-x^2} - \int \sqrt{1-x^2} dx + \int \frac{1}{\sqrt{1-x^2}} dx = \\ &= 2x\sqrt{1-x^2} - \int \sqrt{1-x^2} dx + \arcsin x, \end{aligned}$$

which implies

$$2 \int \sqrt{1-x^2} dx = 2x\sqrt{1-x^2} + \arcsin x + C,$$

i.e.

$$\int \sqrt{1-x^2} dx = \frac{1}{2} (2x\sqrt{1-x^2} + \arcsin x) + C.$$

The substitution method along with (1) then yields

$$\begin{aligned} \int \sqrt{1-x^2} dx &= \left| \begin{array}{l} x = \sin y \\ dx = \cos y dy \end{array} \right| = \int \sqrt{1-\sin^2 y} \cdot \\ \cos y dy &= \int \cos^2 y dy = \frac{1}{2} (y + \sin y \cdot \cos y) + C = \\ &= \frac{1}{2} (\sin y \cdot \sqrt{1-\sin^2 y} + y) + C = \\ &= \frac{1}{2} (x\sqrt{1-x^2} + \arcsin x) + C, \end{aligned}$$

where  $y \in (-\pi/2, \pi/2)$  for  $x \in (-1, 1)$ , thus among other things, we have

$$0 < \cos y = |\cos y| = \sqrt{\cos^2 y} = \sqrt{1-\sin^2 y}.$$

6.B.13. Determine

$$\int e^{\sqrt{x}} dx, \quad x > 0.$$

**Solution.** This problem can illustrate the possibilities of combining the substitution method and integration by parts (in the scope of one problem). First we'll use the substitution  $y = \sqrt{x}$  to get rid of the root from the argument of the exponential function. That leads to the integral

$$\int e^{\sqrt{x}} dx = \left| \begin{array}{l} y^2 = x \\ 2y dy = dx \end{array} \right| = 2 \int y e^y dy.$$

Now by using integration by parts, we'll compute

$$\int y e^y dy = \left| \begin{array}{l} F(y) = y \\ G'(y) = e^y \end{array} \right| \left| \begin{array}{l} F'(y) = 1 \\ G(y) = e^y \end{array} \right| = \\ y e^y - \int e^y dy = y e^y - e^y + C.$$

Thus in total, we have

$$\int e^{\sqrt{x}} dx = 2y e^y - 2e^y + C = 2e^{\sqrt{x}} (\sqrt{x} - 1) + C.$$

RIEMANN INTEGRAL<sup>4</sup>

**Definition.** The Riemann integral of the function  $f$  on the interval  $[a, b]$  exists, if for every sequence of partitions with representatives  $(\xi_k)_{k=0}^{\infty}$  with norms of the partitions  $\delta_k$  approaching zero, the limit

$$\lim_{k \rightarrow \infty} S_{\xi_k} = S$$

exists and its value does not depend on the choice of the sequence of partitions and their representatives. Then we write

$$S = \int_a^b f(x) dx.$$

This definition does not look very practical, but nonetheless it allows us to formulate and prove several simple properties of the Riemann integral:

**Theorem.** (1) Suppose  $f$  is a bounded real function defined on the interval  $[a, b]$ , and  $c \in [a, b]$  is an inner point of this interval. Then the integral  $\int_a^b f(x) dx$  exists if and only if both of the integrals  $\int_a^c f(x) dx$  and  $\int_c^b f(x) dx$  exist. In that case

$$\int_a^b f(x) dx = \int_a^c f(x) dx + \int_c^b f(x) dx.$$

(2) Suppose  $f$  and  $g$  are two real functions defined on the interval  $[a, b]$ , and that both of the integrals  $\int_a^b f(x) dx$  and  $\int_a^b g(x) dx$  exist. Then the integral of their sum also exists and

$$\int_a^b (f(x) + g(x)) dx = \int_a^b f(x) dx + \int_a^b g(x) dx.$$

(3) Suppose  $f$  is a real function defined on the interval  $[a, b]$ ,  $C \in \mathbb{R}$  is a constant, and the integral  $\int_a^b f(x) dx$  exists. Then the integral  $\int_a^b C \cdot f(x) dx$  also exists and

$$\int_a^b C \cdot f(x) dx = C \cdot \int_a^b f(x) dx.$$

<sup>4</sup>Bernhard Riemann (1826-1866) was an extremely influential German mathematician with many contributions to infinitesimal analysis, differential geometry, and in particular complex analysis and analytic number theory.

**6.B.14.** Prove that

$$\frac{1}{2} \sin^4 x = -\frac{1}{4} \cos(2x) + \frac{1}{16} \cos(4x) + \frac{3}{16}.$$

**Solution.** Easier than to compare the given expressions directly is to show that the functions on the right and left hand side have the same derivatives. We have  $L' = 2 \cos x \sin^3 x = \sin(2x) \sin^2 x$ ,

$P' = \frac{1}{2} \sin(2x) + \frac{1}{4} \sin(4x) = \sin 2x(\frac{1}{2} + \frac{1}{2} \cos(2x)) = \sin(2x) \sin^2 x$ . Hence the left and the right hand side differ by a constant. This constant can be determined by comparing the values at one point, for example 0. Both functions are zero at zero, thus they are equal.  $\square$

**Integration of rational functions.**

The key to integration of rational functions lies in decomposition of a rational function as a sum of a simple rational functions, which we know, how to integrate. Let us decompose some rational functions:

**6.B.15.** Carry out the suggested division of polynomials

$$\frac{2x^5 - x^4 + 3x^2 - x + 1}{x^2 - 2x + 4}$$

for  $x \in \mathbb{R}$ .

**6.B.16.** Express the function

$$y = \frac{3x^4 + 2x^3 - x^2 + 1}{3x + 2}$$

as a sum of a polynomial and a rational function.

**6.B.17.** Decompose the rational expression

- (a)  $\frac{4x^2 + 13x - 2}{x^3 + 3x^2 - 4x - 12}$ ,
- (b)  $\frac{2x^5 + 5x^3 - x^2 + 2x - 1}{x^6 + 2x^4 + x^2}$

into partial fractions.

**6.B.18.** Express the function

$$y = \frac{2x^3 + 6x^2 + 3x - 6}{x^4 - 2x^3}$$

in the form of partial fractions.

**6.B.19.** Decompose the expression

$$\frac{7x^2 - 10x + 37}{x^3 - 3x^2 + 9x + 13}$$

into partial fractions.

**6.B.20.** Express the rational function

$$y = \frac{-5x + 2}{x^4 - x^3 + 2x^2}$$

in the form of a sum of partial fractions.

**6.B.21.** Decompose the function

$$y = \frac{1}{x^3(x+1)}$$

**PROOF.** (1) First suppose that the integral over the whole interval exists. When computing it, we can limit ourselves to limits of the Riemann sums whose partitions have the point  $c$  among their partitioning points. Each such sum can be obtained as a sum of two partial Riemann sums. If these two partial sums would depend on the chosen partitions and representatives in the limit, then the total sums could not be independent on the choices in limit. (It suffices to keep the sequence of partitions of the subinterval the same, and change the other so that the limit would change).

Conversely, if both Riemann integrals on both subintervals exists, they can be approximated with arbitrary precision by the Riemann sums, and moreover independently on their choice. If a partitioning point  $c$  is added to any sequence of Riemann sums over the whole interval  $[a, b]$ , the value of the whole sum is changed. Also the values of the partial sums over the intervals belonging to  $[a, c]$  and  $[c, b]$  change at most by a multiple of the norm of the partition and possible differences of the bounded function  $f$  on all of  $[a, b]$ . This is a number arbitrarily close to zero for a decreasing norm of the partition. Necessarily the partial Riemann sums of the function over the two parts of the interval also converge to the limits, whose sum is the Riemann integral over  $[a, b]$ .

(2) In every Riemann sum, the sum of the functions manifests as the sum of the values in the chosen representatives. Because multiplication of real numbers is distributive, each Riemann sum becomes the sum of the two Riemann sums with the same representatives for the two functions. The statement follows from the elementary properties of limits.

(3) Each of the Riemann sums is multiplied by the constant  $C$ . So the claim follows from the elementary properties of limits.  $\square$

**6.2.9. The fundamental theorem.** The following result is crucial for understanding the relation between the integral and the derivative. The complete proof of this theorem is somewhat longer, so it is broken into several subsections.

FUNDAMENTAL THEOREM OF INTEGRAL CALCULUS

**Theorem.** For every continuous function  $f$  on a finite interval  $[a, b]$  there exists its Riemann integral  $\int_a^b f(x)dx$ . Moreover, the function  $F(x)$  given on the interval  $[a, b]$  by the Riemann integral

$$F(x) = \int_a^x f(t)dt$$

is a primitive function to  $f$  on this interval.

**6.2.10. Upper and lower Riemann integral.** In the first step for proving the existence of the integral, we use an alternative definition, in which the choice of representatives and the corresponding value  $f(\xi_i)$  is replaced by the suprema  $M_i$  of the values  $f(x)$  in the corresponding subintervals  $[x_{i-1}, x_i]$ , or by the infima  $m_i$  of

into partial fractions.

**6.B.22.** Determine the form of the decomposition of the rational function

$$y = \frac{2x^2 - 114}{(x-2)x^2(3x^2+x+4)^2}$$

into partial fractions. Don't compute the undetermined coefficients!

**6.B.23.** Express the function

$$y = \frac{x^4 + 6x^2 + x - 2}{x^4 - 2x^3}$$

as a sum of a polynomial and a proper rational function  $Q$ . Then express the obtained function  $Q$  in the form of a sum of partial fractions.

**6.B.24.** Write the primitive function to the rational function

(a)  $y = \frac{3}{x-2}, \quad x \neq 2;$

(b)  $y = -\frac{2}{(x-2)^3}, \quad x \neq 2.$

**6.B.25.** Integrate

(a)  $\int \frac{6}{x-2} dx, \quad x \neq 2;$

(b)  $\int \frac{6}{(x+4)^3} dx, \quad x \neq -4;$

(c)  $\int \frac{3x+7}{x^2-4x+15} dx, \quad x \in \mathbb{R};$

(d)  $\int \frac{30x-77}{(x^2-6x+13)^2} dx, \quad x \in \mathbb{R}.$

**Solution.** Cases (a), (b). We have

$$\int \frac{6}{x-2} dx = \left| \begin{array}{l} y = x - 2 \\ dy = dx \end{array} \right| = \int \frac{6}{y} dy = 6 \ln |y| + C = 6 \ln |x - 2| + C$$

and similarly

$$\int \frac{6}{(x+4)^3} dx = \left| \begin{array}{l} y = x + 4 \\ dy = dx \end{array} \right| = \int \frac{6}{y^3} dy = \frac{6}{-2y^2} + C = -\frac{3}{(x+4)^2} + C.$$

We can see that integrating the partial fractions which correspond to real roots of a denominator of rational function is very easy. Moreover, without loss of generality we can obtain

$$\int \frac{A}{x-x_0} dx = \left| \begin{array}{l} y = x - x_0 \\ dy = dx \end{array} \right| = \int \frac{A}{y} dy = A \ln |y| + C = A \ln |x - x_0| + C$$

and

$$\int \frac{A}{(x-x_0)^n} dx = \left| \begin{array}{l} y = x - x_0 \\ dy = dx \end{array} \right| = \int \frac{A}{y^n} dy = \frac{Ay^{-n+1}}{-n+1} + C = \frac{A}{(1-n)(x-x_0)^{n-1}} + C$$

for all  $A, x_0 \in \mathbb{R}, n \geq 2, n \in \mathbb{N}$ .

Case (c). Now we are to integrate a partial fraction corresponding to a pair of complex conjugate roots. Thus in the

the function  $f(x)$  in the same subintervals, respectively. We speak of upper and lower Riemann sums, respectively (in literature, this process is also called the *Darboux integral*).

Because the function is continuous, it is bounded on a closed interval, hence all the above considered suprema and infima exist and are finite. Then the *upper Riemann sum* corresponding to the partition  $\Xi = (x_0, \dots, x_n)$  is given by the expression

$$\begin{aligned} S_{\Xi, \text{sup}} &= \sum_{i=1}^n \left( \sup_{x_{i-1} \leq \xi \leq x_i} f(\xi) \right) (x_i - x_{i-1}) \\ &= \sum_{i=1}^n M_i (x_i - x_{i-1}). \end{aligned}$$

The *lower Riemann sum* is

$$\begin{aligned} S_{\Xi, \text{inf}} &= \sum_{i=1}^n \left( \inf_{x_{i-1} \leq \xi \leq x_i} f(\xi) \right) (x_i - x_{i-1}) \\ &= \sum_{i=1}^n m_i (x_i - x_{i-1}). \end{aligned}$$

For each partition  $\Xi = (x_0, \dots, x_n; \xi_1, \dots, \xi_n)$  with representatives, there are the inequalities

$$(1) \quad S_{\Xi, \text{inf}} \leq S_{\Xi, \xi} \leq S_{\Xi, \text{sup}}$$

Moreover, the infima and suprema can be approximated with arbitrary precision by the actual values of terms in the sequences. Thus, we might suspect that the Riemann integral exists if and only if for all sequences of partitions with norms approaching zero, the limits of both the upper and lower sums will exist and they will be equal. This is indeed true for all bounded functions:

**Theorem.** Let the function  $f$  be bounded on a closed interval  $[a, b]$ . Then

$$S_{\text{sup}} = \inf_{\Xi} S_{\Xi, \text{sup}}, \quad S_{\text{inf}} = \sup_{\Xi} S_{\Xi, \text{inf}}$$

are the limits of all sequences of upper and lower sums with norm approaching zero, respectively.

The Riemann integral of the function  $f$  exists if and only if  $S_{\text{sup}} = S_{\text{inf}}$ .

**PROOF.** First, notice that  $S_{\text{sup}}$  is well defined since it is the infimum of a set of real values bounded from below by any of the  $S_{\Xi, \text{inf}}$ . Similarly for the value  $S_{\text{inf}}$ , which is bounded from above by any of  $S_{\Xi, \text{sup}}$ .

Refine a partition  $\Xi_1$  to  $\Xi_2$  by adding new points. Then

$$S_{\Xi_1, \text{sup}} \geq S_{\Xi_2, \text{sup}}, \quad S_{\Xi_1, \text{inf}} \leq S_{\Xi_2, \text{inf}}.$$

By the definition of the infimum, there are sequences of partitions  $\Xi_k$  for which  $S_{\text{sup}}$  is the limit of the sums  $S_{\Xi_k, \text{sup}}$ . Moreover, every two partitions have a common refinement. Thus it may be assumed that  $\Xi_k$  in the sequence is always a partition obtained by refining the previous one. Hence the sums  $S_{\Xi_k, \text{sup}}$  form a non-increasing sequence of real numbers converging to  $S_{\text{sup}}$ .

denominator there is a polynomial of degree 2 and in the numerator at most 1. If it's of degree 1, we'll write the partial fraction so that we'll have a multiple of the derivative of the denominator in the numerator and add to it the fraction, in whose numerator there is only a constant. This way we'll obtain

$$\begin{aligned} \int \frac{3x+7}{x^2-4x+15} dx &= \frac{3}{2} \int \frac{2x-4}{x^2-4x+15} dx + 13 \int \frac{dx}{x^2-4x+15} = \\ &= \frac{3}{2} \ln(x^2 - 4x + 15) + 13 \int \frac{dx}{(x-2)^2+11} = \\ &= \frac{3}{2} \ln(x^2 - 4x + 15) + \frac{13}{11} \int \frac{dx}{\left(\frac{x-2}{\sqrt{11}}\right)^2+1} = \left| \begin{array}{l} y = \frac{x-2}{\sqrt{11}} \\ dy = \frac{dx}{\sqrt{11}} \end{array} \right| = \\ &= \frac{3}{2} \ln(x^2 - 4x + 15) + \frac{13}{\sqrt{11}} \int \frac{dy}{y^2+1} = \frac{3}{2} \ln(x^2 - 4x + 15) + \\ &+ \frac{13}{\sqrt{11}} \arctg y + C = \frac{3}{2} \ln(x^2 - 4x + 15) + \frac{13}{\sqrt{11}} \arctg \frac{x-2}{\sqrt{11}} + C. \end{aligned}$$

Again, we can generally express

$$\int \frac{Ax+B}{(x-x_0)^2+a^2} dx = \frac{A}{2} \int \frac{2(x-x_0)}{(x-x_0)^2+a^2} dx + (B+Ax_0) \int \frac{1}{(x-x_0)^2+a^2} dx$$

and compute

$$\begin{aligned} \int \frac{2(x-x_0)}{(x-x_0)^2+a^2} dx &= \left| \begin{array}{l} y = (x-x_0)^2+a^2 \\ dy = 2(x-x_0) dx \end{array} \right| = \int \frac{dy}{y} = \\ &= \ln|y| + C = \ln[(x-x_0)^2+a^2] + C, \\ \int \frac{1}{(x-x_0)^2+a^2} dx &= \frac{1}{a^2} \int \frac{dx}{\left(\frac{x-x_0}{a}\right)^2+1} = \left| \begin{array}{l} z = \frac{x-x_0}{a} \\ dz = \frac{dx}{a} \end{array} \right| = \\ &= \frac{1}{a} \int \frac{dz}{z^2+1} = \frac{1}{a} \arctg z + C = \frac{1}{a} \arctg \frac{x-x_0}{a} + C, \end{aligned}$$

i.e.

$$\int \frac{Ax+B}{(x-x_0)^2+a^2} dx = \frac{A}{2} \ln\left((x-x_0)^2+a^2\right) + \frac{B+Ax_0}{a} \arctg \frac{x-x_0}{a} + C,$$

where the values  $A, B, x_0 \in \mathbb{R}, a > 0$  are arbitrary.

Case (d). All that is left are the partial fractions for multiple complex roots in the form of

$$\frac{Ax+B}{[(x-x_0)^2+a^2]^n}, \quad A, B, x_0 \in \mathbb{R}, a > 0, n \in \mathbb{N} \setminus \{1\},$$

which can be analogically simplified to

$$\frac{A}{2} \cdot \frac{2(x-x_0)}{[(x-x_0)^2+a^2]^n} + (B+Ax_0) \cdot \frac{1}{[(x-x_0)^2+a^2]^n}.$$

Then we'll determine

$$\int \frac{2(x-x_0)}{[(x-x_0)^2+a^2]^n} dx = \left| \begin{array}{l} y = (x-x_0)^2+a^2 \\ dy = 2(x-x_0) dx \end{array} \right| = \int \frac{dy}{y^n} = \frac{1}{(1-n)y^{n-1}} + C = \frac{1}{(1-n)[(x-x_0)^2+a^2]^{n-1}} + C$$

and

$$\begin{aligned} K_n(x_0, a) &:= \int \frac{1}{[(x-x_0)^2+a^2]^n} dx = \\ \left| \begin{array}{l} F(x) = \frac{1}{[(x-x_0)^2+a^2]^n} \\ G'(x) = 1 \end{array} \right| & \left| \begin{array}{l} F'(x) = \frac{-2n(x-x_0)}{[(x-x_0)^2+a^2]^{n+1}} \\ G(x) = x-x_0 \end{array} \right| = \\ &= \frac{x-x_0}{[(x-x_0)^2+a^2]^n} + 2n \int \frac{(x-x_0)^2+a^2}{[(x-x_0)^2+a^2]^{n+1}} - \\ &= \frac{a^2}{[(x-x_0)^2+a^2]^{n+1}} dx = \\ &= \frac{x-x_0}{[(x-x_0)^2+a^2]^n} + 2n (K_n(x_0, a) - a^2 K_{n+1}(x_0, a)), \end{aligned}$$

A similar argument applies to  $S_{\text{inf}}$ . Hence the values

$$S_{\text{sup}} = \inf_{\Xi} S_{\Xi, \text{sup}}, \quad S_{\text{inf}} = \sup_{\Xi} S_{\Xi, \text{inf}}$$

are good candidates for the limits of upper and lower sums.

Next, consider a fixed partition  $\Xi$  with  $n$  inner partitioning points of the interval  $[a, b]$ , and another partition  $\Xi_1$ , whose norm is a small number  $\delta$ . In the common refinement  $\Xi_2$ , there will be only  $n$  intervals contributing to the sum  $S_{\Xi_2, \text{sup}}$  by eventually smaller contribution than in the case of  $\Xi_1$ . Now,  $f$  is a bounded function on  $[a, b]$  and thus each of these contributions will be bounded by a universal constant multiplied by the norm  $\delta$  of the partition. Hence when choosing  $\delta$  sufficiently small, the distance of  $S_{\Xi_1, \text{sup}}$  from  $S_{\text{sup}}$  will not be larger than twice the distance of  $S_{\Xi, \text{sup}}$  from  $S_{\text{sup}}$ .

Finally, return to the sequence of partitions  $\Xi_k$  as chosen above, and choose an  $\varepsilon > 0$ . Then there is some  $m \in \mathbb{N}$  such that the distance of  $S_{\Xi_k, \text{sup}}$  from  $S_{\text{sup}}$  is less than  $\varepsilon$  for all  $k \geq m$ . Hence for arbitrary partition  $\Xi$  with appropriately small norm  $\delta > 0$  the distance of  $S_{\Xi, \text{sup}}$  from  $S_{\text{sup}}$  does not exceed  $2\varepsilon$ .

In summary, for arbitrary  $2\varepsilon > 0$ , there is  $\delta > 0$  such that for all partitions with norm at most  $\delta$  the inequality  $|S_{\Xi, \text{sup}} - S_{\text{sup}}| < 2\varepsilon$  holds. This is exactly the statement that the number  $S_{\text{sup}}$  is the limit of all sequences of upper sums with norms of the partition approaching zero.

The statement for lower sums is proved in exactly the same way.

It remains to deal with the existence of the Riemann integral  $\int_a^b f(x) dx$ . If  $S_{\text{sup}} = S_{\text{inf}}$ , then all Riemann sums of sequences of the partitions have the same limit because of the inequalities (1).

If the Riemann integral does not exist, then there exist two sequences of partitions  $\Xi_k$  and  $\tilde{\Xi}_k$  and their representatives with different limits of Riemann sums. Suppose the first limit is larger than the other one. Then the upper Riemann sums can be selected for the first sequence and the lower Riemann sums for the second sequence. Their difference will then be at least as large. In particular, in view of the previous part of the proof, this implies  $S_{\text{sup}} > S_{\text{inf}}$ .  $\square$

**6.2.11. Uniform continuity.** Until now, we have only used the continuity of the function  $f$  to know that all such functions are bounded on a closed finite interval. It remains to show that for continuous functions  $S_{\text{sup}} = S_{\text{inf}}$ .

From the definition of continuity, for every fixed point  $x \in [a, b]$  and every neighbourhood  $\mathcal{O}_\varepsilon(f(x))$  there exists a neighbourhood  $\mathcal{O}_\delta(x)$  such that  $f(\mathcal{O}_\delta(x)) \subset \mathcal{O}_\varepsilon(f(x))$ . This statement can be rewritten in this way: for  $y, z \in \mathcal{O}_\delta(x)$ , i.e.

$$|y - z| < 2\delta,$$

it is true that  $f(y), f(z) \in \mathcal{O}_\varepsilon(f(x))$ , i.e.

$$|f(y) - f(z)| < 2\varepsilon.$$

A global variant of such a property is needed; it is called the *uniform continuity* of a function  $f$ :

which implies

$$K_{n+1}(x_0, a) = \frac{1}{a^2} \left( \frac{2n-1}{2n} K_n(x_0, a) + \frac{1}{2n} \frac{x-x_0}{[(x-x_0)^2+a^2]^n} \right),$$

which clearly also holds for  $n = 1$ . The last recurrent formula can be extended with the integral (derived in case (c))

$$K_1(x_0, a) = \frac{1}{a} \operatorname{arctg} \frac{x-x_0}{a} + C.$$

In the given problem we have

$$\int \frac{30x-77}{(x^2-6x+13)^2} dx = 15 \int \frac{2x-6}{(x^2-6x+13)^2} dx + 13 \int \frac{1}{(x^2-6x+13)^2} dx$$

and furthermore

$$\begin{aligned} \int \frac{2x-6}{(x^2-6x+13)^2} dx &= \left| \begin{array}{l} y = x^2 - 6x + 13 \\ dy = (2x - 6) dx \end{array} \right| = \int \frac{dy}{y^2} = \\ &= -\frac{1}{y} + C = -\frac{1}{x^2-6x+13} + C, \\ \int \frac{1}{(x^2-6x+13)^2} dx &= \int \frac{dx}{[(x-3)^2+2^2]^2} = \\ &= \frac{1}{2^2} \left( \frac{2-1}{2} K_1(3, 2) + \frac{1}{2} \frac{x-3}{(x-3)^2+2^2} \right) = \\ &= \frac{1}{4} \left( \frac{1}{4} \operatorname{arctg} \frac{x-3}{2} + C + \frac{1}{2} \frac{x-3}{x^2-6x+13} \right) = \\ &= \frac{1}{16} \operatorname{arctg} \frac{x-3}{2} + \frac{1}{8} \frac{x-3}{x^2-6x+13} + C. \end{aligned}$$

In total, we have

$$\int \frac{30x-77}{(x^2-6x+13)^2} dx = -\frac{15}{x^2-6x+13} + \frac{13}{16} \operatorname{arctg} \frac{x-3}{2} + \frac{13}{8} \frac{x-3}{x^2-6x+13} + C = \frac{13}{16} \operatorname{arctg} \frac{x-3}{2} + \frac{13x-159}{8(x^2-6x+13)} + C.$$

### 6.B.26. Integrate the rational functions

- (a)  $\int \frac{x^3+1}{x(x-1)^3} dx, x \neq 0, x \neq 1;$
- (b)  $\int \frac{x-4}{5x^2+6x+3} dx, x \in \mathbb{R};$
- (c)  $\int \frac{1}{(x-4)(x-2)(x^2+2x+2)} dx, x \neq 2, x \neq 4;$
- (d)  $\int \frac{x}{x^4-x^3-x+1} dx, x \neq 1;$
- (e)  $\int \frac{2x+1}{(x^2+4x+13)^2} dx, x \in \mathbb{R};$
- (f)  $\int \frac{5x^2-12}{x^4-12x^3+62x^2-156x+169} dx, x \in \mathbb{R}.$

**Solution.** We'll compute all the given integrals in the way we can always use when integrating rational functions. We won't use any specific simplification or substitution. Even the recurrent formula for  $K_{n+1}(x_0, a)$ , which we derived in a general form, will be used only for  $x_0 = 0, a = 1$  (and also when  $n = 0$ ). Using the aforementioned procedures, we obtain

- (a) 
$$\int \frac{x^3+1}{x(x-1)^3} dx = 2 \int \frac{dx}{x-1} + \int \frac{dx}{(x-1)^2} + 2 \int \frac{dx}{(x-1)^3} - \int \frac{dx}{x} = 2 \ln|x-1| - \frac{1}{x-1} - \frac{1}{(x-1)^2} - \ln|x| + C;$$
- (b)

### UNIFORM CONTINUITY

**Definition.** Let  $f$  be a function on a closed finite interval  $[a, b]$ .  $f$  is *uniformly continuous* on  $[a, b]$ , if for every  $\varepsilon > 0$  there exists  $\delta > 0$  such that for all  $z, y \in [a, b]$  satisfying  $|y - z| < \delta$ , the inequality  $|f(y) - f(z)| < \varepsilon$  holds.

### STEJNOMĚRNÁ SPOJITOST

**Theorem.** Each continuous function on a finite closed interval  $[a, b]$  is uniformly continuous.

**PROOF.** Fixing some  $\varepsilon > 0$ , the definition of continuity of  $f$  provides for each  $x \in [a, b]$  the values  $\delta(x)$ , such that  $f(y) \in \mathcal{O}_\varepsilon(f(x))$  for all  $y \in \mathcal{O}_{2\delta(x)}(x)$ . Since every finite closed interval is compact, it is covered by finitely many of such neighbourhoods  $\mathcal{O}_{\delta(x_i)}(x_i)$ , determined by points  $x_1, \dots, x_k$ . Choose  $\delta$  as the minimum of all the (finitely many)  $\delta(x_i)$ .

□ Choose any two points  $y, z \in [a, b]$  with  $|y - z| < \delta$ , they both belong to one of  $\mathcal{O}_{2\delta(x_i)}(x_i)$ . Thus  $|f(y) - f(z)| \leq |f(y) - f(x_i)| + |f(x_i) - f(z)| < 2\varepsilon$  and  $f$  has the desired property. □

**6.2.12. Finishing the proof of Theorem 6.2.9.** Now we complete the proof of the existence of the Riemann integral. Choose  $\varepsilon$  and  $\delta$  as in the definition of the uniform continuity of  $f$ . Consider any partition  $\Xi$  with  $n$  intervals and norm at most  $\delta$ . Then, writing  $J_i = [x_{i-1}, x_i]$ ,

$$\begin{aligned} & \left| \sum_{i=1}^n \sup_{\xi \in J_i} f(\xi)(x_i - x_{i-1}) - \sum_{i=1}^n \inf_{\xi \in J_i} f(\xi)(x_i - x_{i-1}) \right| \\ &= \sum_{i=1}^n (\sup_{\xi \in J_i} f(\xi) - \inf_{\xi \in J_i} f(\xi))(x_i - x_{i-1}) \\ &\leq \varepsilon \cdot (b - a). \end{aligned}$$

For decreasing norm of the partition, the upper and lower sums are arbitrarily close to each other. In particular the upper Riemann integral and the lower Riemann integral coincide.

To complete the proof of the fundamental theorem of integral calculus, it is still needed to verify the statement about the existence of a primitive function. For a continuous function  $f$  on interval  $[a, b]$  there exists the Riemann integral  $F(x) = \int_a^x f(t) dt$  for every  $x \in [a, b]$ . As in the statement

$$\begin{aligned} & \int \frac{x-4}{5x^2+6x+3} dx = \\ & \frac{1}{10} \int \frac{10x+6}{5x^2+6x+3} dx - \frac{23}{5} \int \frac{dx}{5x^2+6x+3} = \\ & \frac{1}{10} \ln(5x^2+6x+3) - \frac{23}{25} \int \frac{dx}{\left(x+\frac{3}{5}\right)^2+\frac{6}{25}} = \\ & \frac{1}{10} \ln(5x^2+6x+3) - \frac{23}{6} \int \frac{dx}{\left(\frac{5x+3}{\sqrt{6}}\right)^2+1} = \\ & \left| \begin{array}{l} t = \frac{5x+3}{\sqrt{6}} \\ dt = \frac{5}{\sqrt{6}} dx \end{array} \right| = \\ & \frac{1}{10} \ln(5x^2+6x+3) - \frac{23\sqrt{6}}{30} \int \frac{dt}{t^2+1} = \\ & \frac{1}{10} \ln(5x^2+6x+3) - \frac{23\sqrt{6}}{30} \operatorname{arctg} t + C = \\ & \frac{1}{10} \ln(5x^2+6x+3) - \frac{23\sqrt{6}}{30} \operatorname{arctg} \frac{5x+3}{\sqrt{6}} + C; \end{aligned}$$

(c)

$$\begin{aligned} & \int \frac{dx}{(x-4)(x-2)(x^2+2x+2)} = \frac{1}{52} \int \frac{dx}{x-4} - \frac{1}{20} \int \frac{dx}{x-2} + \\ & \frac{1}{130} \int \frac{4x+11}{x^2+2x+2} dx = \frac{1}{52} \ln|x-4| - \frac{1}{20} \ln|x-2| + \\ & \frac{1}{130} \left( 2 \int \frac{2x+2}{x^2+2x+2} dx + 7 \int \frac{dx}{x^2+2x+2} \right) = \\ & \frac{1}{260} \ln \left| \frac{(x-4)^5}{(x-2)^{13}} \right| + \frac{2}{130} \ln(x^2+2x+2) + \\ & \frac{7}{130} \int \frac{dx}{(x+1)^2+1} = \left| \begin{array}{l} t = x+1 \\ dt = dx \end{array} \right| = \\ & \frac{1}{260} \ln \left| \frac{(x-4)^5(x^2+2x+2)^4}{(x-2)^{13}} \right| + \frac{7}{130} \int \frac{dt}{t^2+1} = \\ & \frac{1}{260} \ln \left| \frac{(x-4)^5(x^2+2x+2)^4}{(x-2)^{13}} \right| + \frac{7}{130} \operatorname{arctg} t + C = \\ & \frac{1}{260} \left[ \ln \left| \frac{(x-4)^5(x^2+2x+2)^4}{(x-2)^{13}} \right| + 14 \operatorname{arctg}(x+1) \right] + C; \end{aligned}$$

(d)

$$\begin{aligned} & \int \frac{x}{x^4-x^3-x+1} dx = \frac{1}{3} \int \frac{dx}{(x-1)^2} - \frac{1}{3} \int \frac{dx}{x^2+x+1} = \\ & -\frac{1}{3(x-1)} - \frac{1}{3} \int \frac{dx}{\left(x+\frac{1}{2}\right)^2+\frac{3}{4}} = \\ & -\frac{1}{3(x-1)} - \frac{4}{9} \int \frac{dx}{\left(\frac{2x+1}{\sqrt{3}}\right)^2+1} = \left| \begin{array}{l} t = \frac{2x+1}{\sqrt{3}} \\ dt = \frac{2}{\sqrt{3}} dx \end{array} \right| = \\ & -\frac{1}{3(x-1)} - \frac{2}{3\sqrt{3}} \int \frac{dt}{t^2+1} = -\frac{1}{3(x-1)} - \frac{2}{3\sqrt{3}} \operatorname{arctg} t + C = \\ & -\frac{1}{3(x-1)} - \frac{2}{3\sqrt{3}} \operatorname{arctg} \frac{2x+1}{\sqrt{3}} + C; \end{aligned}$$

(e)

$$\begin{aligned} & \int \frac{2x+1}{(x^2+4x+13)^2} dx = \int \frac{2x+4}{(x^2+4x+13)^2} dx - \\ & 3 \int \frac{dx}{(x^2+4x+13)^2} = \left| \begin{array}{l} t = x^2+4x+13 \\ dt = (2x+4) dx \end{array} \right| = \\ & \int \frac{dt}{t^2} - 3 \int \frac{dx}{[(x+2)^2+9]^2} = -\frac{1}{t} - \frac{1}{27} \int \frac{dx}{\left[\left(\frac{x+2}{3}\right)^2+1\right]^2} = \\ & \left| \begin{array}{l} u = \frac{x+2}{3} \\ du = \frac{1}{3} dx \end{array} \right| = -\frac{1}{x^2+4x+13} - \frac{1}{9} \int \frac{du}{(u^2+1)^2} = \\ & -\frac{1}{x^2+4x+13} - \frac{1}{9} \left( \frac{1}{2} \operatorname{arctg} u + \frac{1}{2} \frac{u}{u^2+1} \right) + C = \\ & -\frac{1}{x^2+4x+13} - \frac{1}{18} \operatorname{arctg} \frac{x+2}{3} - \frac{1}{18} \frac{\frac{x+2}{3}}{\left(\frac{x+2}{3}\right)^2+1} + C = \\ & -\frac{1}{18} \operatorname{arctg} \frac{x+2}{3} - \frac{1}{6} \frac{x+8}{x^2+4x+13} + C; \end{aligned}$$

(f)

$$\begin{aligned} & \int \frac{5x^2-12}{x^4-12x^3+62x^2-156x+169} dx = \int \frac{5x^2-12}{(x^2-6x+13)^2} dx = \\ & 5 \int \frac{dx}{x^2-6x+13} + \int \frac{30x-77}{(x^2-6x+13)^2} dx = 5 \int \frac{dx}{(x-3)^2+4} + \end{aligned}$$

about uniform continuity, there is  $\delta > 0$ , dependent on a fixed small  $\varepsilon > 0$ , such that

$$|f(x+\Delta x) - f(x)| < \varepsilon$$

for all  $0 \leq \Delta x < \delta$  on the interval  $[a, b]$ . The difference of the derivative of  $F(x)$  and the integrated function  $f(x)$  is expressed by the limit of the expressions

$$\begin{aligned} \alpha &= \frac{1}{\Delta x} \left( \int_a^{x+\Delta x} f(t) dt - \int_a^x f(t) dt \right) - f(x) \\ &= \frac{1}{\Delta x} \left( \int_x^{x+\Delta x} f(t) dt \right) - f(x) \end{aligned}$$

for  $\Delta x$  approaching zero.

Now choose  $0 < \Delta x < \delta$  and replace the integrated function by the constant value  $f(x)$ . Then the values  $f(\xi)$  at any point  $\xi \in [x, x+\Delta]$  are distant from  $f(x)$  by at most  $\varepsilon$ . Hence the Riemann integral in question cannot be different from  $f(x)\Delta$  by more than  $\varepsilon\Delta$ . Thus, we arrived at the following estimate:

$$|\alpha| = \left| \frac{1}{\Delta x} \left( \int_x^{x+\Delta x} f(t) dt \right) - f(x) \right| < \varepsilon.$$

But that means that at the point  $x$ , the one-sided right derivative of the function  $F(x)$  exists and equals  $f(x)$ . The result for the left derivative is proved in the same way, just working with the interval  $[x-\Delta, x]$ . This finishes the proof of the theorem 6.2.9.

**6.2.13. Important remarks.** (1) Theorems 6.2.9 and 6.2.8 claim that the Riemann integral is a linear map

$$\int : C[a, b] \rightarrow \mathbb{R}$$

from the vector space of continuous functions on the interval  $[a, b]$  to real numbers. Hence it is a linear form on the space  $C[a, b]$ .

(2) We proved that every continuous function is a derivative of some function. Hence the concepts of the Newton and Riemann integrals coincide for continuous functions. Therefore the Riemann integral of continuous functions can be computed as the difference of values  $F(b)-F(a)$  of the primitive function  $F$ .

(3) In the first step of the proof of the theorem 6.2.9 we proved the important statement that for bounded functions  $f$  on finite intervals  $[a, b]$  the limits of the upper and lower sums always exist. They are called respectively *the upper Riemann integral* and *the lower Riemann integral* and they are also denoted by  $\int_a^b f(x) dx$  and  $\int_a^b f(x) dx$ .

In this way we can define the Riemann integral for continuous functions as in the above proof.

(4) We derived the important property of continuous functions called *the uniform continuity* on finite closed intervals  $[a, b]$ . Clearly every uniformly continuous function is continuous as well, but the converse is not true on open intervals. As an example, consider the function  $f(x) = \sin(1/x)$  on the interval  $(0, 1)$ .

$$\begin{aligned}
 & 15 \int \frac{2x-6}{(x^2-6x+13)^2} dx + 13 \int \frac{dx}{(x^2-6x+13)^2} = \\
 & \frac{5}{4} \int \frac{dx}{\left(\frac{x-3}{2}\right)^2+1} + 15 \int \frac{2x-6}{(x^2-6x+13)^2} dx + \\
 & \quad 13 \int \frac{dx}{[(x-3)^2+4]^2} = \\
 & \left| \begin{array}{l} t = \frac{x-3}{2} \\ dt = \frac{1}{2} dx \\ u = x^2 - 6x + 13 \\ du = (2x - 6) dx \end{array} \right| = \\
 & \frac{5}{2} \int \frac{dt}{t^2+1} + 15 \int \frac{du}{u^2} + \frac{13}{16} \int \frac{dx}{\left[\left(\frac{x-3}{2}\right)^2+1\right]^2} = \\
 & \frac{5}{2} \arctg t - \frac{15}{u} + \frac{13}{8} \int \frac{dt}{[t^2+1]^2} = \frac{5}{2} \arctg \frac{x-3}{2} - \\
 & \frac{15}{x^2-6x+13} + \frac{13}{8} \left( \frac{1}{2} \arctg t + \frac{1}{2} \frac{t}{t^2+1} \right) + C = \\
 & \frac{5}{2} \arctg \frac{x-3}{2} - \frac{15}{x^2-6x+13} + \frac{13}{16} \arctg \frac{x-3}{2} + \frac{13}{16} \frac{\frac{x-3}{2}}{\left(\frac{x-3}{2}\right)^2+1} + \\
 & C = \frac{5}{2} \arctg \frac{x-3}{2} + \frac{13}{16} \arctg \frac{x-3}{2} - \frac{15}{x^2-6x+13} + \\
 & \frac{13}{8} \frac{x-3}{(x-3)^2+4} + C = \frac{53}{16} \arctg \frac{x-3}{2} + \frac{13x-159}{8(x^2-6x+13)} + C.
 \end{aligned}$$

□

**6.B.27.** Compute

$$\int \frac{x}{(x-1)^2(x^2+2x+2)} dx, \quad x \neq 1.$$

**Solution.** Because the degree of the polynomial in the denominator is lower than in the numerator, these polynomials don't have a common root and we know the representation of the denominator in the form of a product of root factors, we know the form of the decomposition of the integrated function into partials fractions

$$\frac{x}{(x-1)^2(x^2+2x+2)} = \frac{A}{x-1} + \frac{B}{(x-1)^2} + \frac{Cx+D}{x^2+2x+2}$$

for  $A, B, C, D \in \mathbb{R}$ . If we multiply this equation by the denominator of the left hand side, we'll obtain the identity

$$\begin{aligned}
 x &= A(x-1)(x^2+2x+2) + B(x^2+2x+2) + \\
 & \quad (Cx+D)(x-1)^2,
 \end{aligned}$$

which hold for all  $x \in \mathbb{R} \setminus \{1\}$ . But on its both sided there are polynomials, so the equality must also occur for  $x = 1$ . By substituting this value we immediately get  $1 = B(1+2+2)$ , i.e.  $B = 1/5$ .

We could choose other real (eventually complex) numbers and substitute them into the given equation, but we cannot expect to directly determine another of the variables (if we don't substitute a root of the denominator). Thus we'll rather compare the coefficients at the same powers of the polynomials

$$\begin{aligned}
 x - \frac{1}{5}(x^2+2x+2) &= -\frac{1}{5}x^2 + \frac{3}{5}x - \frac{2}{5}, \\
 A(x-1)(x^2+2x+2) + (Cx+D)(x-1)^2 &= \\
 (A+C)x^3 + (A-2C+D)x^2 + (C-2D)x - 2A + D,
 \end{aligned}$$

(5) Consider a function  $f$  on an interval  $[a, b]$ , which is only *piece-wise continuous*. This means that  $f$  is continuous in all points  $c \in [a, b]$  except for finitely many *discontinuities*  $c_i$ ,  $a < c_i < b$ , in which it has finite one-sided limits. Because of the additivity of the integral with respect to the interval of integration, see 6.2.8(1), the last theorem implies that in this case the integral

$$F(x) = \int_a^x f(t) dt$$

exists for all  $x \in [a, b]$  and the derivative of the function  $F(x)$  exists at all points  $x$  where  $f$  is continuous. It can be verified that  $F(x)$  is continuous at the remaining points. So it is a continuous function on the whole interval  $[a, b]$ . When evaluating the integral by primitive functions, it is necessary to choose its individual parts so that they are connected continuously at the points  $c_i$ . Then the entire integral can be again computed as a difference of the function  $F(x)$  at its boundary values.

(6) Lagrange's mean value theorem for differentiable functions has an analogue which is called *the integral mean value theorem*. Suppose  $f(x)$  is continuous on an interval  $[a, b]$  and its primitive function is  $F(x)$ . The mean value theorem claims that there exists a point  $c$ ,  $a < c < b$  such that

$$\int_a^b f(x) dx = F(b) - F(a) = F'(c)(b-a) = f(c)(b-a).$$

This statement can be derived directly from the definition of the Riemann integral. It can be used in the final step of the proof of the fundamental theorem of integral calculus.

**6.2.14. Differential equations.** Theorem 6.2.9 can be understood in the following way. Given a continuous function  $f(x)$  on a bounded interval  $[a, b]$ , the set of all functions  $y$  of one variable  $x$  satisfying the equality

$$y' = f(x)$$

is given by the formula

$$y(x) = \int_a^x f(t) dt + C$$

with the constant  $C = y(a)$ . This is the simplest instance of *differential equations*. More generally, ordinary differential equations of first order are given as

$$y' = f(x, y),$$

where  $f(x, y)$  depends on two unknown variables  $x$  and  $y$ . A solution to this equation is a function  $y = y(x)$ , such that the equality is true upon substitution. Similarly, dependence on higher derivatives of  $y$  may be included.

We return to this concept in Chapter 8, see 8.3.2. For the present, we discuss one very special type of equation with *separated variables*

$$y' = f(x)g(y)$$

which leads to a system of equations

$$\begin{aligned} 0 &= A + C, \\ -1/5 &= A - 2C + D, \\ 3/5 &= C - 2D, \\ -2/5 &= -2A + D. \end{aligned}$$

Note that this system must have exactly one solution (which is uniquely determined by any three of the given equations).

The sought solution is then

$$A = \frac{1}{25}, \quad C = -\frac{1}{25}, \quad D = -\frac{8}{25}.$$

Thus

$$\int \frac{dx}{25(x-1)} + \int \frac{dx}{5(x-1)^2} - \int \frac{x+8}{25(x^2+2x+2)} dx = \frac{1}{25} \ln|x-1| - \frac{1}{5(x-1)} - \frac{1}{50} \ln(x^2+2x+2) - \frac{7}{25} \arctg(x+1) + C,$$

where we used

$$\begin{aligned} \int \frac{x+8}{x^2+2x+2} dx &= \int \frac{\frac{1}{2}(2x+2)}{x^2+2x+2} + \frac{7}{x^2+2x+2} dx = \\ &= \frac{1}{2} \int \frac{2x+2}{x^2+2x+2} dx + \\ 7 \int \frac{1}{(x+1)^2+1} dx &= \frac{1}{2} \ln(x^2+2x+2) + 7 \arctg(x+1) + C. \end{aligned}$$

□

**6.B.28.** Determine

- (a)  $\int \frac{x^3+2x^2+x-1}{x^2-x+1} dx, x \in \mathbb{R};$
- (b)  $\int \frac{x^8}{x^8-1} dx, x \neq \pm 1.$

**Solution.** Case (a). First we must do the division of polynomials

$$(x^3 + 2x^2 + x - 1) : (x^2 - x + 1) = x + 3 + \frac{3x-4}{x^2-x+1},$$

to consider a proper rational function (with the degree of the numerator lower than the degree of the denominator). Now we'll compute

$$\begin{aligned} \int \frac{x^3+2x^2+x-1}{x^2-x+1} dx &= \int x + 3 dx + \int \frac{3x-4}{x^2-x+1} dx = \\ \frac{x^2}{2} + 3x + \frac{3}{2} \int \frac{2x-1}{x^2-x+1} dx - \frac{5}{2} \int \frac{dx}{(x-\frac{1}{2})^2 + (\frac{\sqrt{3}}{2})^2} &= \\ \frac{x^2}{2} + 3x + \frac{3}{2} \ln(x^2-x+1) - \frac{5}{\sqrt{3}} \arctg \frac{2x-1}{\sqrt{3}} + C. \end{aligned}$$

Case (b). We have

$$\begin{aligned} \int \frac{x^8}{x^8-1} dx &= \int 1 dx + \frac{1}{8} \int \frac{dx}{x-1} - \frac{1}{8} \int \frac{dx}{x+1} - \frac{1}{4} \int \frac{dx}{x^2+1} + \\ \frac{1}{8} \int \frac{\sqrt{2x-2}}{x^2-\sqrt{2x+1}} dx - \frac{1}{8} \int \frac{\sqrt{2x+2}}{x^2+\sqrt{2x+1}} dx &= x + \frac{1}{8} \ln|x-1| - \\ \frac{1}{8} \ln|x+1| - \frac{1}{4} \arctg x + \frac{\sqrt{2}}{16} \int \frac{2x-\sqrt{2}}{x^2-\sqrt{2x+1}} dx - \\ \frac{1}{8} \int \frac{dx}{(x-\frac{\sqrt{2}}{2})^2 + (\frac{\sqrt{2}}{2})^2} - \frac{\sqrt{2}}{16} \int \frac{2x+\sqrt{2}}{x^2+\sqrt{2x+1}} dx - \\ \frac{1}{8} \int \frac{dx}{(x+\frac{\sqrt{2}}{2})^2 + (\frac{\sqrt{2}}{2})^2} &= x + \frac{1}{8} \ln|x-1| - \frac{1}{8} \ln|x+1| - \\ \frac{1}{4} \arctg x + \frac{\sqrt{2}}{16} \ln(x^2-\sqrt{2x+1}) - \frac{\sqrt{2}}{8} \arctg(\sqrt{2x-1}) - \\ \frac{\sqrt{2}}{16} \ln(x^2+\sqrt{2x+1}) - \frac{\sqrt{2}}{8} \arctg(\sqrt{2x+1}) + C. \end{aligned}$$

and add a few observations concerning analytic solutions. Rewrite the equation in terms of the differentials, cf. 6.1.11,

$$\frac{1}{g(y)} dy = f(x) dx.$$

Find the primitive functions on both sides to determine the unknown function  $y = y(x)$  implicitly.

Indeed, if  $G(y)$  and  $F(x)$  are the primitive functions with  $G'(y) = \frac{1}{g(y)}$  and  $F'(x) = f(x)$ , and  $y(x)$  satisfies  $G(y(x)) = F(x)$ , then differentiating both sides with respect to  $x$  yields

$$0 = G'(y(x))y'(x) - F'(x) = \frac{y'(x)}{g(y(x))} - f(x)$$

as expected. Of course, it is necessary to be careful with the values  $y$  for which  $g(y) = 0$ , which need to be discussed separately.

For example, the equation  $y' = y$  leads to the implicit definition

$$\ln|y| = x + C,$$

which for positive  $y$  provides  $y(x) = D e^x$  with positive constant  $D$ , the constant solution  $y = 0$  corresponds to  $D = 0$ . Negative values of  $y$  correspond to negative constants  $D$  in the same expression.

If  $y(0) = 1$ , we recover the exponential  $y(x) = e^x$ .

**6.2.15. Analytic solutions.** In the next part of this chapter, we shall prove that the power series are differentiated and integrated term by term, thus the solution  $y(x)$  to the equation  $y' = f(x)$  with a known analytic function  $f(x) = \sum_{n=0}^{\infty} \frac{a_n}{n!} x^n$  is

$$y(x) = \sum_{n=0}^{\infty} \frac{1}{n+1} a_n x^{n+1} + y(0),$$

where  $y(0)$  is the free integration constant. The solution is defined on the convergence domain of the power series. Of course we might use series centered in other points  $x_0$  if prescribing the initial value  $y(x_0)$ . (We shall prove much later, that actually there is always the unique solution with the given initial prescribed value  $y(0)$  in Chapter 8.)

The latter equation  $y' = y$  had the analytic solution  $e^x$ , too. Let us consider the general case of this type, i.e. equations of the form

$$(1) \quad y' = f(y)$$

with an analytic right-hand side  $f(y)$ . Given the initial condition  $y(x_0) = y_0$ , straightforward differentiation with the help of the chain rule and the equation (1) shows

$$\begin{aligned} y'(x_0) &= f(y_0) \\ y''(x_0) &= f'(y)y'|_{x=x_0} = f'(y)f(y)|_{x=x_0} = f'(y_0)f(y_0) \\ y'''(x_0) &= (f''(y)y'f(y) + f'(y)f'(y)y')|_{x=x_0} \\ &= f''(y_0)(f(y_0))^2 + (f'(y_0))^2 f(y_0) \\ &\vdots \end{aligned}$$

**6.B.29.** Compute

$$\int \frac{2x^4+2x^2-5x+1}{x(x^2-x+1)^2} dx, \quad x \neq 0.$$

**Solution.** We have

$$\begin{aligned} & \int \frac{2x^4+2x^2-5x+1}{x(x^2-x+1)^2} dx = \\ & \int \frac{dx}{x} + \int \frac{x+3}{x^2-x+1} dx + \int \frac{x-6}{(x^2-x+1)^2} dx = \\ \ln|x| + \frac{1}{2} \int \frac{2x-1}{x^2-x+1} dx + \frac{7}{2} \int \frac{dx}{x^2-x+1} + \frac{1}{2} \int \frac{2x-1}{(x^2-x+1)^2} dx - \\ & \frac{11}{2} \int \frac{dx}{(x^2-x+1)^2} = \left| \begin{array}{l} t = x^2 - x + 1 \\ dt = (2x - 1) dx \end{array} \right| = \\ \ln|x| + \frac{1}{2} \ln(x^2 - x + 1) + \frac{7}{2} \int \frac{dx}{(x-\frac{1}{2})^2 + \frac{3}{4}} + \frac{1}{2} \int \frac{dt}{t^2} - \\ & \frac{11}{2} \int \frac{dx}{[(x-\frac{1}{2})^2 + \frac{3}{4}]^2} = \ln|x\sqrt{x^2-x+1}| + \\ & \frac{14}{3} \int \frac{dx}{(\frac{2x-1}{\sqrt{3}})^2 + 1} - \frac{1}{2t} - \frac{88}{9} \int \frac{dx}{[(\frac{2x-1}{\sqrt{3}})^2 + 1]^2} = \\ \left| \begin{array}{l} u = \frac{2x-1}{\sqrt{3}} \\ du = \frac{2}{\sqrt{3}} dx \end{array} \right| = \ln|x\sqrt{x^2-x+1}| + \frac{7\sqrt{3}}{3} \int \frac{du}{u^2+1} - \\ & \frac{1}{2(x^2-x+1)} - \frac{44\sqrt{3}}{9} \int \frac{du}{[u^2+1]^2} = \ln|x\sqrt{x^2-x+1}| + \\ & \frac{7\sqrt{3}}{3} \arctg u - \frac{1}{2(x^2-x+1)} - \frac{44\sqrt{3}}{9} \left( \frac{1}{2} \arctg u + \frac{1}{2} \frac{u}{u^2+1} \right) + C = \\ & \ln|x\sqrt{x^2-x+1}| + \frac{7\sqrt{3}}{3} \arctg \frac{2x-1}{\sqrt{3}} - \\ & \frac{22\sqrt{3}}{9} \arctg \frac{2x-1}{\sqrt{3}} - \frac{1}{2(x^2-x+1)} - \frac{22\sqrt{3}}{9} \frac{\frac{2x-1}{\sqrt{3}}}{(\frac{2x-1}{\sqrt{3}})^2 + 1} + C = \\ & \ln|x\sqrt{x^2-x+1}| - \frac{\sqrt{3}}{9} \arctg \frac{2x-1}{\sqrt{3}} - \frac{1}{3} \frac{11x-4}{x^2-x+1} + C. \end{aligned}$$

**6.B.30.** Integrate

- (a)  $\int \frac{x}{1+x^4} dx, x \in \mathbb{R};$   
 (b)  $\int \frac{5 \ln x}{x \ln^3 x + x \ln^2 x - 2x} dx, x > 0, x \neq e.$

**Solution.** Case(a). The advantage of the method of integrating rational functions described above is its universality (using it, we can find primitive functions of every rational function). Sometimes though, using the substitution method or integrating by parts is more convenient. For example,

$$\int \frac{x}{1+x^4} dx = \left| \begin{array}{l} y = x^2 \\ dy = 2x dx \end{array} \right| = \int \frac{dy}{2(1+y^2)} = \frac{1}{2} \int \frac{dy}{1+y^2} = \frac{1}{2} \arctg y + C = \frac{1}{2} \arctg x^2 + C.$$

Case (b). Using substitution, we obtain an integral of a rational function

$$\begin{aligned} & \int \frac{5 \ln x}{x \ln^3 x + x \ln^2 x - 2x} = \int \frac{5 \ln x}{\ln^3 x + \ln^2 x - 2} \cdot \frac{1}{x} dx = \\ & \left| \begin{array}{l} y = \ln x \\ dy = \frac{1}{x} dx \end{array} \right| = \int \frac{5y}{y^3+y^2-2} dy = \int \frac{1}{y-1} + \frac{-y+2}{y^2+2y+2} dy = \\ & \int \frac{1}{y-1} dy - \frac{1}{2} \int \frac{2y+2}{y^2+2y+2} dy + 3 \int \frac{1}{(y+1)^2+1^2} dy = \ln|y| - \end{aligned}$$

Two crucial observations are due here. First, giving the initial condition  $y(x_0) = y_0$ , all derivatives  $y^{(k)}(x_0)$  are given at this point by the equation. Thus, if an analytic solution exists, we know it explicitly. So we have to focus on the convergence of the known formal expression of the series  $y(x) = \sum_{n=0}^{\infty} \frac{1}{n!} y^{(n)}(x_0)(x-x_0)^n$  and we arrive at the theorem below.

In its proof, the second observation will be most helpful: the expressions for the derivatives  $y^{(n)}$  are universal polynomials  $P_n$

$$y^{(n)}(x) = P_n(f(x), f'(x), \dots, f^{(n-1)}(x))$$

in the derivatives of the function  $f$ , all with non-negative coefficients and independent of the particular equation.<sup>5</sup>

CAUCHY-KOVALEVSKAYA THEOREM IN DIMENSION ONE

**Theorem.** Assume  $f(y)$  is a real analytic function convergent on the interval  $(x_0-a, x_0+a) \subset \mathbb{R}$  and consider the differential equation (1) with the condition  $y(x_0) = y_0$ . Then the formal power series  $y(x) = \sum_{n=0}^{\infty} \frac{1}{n!} y^{(n)}(x_0)(x-x_0)^n$  converges on a neighborhood of  $x_0$  and provides the solution to (1) satisfying the initial condition.

**PROOF.** The second observation above suggests how to prove the convergence of the “candidate series” similarly as we proved the convergence of power series in general, i.e. by finding another converging series whose partial sums will bound our’s from above. This was the original Cauchy’s approach to this theorem and we talk about the *method of majorants*.

Without loss of generality we shall fix  $x_0 = 0$  and  $y(0) = 0$  (we may always use shifted quantities  $z = y - y_0$  and  $t = x - x_0$  to transform the general case). Assume we can find another analytic function  $g(x) = \sum_{n=0}^{\infty} \frac{1}{n!} b_n x^n$  with all  $b_n = g^{(n)} \geq 0$ , i.e.  $g$  has got all derivatives non-negative at the origin, such that  $g^{(n)}(0) \geq |f^{(n)}(0)|$  for all  $n$ .

Now, replace  $f$  in the equation (1) by  $g$  and write formal power series  $z(x) = \sum_{n=0}^{\infty} \frac{z^{(n)}}{n!} x^n$  for the potential solution of this equation as above. In particular, we deduce (recall the universal polynomials  $P_n$  have got non-negative coefficients)

$$\begin{aligned} z^{(n)}(0) &= P_n(g(z(0)), \dots, g^{(n-1)}(z(0))) \\ &\geq P_n(|f(y(0))|, \dots, |f^{(n-1)}(y(0))|) \geq |y^{(n)}(0)| \end{aligned}$$

and, consequently, convergence of  $z(x)$  will imply absolute convergence of  $y(x)$ , i.e. the claim of the Theorem. We try to find a majorant in the form of a geometric series.

Let us pick  $r > 0$ , smaller than the radius of convergence of  $f$ . Then obviously, there is a constant  $C > 0$  such that the derivatives  $a_n = f^{(n)}(0)$  satisfy  $|\frac{1}{n!} a_n r^n| \leq C$  for all  $n$ , i.e.  $|a_n| \leq C \frac{n!}{r^n}$  (the series would certainly not converge

<sup>5</sup>Although we shall not need the explicit formulae for these polynomials, they are well known under the name *Faà di Bruno’s formula*. In principle, they are direct generalization of the Leibniz rule to higher order derivatives.

$$1 \mid - \frac{1}{2} \ln (y^2 + 2y + 2) + 3 \operatorname{arctg} (y + 1) + C = \ln \mid \ln x - 1 \mid - \frac{1}{2} \ln (\ln^2 x + 2 \ln x + 2) + 3 \operatorname{arctg} (\ln x + 1) + C.$$

□

For an arbitrary function  $f$  that is continuous and bounded on a bounded interval  $(a, b)$ , the so called Newton-Leibniz formula

$$(1) \int_a^b f(x) dx = [F(x)]_a^b := \lim_{x \rightarrow b^-} F(x) - \lim_{x \rightarrow a^+} F(x)$$

holds, where  $F'(x) = f(x)$ ,  $x \in (a, b)$ . Emphasise that under the given conditions, the primitive function  $F$  always exists and so do both proper limits in (1). Hence to compute the definite integral, we only need to find the antiderivative and determine the respective one-sided limits (eventually only values of the function, if the primitive function is continuous at the boundary points of the interval).

**6.B.31.** Determine

- (a)  $\int \frac{1}{\sqrt{x^3 + \sqrt[3]{x^7}}} dx, x > 0;$
- (b)  $\int \frac{x+1}{\sqrt[3]{3x+1}} dx, x \neq -\frac{1}{3};$
- (c)  $\int \frac{1}{x} \sqrt{\frac{x+1}{x-1}} dx, x \in \mathbb{R} \setminus [-1, 1];$
- (d)  $\int \frac{1}{(x+4)\sqrt{x^2+3x-4}} dx, x \in (-\infty, -4) \cup (1, +\infty);$
- (e)  $\int \frac{1}{1+\sqrt{-x^2+x+2}} dx, x \in (-1, 2);$
- (f)  $\int \frac{1}{(x-1)\sqrt{x^2+x+1}} dx, x \neq 1.$

**Solution.** In this problem, we'll illustrate the use of the substitution method while integrating expressions containing roots.

Case (a). If the integral is in the form of

$$\int f ( \sqrt[p(1)]{x}, \sqrt[p(2)]{x}, \dots, \sqrt[p(j)]{x} ) dx$$

for certain numbers  $p(1), p(2), \dots, p(j) \in \mathbb{N}$  and a rational function  $f$  (of more variables), the substitution  $t^n = x$  is suggested, where  $n$  is the (least) common multiple of numbers  $p(1), \dots, p(j)$ . Using this substitution, we can always reduce the integrand (the integrated function) to a rational function, which we can always integrate. We'll get

$$\begin{aligned} \int \frac{dx}{\sqrt{x^3 + \sqrt[3]{x^7}}} &= \int \frac{dx}{x(\sqrt{x + \sqrt[3]{x^2}})} = \left| \begin{matrix} t^{10} = x, & \sqrt[10]{x} = t \\ 10t^9 dt = dx \end{matrix} \right| = \\ &= \int \frac{10t^9}{t^{10}(t^5 + t^4)} dt = 10 \int \frac{dt}{t^6 + t^5} = \\ &= 10 \int \left( \frac{1}{t} - \frac{1}{t^2} + \frac{1}{t^3} - \frac{1}{t^4} + \frac{1}{t^5} - \frac{1}{t+1} \right) dt = \\ &= 10 \left[ \ln t + \frac{1}{t} - \frac{1}{2t^2} + \frac{1}{3t^3} - \frac{1}{4t^4} - \ln(1+t) \right] + C = \\ &= \ln \frac{x}{(1 + \sqrt[10]{x})^{10}} + \frac{10}{\sqrt[10]{x}} - \frac{5}{\sqrt[5]{x}} + \frac{10}{3\sqrt[3]{x^3}} - \frac{5}{2\sqrt{x^2}} + C. \end{aligned}$$

Case (b). For integrals

$$\int f ( x, \sqrt[p(1)]{ax + b}, \sqrt[p(2)]{ax + b}, \dots, \sqrt[p(j)]{ax + b} ) dx,$$

otherwise). We may recognize the derivatives of a geometric series and write

$$(2) \quad g(z) = C \sum_{n=0}^{\infty} \frac{z^n}{r^n} = C \frac{r}{r-z}$$

with derivatives  $g^{(n)} = C \frac{n!}{r^n}$ .

Finally, we have to prove that the solution of the equation  $z' = g(z)$  is analytic. We can easily integrate this equation with separated variables directly. Written with the help of differentials,  $(r - z) dz = Cr dx$ . Thus, the implicit equation reads  $\frac{1}{2}(r - z)^2 = -Cr x + D$ , where the constant  $D$  is determined by  $z(0) = 0$ . Consequently  $D = \frac{1}{2}r^2$  and a simple computation reveals the solution of the implicit equation

$$z(x) = r \left( 1 \pm \sqrt{1 - \frac{2Cx}{r}} \right).$$

The option with the minus sign satisfies our initial condition. This clearly is an analytic function,  $g$  provides the requested majorant, and the proof is finished. □

**6.2.16. Improper integrals.** When discussing the integration of rational functions  $f$ , there is a need to consider definite integrals over intervals, where  $f(x)$  has improper (one-sided) limits. Here  $f$  is neither continuous nor bounded. Thus earlier definitions and results may not apply. We speak of "improper" integrals.

A simple solution is to discuss the definite integral on a smaller sub-interval, and determine whether the limit value of such a definite integral exists when the boundary approaches the problematic point. If it does, the corresponding improper integral exists and equals this limit. We illustrate this procedure by an example:

$$I = \int_0^2 \frac{dx}{(2-x)^{1/4}}.$$

This is an improper integral, because the integrand  $f(x) = (2-x)^{-1/4} = \frac{1}{\sqrt[4]{2-x}}$  has its left-sided limit  $\infty$  at the point  $b = 2$ . The integrand is continuous at all other points. Thus, for  $0 < \delta < 2$ , consider the integrals (substituting  $y = 2 - x$ )

$$\begin{aligned} I_\delta &= \int_0^{2-\delta} \frac{dx}{\sqrt[4]{2-x}} = \int_\delta^2 y^{-1/4} dy \\ &= \left[ \frac{4}{3} y^{3/4} \right]_\delta^2 = \frac{4}{3} [2^{3/4} - \delta^{3/4}]. \end{aligned}$$

Notice that  $dy = -dx$ . When  $x = 2 - \delta, y = \delta$ . When  $x = 0, y = 2$ .

The limit when  $\delta \rightarrow 0$  from the right clearly exists, so the improper integral is evaluated.

$$I = \int_0^2 \frac{dx}{\sqrt[4]{2-x}} = \frac{4}{3} 2^{3/4}.$$

We proceed in the same way to integrate over an unbounded interval. In this case, we speak of *improper Riemann*

where again  $p(1), \dots, p(j) \in \mathbb{N}$ ,  $f$  is a rational expression and  $a, b \in \mathbb{R}$ , we choose the substitution  $t^n = ax + b$  while preserving the meaning of  $n$ . In this way, we'll get

$$\begin{aligned} \int \frac{x+1}{\sqrt[3]{3x+1}} dx &= \left| \begin{array}{l} t^3 = 3x + 1 \\ dx = t^2 dt \end{array} \right| = \int \frac{t^3-1+1}{t} t^2 dt = \\ \int \frac{t^3-1+3}{3} t dt &= \frac{1}{3} \int t^4 + 2t dt = \frac{1}{3} \left( \frac{t^5}{5} + t^2 \right) + C = \\ \frac{t^2}{3} \left( \frac{t^3}{5} + 1 \right) + C &= \frac{\sqrt[3]{(3x+1)^2}}{3} \left( \frac{3x+1}{5} + 1 \right) + C = \\ &= \sqrt[3]{(3x+1)^2} \frac{x+2}{5} + C. \end{aligned}$$

Case(c). Another generalizations are the integrals of the type

$$\int f \left( x, \sqrt[p(1)]{\frac{ax+b}{cx+d}}, \sqrt[p(2)]{\frac{ax+b}{cx+d}}, \dots, \sqrt[p(j)]{\frac{ax+b}{cx+d}} \right) dx,$$

with the only additional condition on the values  $a, b, c, d \in \mathbb{R}$  being  $ad - bc \neq 0$ . Preserving the meaning of the aforementioned symbols, we now put  $t^n = \frac{ax+b}{cx+d}$ . Specifically,

$$\begin{aligned} \int \frac{1}{x} \sqrt{\frac{x+1}{x-1}} dx &= \left| \begin{array}{l} t^2 = \frac{x+1}{x-1} \\ x = \frac{t^2+1}{t^2-1} \\ dx = -\frac{4t}{(t^2-1)^2} dt \end{array} \right| = \\ \int \frac{t^2-1}{t^2+1} \frac{-4t^2}{(t^2-1)^2} dt &= \int \frac{-4t^2}{(t^2+1)(t^2-1)} dt = \\ \int \left( \frac{1}{t+1} - \frac{1}{t-1} - \frac{2}{t^2+1} \right) dt &= \\ \ln |t+1| - \ln |t-1| - 2 \operatorname{arctg} t + C &= \\ \ln \left| \sqrt{\frac{x+1}{x-1}} + 1 \right| - \ln \left| \sqrt{\frac{x+1}{x-1}} - 1 \right| - 2 \operatorname{arctg} \sqrt{\frac{x+1}{x-1}} + C. \end{aligned}$$

The simplifications

$$\begin{aligned} \ln \left| \sqrt{\frac{x+1}{x-1}} + 1 \right| - \ln \left| \sqrt{\frac{x+1}{x-1}} - 1 \right| &= \ln \left| \frac{\sqrt{\frac{x+1}{x-1}} + 1}{\sqrt{\frac{x+1}{x-1}} - 1} \right| = \\ \ln \left| \frac{\sqrt{\frac{|x+1|}{|x-1|}} + 1}{\sqrt{\frac{|x+1|}{|x-1|}} - 1} \right| &= \ln \left| \frac{\sqrt{|x+1|} + \sqrt{|x-1|}}{\sqrt{|x+1|} - \sqrt{|x-1|}} \right| = \\ \ln \frac{(\sqrt{|x+1|} + \sqrt{|x-1|})^2}{||x+1| - |x-1||} &= \\ 2 \ln \left( \sqrt{|x+1|} + \sqrt{|x-1|} \right) - \ln 2 \end{aligned}$$

for  $x \in (-\infty, -1) \cup (1, \infty)$  then allow to write

$$\begin{aligned} \int \frac{1}{x} \sqrt{\frac{x+1}{x-1}} dx &= \\ 2 \ln \left( \sqrt{|x+1|} + \sqrt{|x-1|} \right) - 2 \operatorname{arctg} \sqrt{\frac{x+1}{x-1}} + C. \end{aligned}$$

Cases (d), (e), (f). Now we'll focus on the integrals

$$\int f(x, \sqrt{ax^2 + bx + c}) dx,$$

where we expect  $a \neq 0$  and  $b^2 - 4ac \neq 0$  for otherwise arbitrary numbers  $a, b, c \in \mathbb{R}$ . Recall that  $f$  is a rational expression. We'll distinguish two cases, when the quadratic polynomial  $ax^2 + bx + c$  has real roots and when it doesn't.

If  $a > 0$  and the polynomial  $ax^2 + bx + c$  has real roots  $x_1, x_2$ , we'll use the representation

$$\begin{aligned} \sqrt{ax^2 + bx + c} &= \sqrt{a} \sqrt{(x-x_1)^2 \frac{x-x_2}{x-x_1}} = \\ \sqrt{a} |x-x_1| \sqrt{\frac{x-x_2}{x-x_1}} \end{aligned}$$

*integrals of the first kind.* The integrals of unbounded functions on finite intervals are *improper Riemann integrals of the second kind.*

More explicitly, for  $a \in \mathbb{R}$

$$I = \int_a^\infty f(x) dx = \lim_{b \rightarrow \infty} \int_a^b f(x) dx,$$

if the integrals and limit on the right hand side exist. Similarly we can have a finite upper bound an infinite lower bound. If both  $a$  and  $b$  are infinite, we can evaluate the integral as a sum of two integrals with a chosen fixed bound in the middle as in

$$\int_{-\infty}^\infty f(x) dx = \int_{-\infty}^a f(x) dx + \int_a^\infty f(x) dx.$$

Its existence and its value do not depend on the choice of such bound, because by changing it, we only change both summands by the same finite value, but with opposite sign.

At the same time a limit for which the upper and lower bound would approach  $\pm\infty$  at the same speed can lead to different results! For example

$$\int_{-a}^a x dx = \left[ \frac{1}{2} x^2 \right]_{-a}^a = 0,$$

even though the values of the integrals  $\int_a^b x dx$  with  $a$  fixed and  $b \rightarrow \infty$  diverge to infinity.

The integrated functions may have more discontinuities with infinite one-sided limits. The interval of integration may be unbounded. Then the integration intervals must be split in such a way that the individual intervals of integration include only one of the above phenomena.

Hence when evaluating the improper integral of a rational function, divide the given interval according to the discontinuities of the integrated function. Then compute all the improper integrals separately.

**6.2.17. New acquisitions to the ZOO.** It might seem that indefinite integrals can be described in terms of known elementary functions. But this is false.

On the contrary, nearly all continuous functions lead to integrals which we cannot express in this way. Functions obtained by integration often appear in applications. Many of them have names and there are efficient methods how to approximate them numerically (we shall come to this point briefly in 6.3.11 below).

In the methods of signal processing, the function

$$\operatorname{sinc}(x) = \frac{\sin(x)}{x}$$

is important (cf. the discussion of Fourier transform in 7.2.6). Check yourself that it is a smooth function with limit values

$$f(0) = 1, f'(0) = 0, f''(0) = -\frac{2}{3}.$$

This even function has its absolute maximum at the point  $x = 0$ . It oscillates with a fast decreasing amplitude as  $x$  approaches infinity.

and let  $t^2 = \frac{x-x_2}{x-x_1}$ . If  $a < 0$  and the polynomial  $ax^2 + bx + c$  has real roots  $x_1 < x_2$ , we'll use the representation

$$\begin{aligned} \sqrt{ax^2 + bx + c} &= \sqrt{-a} \sqrt{(x-x_1)^2 \frac{x_2-x}{x-x_1}} = \\ &= \sqrt{-a} (x-x_1) \sqrt{\frac{x_2-x}{x-x_1}} \end{aligned}$$

and let  $t^2 = \frac{x_2-x}{x-x_1}$ . If the polynomial  $ax^2 + bx + c$  doesn't have real roots (necessarily for  $a > 0$ ), we choose the substitution

$$\sqrt{ax^2 + bx + c} = \pm \sqrt{a} \cdot x \pm t$$

with any choice of the signs. Note that we of course choose the signs so that we get as easy expression to integrate as possible. In all these cases, these substitutions again lead to rational functions.

Hence

(d)

$$\begin{aligned} \int \frac{dx}{(x+4)\sqrt{x^2+3x-4}} &= \int \frac{dx}{(x+4)\sqrt{(x-1)(x+4)}} = \\ &= \int \frac{dx}{(x+4) \left| x+4 \right| \sqrt{\frac{x-1}{x+4}}} = \begin{cases} t^2 = \frac{x-1}{x+4} \\ x = \frac{5}{1-t^2} - 4 \\ dx = \frac{10t}{(1-t^2)^2} dt \end{cases} = \\ &= \int \frac{\frac{10t}{(1-t^2)^2}}{\left( \frac{5}{1-t^2} \right) \left| \frac{5}{1-t^2} \right| t} dt = \int \frac{2}{5} \frac{1-t^2}{1-t^2} dt = \\ &= \frac{2}{5} \operatorname{sgn}(1-t^2) \int 1 dt = \frac{2}{5} \operatorname{sgn}\left(\frac{5}{x+4}\right) t + C = \\ &= \frac{2}{5} \operatorname{sgn}(x) \sqrt{\frac{x-1}{x+4}} + C; \end{aligned}$$

(e)

$$\begin{aligned} \int \frac{dx}{1+\sqrt{-x^2+x+2}} &= \int \frac{dx}{1+\sqrt{-(x-2)(x+1)}} = \\ \int \frac{dx}{1+(x+1)\sqrt{\frac{2-x}{x+1}}} &= \begin{cases} t^2 = \frac{2-x}{x+1} \\ x = \frac{3}{t^2+1} - 1 \\ dx = \frac{-6t}{(t^2+1)^2} dt \end{cases} = \\ \int \frac{\frac{-6t}{(t^2+1)^2}}{1+\frac{3}{t^2+1}t} dt &= \int \frac{-6t}{(t^2+1)^2} \frac{t^2+1}{t^2+3t+1} dt = \\ \int \frac{-6t}{(t^2+1)(t^2+3t+1)} dt &= \\ \int \left( -\frac{4}{5} \frac{\sqrt{5}}{2t+3+\sqrt{5}} - \frac{2}{t^2+1} - \frac{4}{5} \frac{\sqrt{5}}{-2t-3+\sqrt{5}} \right) dt &= \\ -\frac{2\sqrt{5}}{5} \ln \left| 2t+3+\sqrt{5} \right| - 2 \operatorname{arctg} t + & \\ \frac{2\sqrt{5}}{5} \ln \left| -2t-3+\sqrt{5} \right| + C = & \\ -\frac{2\sqrt{5}}{5} \ln \left| 2\sqrt{\frac{2-x}{x+1}} + 3 + \sqrt{5} \right| - 2 \operatorname{arctg} \sqrt{\frac{2-x}{x+1}} + & \\ \frac{2\sqrt{5}}{5} \ln \left| -2\sqrt{\frac{2-x}{x+1}} - 3 + \sqrt{5} \right| + C = & \\ \frac{2\sqrt{5}}{5} \ln \frac{2\sqrt{\frac{2-x}{x+1}} + 3 - \sqrt{5}}{2\sqrt{\frac{2-x}{x+1}} + 3 + \sqrt{5}} - 2 \operatorname{arctg} \sqrt{\frac{2-x}{x+1}} + C; & \end{aligned}$$

(f)

$$\begin{aligned} \int \frac{dx}{(x-1)\sqrt{x^2+x+1}} &= \begin{cases} \sqrt{x^2+x+1} = x+t \\ x^2+x+1 = x^2+2xt+t^2 \\ x = -\frac{t^2+2t-2}{2t-1} + 1 \\ dx = \frac{-2(t^2-t+1)}{(2t-1)^2} dt \end{cases} = \\ \int \frac{\frac{-2(t^2-t+1)}{(2t-1)^2}}{-\frac{t^2+2t-2}{2t-1} \frac{t^2-t+1}{2t-1}} dt &= \int \frac{2}{t^2+2t-2} dt = \end{aligned}$$

The *sine integral function* is defined by

$$\operatorname{Si}(x) = \int_0^x \operatorname{sinc}(t) dt.$$

Other important functions are *Fresnel's sine and cosine integrals*

$$\begin{aligned} \operatorname{FresnelS}(x) &= \int_0^x \sin\left(\frac{1}{2}\pi t^2\right) dt \\ \operatorname{FresnelC}(x) &= \int_0^x \cos\left(\frac{1}{2}\pi t^2\right) dt. \end{aligned}$$

The function  $\operatorname{Si}(x)$  is shown in the left figure. Both Fresnel's functions are shown on the right.

An even more important way how to get new functions is to add some free parameter in the integral. One of the most important mathematical functions ever is the *Gamma function*. It is defined for all positive real numbers  $z$  by

$$\Gamma(z) = \int_0^\infty e^{-t} t^{z-1} dt.$$

It can be proved that this function is analytic at all points  $0 < z \in \mathbb{R}$ . For small  $z \in \mathbb{N}$ , we can evaluate:

$$\begin{aligned} \Gamma(1) &= \int_0^\infty e^{-t} t^0 dt = [-e^{-t}]_0^\infty = 1 \\ \Gamma(2) &= \int_0^\infty e^{-t} t^1 dt = [-e^{-t}t]_0^\infty + \int_0^\infty e^{-t} dt = 1 \\ \Gamma(3) &= \int_0^\infty e^{-t} t^2 dt = 0 + 2 \int_0^\infty e^{-t} t dt = 0 + 2 = 2. \end{aligned}$$

Integration by parts reveals immediately

$$\Gamma(z+1) = z\Gamma(z).$$

Hence for all positive integers  $n$  this function yields the value of the factorial:

$$\Gamma(n) = (n-1)!.$$

The following figure shows the behaviour of the function  $f(x) = \ln(\Gamma(x+1))$ .

$$\begin{aligned} & \int \left( \frac{\sqrt{3}}{3} \frac{1}{t+1-\sqrt{3}} - \frac{\sqrt{3}}{3} \frac{1}{t+1+\sqrt{3}} \right) dt = \\ & \frac{\sqrt{3}}{3} \ln |t+1-\sqrt{3}| - \frac{\sqrt{3}}{3} \ln |t+1+\sqrt{3}| + C = \\ & \frac{\sqrt{3}}{3} \ln \left| \frac{t+1-\sqrt{3}}{t+1+\sqrt{3}} \right| + C = \frac{\sqrt{3}}{3} \ln \left| \frac{\sqrt{x^2+x+1}-x+1-\sqrt{3}}{\sqrt{x^2+x+1}-x+1+\sqrt{3}} \right| + C. \end{aligned}$$

□

**6.B.32.** Using a suitable substitution, compute

$$\int \frac{dx}{x+\sqrt{x^2+x-1}} dx, \quad x \in \left(-\infty, \frac{-\sqrt{5}-1}{2}\right) \cup \left(\frac{\sqrt{5}-1}{2}, +\infty\right).$$

**Solution.** Even though the quadratic polynomial under the root has real roots  $x_1, x_2$ , we won't solve this problem by substitution  $t^2 = \frac{x-x_2}{x-x_1}$ . We could proceed that way, but we'll rather use a method we introduced for the complex roots case. That's because this method yields a very simple integral of a rational function, as can be seen from the calculation

$$\begin{aligned} \int \frac{dx}{x+\sqrt{x^2+x-1}} &= \left| \begin{array}{l} \sqrt{x^2+x-1} = x+t \\ x^2+x-1 = x^2+2xt+t^2 \\ x = \frac{t^2+1}{1-2t} \\ dx = \frac{-2t^2+2t+2}{(1-2t)^2} dt \end{array} \right| = \\ & \int \frac{-2t^2+2t+2}{(t+2)(1-2t)} dt = \\ & \int \left( 1 - \frac{2}{t+2} - \frac{1}{2} \frac{1}{t-\frac{1}{2}} \right) dt = \\ & t - 2 \ln |t+2| - \frac{1}{2} \ln \left| t - \frac{1}{2} \right| + C = \\ & \sqrt{x^2+x-1} - x - 2 \ln (\sqrt{x^2+x-1} - x + 2) - \\ & \frac{1}{2} \ln \left| \sqrt{x^2+x-1} - x - \frac{1}{2} \right| + C. \end{aligned}$$

Note that each recommended substitution (see the above problems) can be in most specific problems usually replaced by another substitution, which allows to obtain the result in a much easier way. An undeniable advantage of the recommended substitutions is their universality though: by using them, one can compute all integrals of the respective type. □

**6.B.33.** For  $x > 0$  determine

- (a)  $\int \frac{(2+5x)^3}{\sqrt{x^3}} dx;$   
 (b)  $\int \frac{\sqrt[3]{1+\sqrt{x}}}{\sqrt{x}} dx;$   
 (c)  $\int \frac{1}{\sqrt[4]{1+x^4}} dx.$

**Solution.** All three given integrals are binomial, i.e. they can be written as

$$\int x^m (a + bx^n)^p dx \quad \text{for some } a, b \in \mathbb{R}, m, n, p \in \mathbb{Q}.$$

The binomial integrals are usually solved by applying the substitution method. If  $p \in \mathbb{Z}$  (not necessarily  $p < 0$ ), we choose the substitution  $x = t^s$ , where  $s$  is the common denominator of numbers  $m$  and  $n$ ; if  $\frac{m+1}{n} \in \mathbb{Z}$  and  $p \notin \mathbb{Z}$ , we choose  $a + bx^n = t^s$ , where  $s$  is the denominator of number  $p$ ; and if  $\frac{m+1}{n} + p \in \mathbb{Z}$  ( $p \notin \mathbb{Z}, \frac{m+1}{n} \notin \mathbb{Z}$ ), we choose  $a + bx^n = t^s x^n$ ,

If we draw the function  $x \ln x - x$  instead, there is not much difference to be seen. Hence it seems that the factorial  $n!$  grows similarly to  $e^{n \ln n - n} = n^n e^{-n}$ . This is the famous *Stirling's approximation* formula. More precisely, one can verify

$$\sqrt{2\pi n} n^{n+\frac{1}{2}} e^{-n} \leq n! \leq e n^{n+\frac{1}{2}} e^{-n}.$$

In order to understand the qualitative behavior of such functions (e.g. their differentiability) we need to understand the limit processes much better. Before diving into this in the next section, we introduce several direct applications of the Riemann integral.

**6.2.18. Riemann measurable sets.** The definition of the

Riemann integral is motivated by the concept of the area of rectangles in the plane with coordinates  $x$  and  $y$ . The definite integral  $\int_a^b$  is designed to correspond to the area of the region bounded by the  $x$  axis, the values of the function  $y = f(x)$  and boundary lines  $x = a, x = b$ . Moreover, the area of the region above the  $x$  axis is given with a positive sign, while values under the axis lead to a negative sign.

From geometry, the length of an interval on the real line, and the area of a parallelogram determined by two vectors in the plane are basic concepts. This extends to the area of a parallelepiped in Euclidean vector space  $\mathbb{R}^n$ . The areas/volumes of other subsets are yet to be defined. For some simple objects like triangles, polygons and polyhedrons, their area is given naturally by the generally expected properties of area (invariance with respect to Euclidean motions and additivity with respect to finite union of disjoint objects). Open questions include: What are the “measurable objects” in the real line? How can the concept of area and volume be extended to higher dimensions?

The questions are answered partially with the help of the Riemann integral. First, measure the “volume” of one-dimensional subsets.

We say that the subset  $A \subset \mathbb{R}$  is (*Riemann*) *measurable*, if the function  $\chi : \mathbb{R} \rightarrow \mathbb{R}$

$$\chi_A(x) = \begin{cases} 1 & \text{if } x \in A \\ 0 & \text{if } x \notin A. \end{cases}$$

is Riemann integrable. That is, the (improper) integral

$$m(A) = \int_{-\infty}^{\infty} \chi_A(x) dx$$

where  $s$  is the denominator of  $p$ . In these three cases, a reduction to an integration of a rational function is guaranteed.

Hence we can easily compute

(a)

$$\int \frac{(2+5x)^3}{\sqrt[4]{x^3}} dx = \int x^{-\frac{3}{4}}(2+5x)^3 dx = \left| \begin{array}{l} p \in \mathbb{Z} \\ x = t^4 \\ dx = 4t^3 dt \end{array} \right| = 4 \int (2+5t^4)^3 dt = 4 \int (8+60t^4+150t^8+125t^{12}) dt = 4(8t+12t^5+\frac{50}{3}t^9+\frac{125}{13}t^{13})+C = 4\left(8\sqrt[4]{x}+12\sqrt[4]{x^5}+\frac{50}{3}\sqrt[4]{x^9}+\frac{125}{13}\sqrt[4]{x^{13}}\right)+C;$$

(b)

$$\int \frac{\sqrt[3]{1+\sqrt{x}}}{\sqrt{x}} dx = \int x^{-\frac{1}{2}} \left(1+x^{\frac{1}{4}}\right)^{\frac{1}{3}} dx = \left| \begin{array}{l} p \notin \mathbb{Z}, \frac{m+1}{n} \in \mathbb{Z} \\ 1+x^{\frac{1}{4}} = t^3 \\ x = (t^3-1)^4 \\ dx = 12t^2(t^3-1)^3 dt \end{array} \right| = 12 \int t^3(t^3-1) dt = 12 \int t^6 - t^3 dt = 12\left(\frac{t^7}{7} - \frac{t^4}{4}\right) + C = 12\sqrt[3]{(1+\sqrt{x})^4} \left(\frac{1+\sqrt{x}}{7} - \frac{1}{4}\right) + C;$$

(c)

$$\int \frac{1}{\sqrt[4]{1+x^4}} dx = \int (1+x^4)^{-\frac{1}{4}} dx = \left| \begin{array}{l} p \notin \mathbb{Z}, \frac{m+1}{n} \notin \mathbb{Z}, \frac{m+1}{n} + p \in \mathbb{Z} \\ 1+x^4 = t^4 x^4 \\ x = (t^4-1)^{-\frac{1}{4}} \\ dx = -t^3(t^4-1)^{-\frac{5}{4}} dt \end{array} \right| = -\int \frac{t^2}{t^4-1} dt = -\int \frac{t^2}{(t-1)(t+1)(t^2+1)} dt = -\frac{1}{4} \int \left(\frac{1}{t-1} - \frac{1}{t+1} + \frac{2}{t^2+1}\right) dt = -\frac{1}{4}(\ln|t-1| - \ln|t+1| + 2 \arctg t) + C = -\frac{1}{4} \left[ \ln \frac{\sqrt[4]{\frac{1}{x^4}+1}-1}{\sqrt[4]{\frac{1}{x^4}+1}+1} + 2 \arctg \left(\sqrt[4]{\frac{1}{x^4}+1}\right) \right] + C.$$

**6.B.34.** For  $x \in \left(-\frac{\pi}{2}, \frac{\pi}{2}\right)$ , integrate

- (a)  $\int \frac{\sin^3 x}{1+4 \cos^2 x+3 \sin^2 x} dx;$
- (b)  $\int \frac{1}{1+\sin^2 x} dx;$
- (c)  $\int \frac{1}{2-\cos x} dx.$

**Solution.** Integrals in the form of  $\int f(\sin x, \cos x) dx$  for some rational function  $f$  are usually solved by the substitution method. If  $f(\sin x, -\cos x) = -f(\sin x, \cos x)$ , we choose  $t = \sin x$ ; if  $f(-\sin x, \cos x) = -f(\sin x, \cos x)$ , we choose  $t = \cos x$ ; and if  $f(-\sin x, -\cos x) = f(\sin x, \cos x)$ , then  $t = \operatorname{tg} x$ . If none of these equalities

exists (the finiteness of its value doesn't matter). The function  $\chi_A$  is called the *characteristic function of the set A*, the value  $m(A)$  is called the *Riemann measure of the set A*. Notice that for an interval  $A = [a, b]$  this yields the value

$$\int_{-\infty}^{\infty} \chi_A(x) dx = \int_a^b dx = b - a,$$

just as expected.

The elementary properties of the Riemann integral imply that this definition of "size" has the expected properties. The measure of a union of finitely many measurable pairwise disjoint subsets is the sum of their measures. In particular, every finite set  $A$  has zero measure.

If instead we choose a countable union, this property is no longer true. For example, consider the set  $\mathbb{Q}$  of all rational numbers as the union of one-element subsets. While every set containing only finitely many points has a zero measure by our definition, the characteristic function  $\chi_{\mathbb{Q}}$  is not Riemann integrable.

The upper Riemann integral of the characteristic set  $\chi_A$  corresponds to the infimum of the sums of lengths of finitely many disjoint intervals, by which we can cover the given set  $A$ . The lower integral is the supremum of the sums of lengths of finitely many disjoint intervals that can be embedded into the set  $A$ . We proceed in the same way in higher dimensions when defining the *Jordan measure*. For the definition of area (volume) in higher-dimensional space we generalize the concept of the Riemann integral. We return to this in chapter 8. We remark here that the area of a plane figure bounded by a graph of a function in the way described above is consistent with expectations.

**6.2.19. Mean value of a function.** For a finite set of  $n$  numbers, the mean value, or arithmetic mean, is obtained by summing the numbers and dividing by  $n$ . For a Riemann integrable function  $f(x)$  on an interval (finite or infinite)  $[a, b]$ , the *mean value* is defined by

$$m(f) = \frac{1}{b-a} \int_a^b f(x) dx.$$

By definition,  $m(f)$  is the altitude of the rectangle (oriented according to the sign) over the interval  $[a, b]$ , which has the same area as that of the region between the  $x$  axis and the graph of the  $f(x)$ . Hence the *integral mean value theorem* is true in general:

**Proposition.** If  $f(x)$  is a Riemann integrable function on an interval  $[a, b]$ , then there exists a number  $m(f)$  satisfying

$$\int_a^b f(x) dx = m(f)(b-a).$$

**6.2.20. Length of a space curve.** The Riemann integral can be effectively used to compute the *length of a curve* in multidimensional Euclidean vector space  $\mathbb{R}^n$ . For the sake of simplicity, we deal with a curve in  $\mathbb{R}^2$  with coordinates  $x, y$ . Suppose a parametric description of a curve  $F : \mathbb{R} \rightarrow \mathbb{R}^2$ ,

hold, the substitution  $t = \operatorname{tg} \frac{x}{2}$  is used. We'll show it on the given integrals.

Case (a). In the denominator, we have

$$1 + 4 \cos^2 x + 3 \sin^2 x = 4 + \cos^2 x$$

and in the numerator only the sine function to an odd power, i.e. the substitution  $t = \cos x$ , where  $dt = -\sin x dx$ , allows to replace all the sines and cosines and thus obtain

$$\begin{aligned} \int \frac{\sin^3 x}{1+4 \cos^2 x+3 \sin^2 x} dx &= \int \frac{\sin x(1-\cos^2 x)}{4+\cos^2 x} dx = \\ \int \frac{-(1-t^2)}{4+t^2} dt &= \int \left(1 - \frac{5}{4+t^2}\right) dt = t - \frac{5}{2} \operatorname{arctg} \frac{t}{2} + C = \\ \cos x - \frac{5}{2} \operatorname{arctg} \frac{\cos x}{2} &+ C. \end{aligned}$$

Case (b). Because both the sine and cosine appear here to an even power, the substitution  $t = \operatorname{tg} x$  leads to

$$\sin^2 x = \frac{t^2}{1+t^2}, \quad \cos^2 x = \frac{1}{1+t^2}, \quad dx = \frac{1}{1+t^2} dt,$$

by which we obtain

$$\begin{aligned} \int \frac{dx}{1+\sin^2 x} &= \int \frac{\frac{1}{1+t^2}}{1+\frac{t^2}{1+t^2}} dt = \int \frac{1}{1+2t^2} dt = \\ \frac{\sqrt{2}}{2} \operatorname{arctg}(\sqrt{2}t) + C &= \frac{\sqrt{2}}{2} \operatorname{arctg}(\sqrt{2} \operatorname{tg} x) + C. \end{aligned}$$

Case (c). Now we'll use the universal substitution  $t = \operatorname{tg} \frac{x}{2}$ , where

$$\sin x = \frac{2t}{1+t^2}, \quad \cos x = \frac{1-t^2}{1+t^2}, \quad dx = \frac{2}{1+t^2} dt.$$

Then we can determine

$$\begin{aligned} \int \frac{dx}{2-\cos x} &= \int \frac{\frac{2}{1+t^2}}{2-\frac{1-t^2}{1+t^2}} dt = 2 \int \frac{dt}{1+3t^2} = \\ \frac{2\sqrt{3}}{3} \operatorname{arctg}(\sqrt{3}t) + C &= \frac{2\sqrt{3}}{3} \operatorname{arctg}(\sqrt{3} \operatorname{tg} \frac{x}{2}) + C. \end{aligned}$$

### Definite integrals.

#### 6.B.35. Compute the definite integrals

$$\int_{\frac{\pi}{6}}^{\frac{\pi}{3}} \operatorname{tg}^2 x dx, \quad \int_0^{\frac{\pi}{4}} \frac{x}{\cos^2 x} dx.$$

**Solution.** For  $x \neq \frac{\pi}{2} + k\pi$ , where  $k \in \mathbb{Z}$ , we have

$$\int \operatorname{tg}^2 x dx = \operatorname{tg} x - x + C,$$

as we have compute earlier. This implies that

$$\begin{aligned} \int_{\frac{\pi}{6}}^{\frac{\pi}{3}} \operatorname{tg}^2 x dx &= [\operatorname{tg} x - x]_{\frac{\pi}{6}}^{\frac{\pi}{3}} = \sqrt{3} - \frac{\pi}{3} - \left(\frac{1}{\sqrt{3}} - \frac{\pi}{6}\right) = \\ &= \frac{2}{\sqrt{3}} - \frac{\pi}{6}. \end{aligned}$$

Of course, definite integrals can be also computed directly. For example, the substitution  $y = \operatorname{tg} x$  yields

$$F(t) = [f(t), g(t)]$$

is given. Look at it as a trajectory of a movement. Assume that  $f(t)$  and  $g(t)$  have piece-wise continuous derivatives.

By differentiating the map  $F(t)$  we obtain vectors corresponding to the speed of the movement along this trajectory. Hence the total length of the curve (i.e. distance traveled over time between the values  $t = a$ ,  $t = b$ ) is given by the integral over the interval  $[a, b]$ , with the integrated function  $h(t)$  being the length of the vectors  $F'(t)$ . Therefore the length  $s$  is given by the formula

$$s = \int_a^b h(t) dt = \int_a^b \sqrt{(f'(t))^2 + (g'(t))^2} dt.$$

The result can be seen intuitively as a corollary of Pythagoras' theorem: the linear increment  $\Delta s$  of the length of the curve corresponding to the increment  $\Delta t$  of variable  $t$  is given by the proportion in the orthogonal triangle and thus at the level of differentials

$$ds = \sqrt{(g'(t))^2 + (f'(t))^2} dt.$$

In the special case when the curve is the graph of a function  $y = f(x)$  between points  $a < b$ , we obtain

$$s = \int_a^b \sqrt{1 + (f'(x))^2} dx$$

and at the level of differentials,

$$ds = \sqrt{1 + (y'(x))^2} dx,$$

just as expected.

As an example, we calculate the circumference of the unit circle as twice the integral of the function  $y = \sqrt{1 - x^2}$  over  $[-1, 1]$ . We know that the result is  $2\pi$ , because  $\pi$  is defined in this way.

$$\begin{aligned} \square \quad s &= 2 \int_{-1}^1 \sqrt{1 + (y')^2} dx = 2 \int_{-1}^1 \sqrt{1 + \frac{x^2}{1-x^2}} dx \\ &= 2 \int_{-1}^1 \frac{1}{\sqrt{1-x^2}} dx = 2[\arcsin x]_{-1}^1 = 2\pi. \end{aligned}$$

If we instead use

$$y = \sqrt{r^2 - x^2} = r \sqrt{1 - (x/r)^2}$$

and bounds  $[-r, r]$  in the previous calculation, by substituting  $x = rt$  we obtain the circumference of the circle with radius  $r$ :

$$\begin{aligned} s(r) &= 2 \int_{-r}^r \sqrt{1 + \frac{(x/r)^2}{1-(x/r)^2}} dx = 2 \int_{-1}^1 \frac{r}{\sqrt{1-t^2}} dt \\ &= 2r[\arcsin x]_{-1}^1 = 2\pi r. \end{aligned}$$

The result is of course well known from elementary geometry. Nevertheless, by using integral calculus, we derive the important fact that the length of a circle is linearly dependent on its diameter  $2r$ . The number  $\pi$  is exactly the ratio, appearing in this dependency.

$$\int_{\pi/6}^{\pi/3} \operatorname{tg}^2 x \, dx = \int_{\pi/6}^{\pi/3} \frac{\sin^2 x}{\cos^2 x} \, dx = \left| \begin{array}{l} y = \operatorname{tg} x; \, dy = \frac{dx}{\cos^2 x} \\ \sin^2 x = \frac{\operatorname{tg}^2 x}{1+\operatorname{tg}^2 x} = \frac{y^2}{1+y^2} \end{array} \right| = \int_{1/\sqrt{3}}^{\sqrt{3}} \frac{y^2}{1+y^2} \, dy = \int_{1/\sqrt{3}}^{\sqrt{3}} 1 - \frac{1}{1+y^2} \, dy = [y - \operatorname{arctg} y]_{1/\sqrt{3}}^{\sqrt{3}} = \frac{2}{\sqrt{3}} - \frac{\pi}{6}.$$

When doing the substitution, we only need to not forget to change the limits of the integral to values gained by substituting  $\sqrt{3} = \operatorname{tg}(\pi/3)$ ,  $1/\sqrt{3} = \operatorname{tg}(\pi/6)$ .

We'll compute the second integral by integration by parts for the definite integral. (Note that we also found the primitive function to function  $y = x \cos^{-2} x$  earlier.) We have

$$\int_0^{\pi/4} \frac{x}{\cos^2 x} \, dx = \left| \begin{array}{l} F(x) = x \\ G'(x) = \frac{1}{\cos^2 x} \end{array} \right| \left| \begin{array}{l} F'(x) = 1 \\ G(x) = \operatorname{tg} x \end{array} \right| = [x \operatorname{tg} x]_0^{\pi/4} - \int_0^{\pi/4} \operatorname{tg} x \, dx = [x \operatorname{tg} x]_0^{\pi/4} + \int_0^{\pi/4} \frac{-\sin x}{\cos x} \, dx = [x \operatorname{tg} x]_0^{\pi/4} + [\ln(\cos x)]_0^{\pi/4} = \frac{\pi}{4} + \ln \frac{\sqrt{2}}{2} = \frac{\pi - 2 \ln 2}{4}.$$

□

**6.B.36.** Compute the definite integrals

- (a)  $\int_0^1 \frac{x}{\sqrt{1-x^2}} \, dx;$
- (b)  $\int_1^2 \frac{1}{\sqrt{x^2-1}} \, dx;$
- (c)  $\int_0^1 \left( \frac{e^x}{e^{2x}+3} + \frac{1}{\cos^2 x} \right) \, dx;$

**Solution.** We have

(a) 
$$\int_0^1 \frac{x}{\sqrt{1-x^2}} \, dx = \left| \begin{array}{l} y = 1 - x^2 \\ dy = -2x \, dx \end{array} \right| = - \int_1^0 \frac{y^{-1/2}}{2} \, dy = \int_0^1 \frac{y^{-1/2}}{2} \, dy = [\sqrt{y}]_0^1 = 1;$$

(b) 
$$\int_1^2 \frac{dx}{\sqrt{x^2-1}} = \left| \begin{array}{l} z = x + \sqrt{x^2-1} \\ dz = \frac{\sqrt{x^2-1}+x}{\sqrt{x^2-1}} \, dx \end{array} \right| = \int_1^{2+\sqrt{3}} \frac{1}{z} \, dz = [\ln z]_1^{2+\sqrt{3}} = \ln(2 + \sqrt{3});$$

(c) 
$$\int_0^1 \left( \frac{e^x}{e^{2x}+3} + \frac{1}{\cos^2 x} \right) \, dx = \int_0^1 \frac{e^x}{e^{2x}+3} \, dx + \int_0^1 \frac{1}{\cos^2 x} \, dx = \left| \begin{array}{l} p = e^x \\ dp = e^x \, dx \end{array} \right| = \int_1^e \frac{1}{p^2+3} \, dp + [\operatorname{tg} x]_0^1 = \frac{1}{3} \int_1^e \frac{1}{\left(\frac{p}{\sqrt{3}}\right)^2+1} \, dp + \operatorname{tg} 1 = \left| \begin{array}{l} s = \frac{p}{\sqrt{3}} \\ ds = \frac{1}{\sqrt{3}} \, dp \end{array} \right| = \frac{\sqrt{3}}{3} \int_{1/\sqrt{3}}^{e/\sqrt{3}} \frac{1}{s^2+1} \, ds + \operatorname{tg} 1 = \frac{\sqrt{3}}{3} [\operatorname{arctg} s]_{1/\sqrt{3}}^{e/\sqrt{3}} + \operatorname{tg} 1 = \frac{\sqrt{3}}{3} \left( \operatorname{arctg} \frac{e\sqrt{3}}{3} - \frac{\pi}{6} \right) + \operatorname{tg} 1;$$

**6.2.21. Areas and volumes.** The Riemann integral can be used to compute areas or volumes of shapes defined by a graph of a function. As an example, calculate the area of a circle with radius  $r$ . The quarter-circle bounded by the function  $\sqrt{r^2 - x^2}$  for  $0 \leq x \leq r$  determines one quarter the area. Use the substitution  $x = r \sin t$ ,  $dx = r \cos t \, dt$  (using the corollary for  $I_2$  in the paragraph 6.2.6) to obtain by symmetry

$$\begin{aligned} a(r) &= 4 \int_0^r \sqrt{r^2 - x^2} \, dx = 4r^2 \int_0^{\pi/2} \cos^2 t \, dt \\ &= 4r^2 \int_0^{\pi/2} \sin^2 t \, dt = \frac{1}{2} 4r^2 \int_0^{\pi/2} \cos^2 t + \sin^2 t \, dt \\ &= 2r^2 \int_0^{\pi/2} dt = \pi r^2. \end{aligned}$$

It is worth noticing that this well known formula is derived from the principles of integral calculus. The area of a circle is not only proportional to the square of the radius, but this proportion is again given by the constant  $\pi$ .

Notice the ratio of the area to the perimeter of a circle.

$$\frac{\pi r^2}{2\pi r} = \frac{1}{2} r.$$

The square with the same area has the side of length  $\sqrt{\pi r}$  and therefore its perimeter is  $4\sqrt{\pi r}$ . Hence the perimeter of a square with the area of the unit circle is  $4\sqrt{\pi}$ , compared to the perimeter  $2\pi$  of the unit circle, which is about 0.8 less. It can be shown that in fact the circle is the shape with the smallest perimeter among all with the same area. We derive such results in comments about the calculus of variations in chapter 9.

Another analogy of this approach is the computation of the volume or the surface area of a *solid of revolution*. Such a set in  $\mathbb{R}^3$  is defined by plotting the graph of a function  $y = f(x)$  (for  $x$  in an interval  $[a, b]$ ) in the plane  $xy$  and rotating this plane around the  $x$  axis. This is exactly what happens when producing pottery on a jigger – the hands shape the clay in the form of  $y = f(x)$ .

add appropriate picture here!

When computing the area of the surface, an increment  $\Delta x$  causes the area to increase by the multiple of the length  $\Delta s$  of the curve given by the graph of the function  $y = f(x)$  and the size of the circle with radius  $f(x)$ . Hence the surface area  $A(f)$  is computed by the formula

$$A(f) = 2\pi \int_a^b f(x) \, ds = 2\pi \int_a^b f(x) \sqrt{1 + (f'(x))^2} \, dx,$$

where the differential  $ds$  is given by the increment on the length of curve  $y = f(x)$ , see above. If instead we determine the solid of revolution by its bound parametrized in the  $xy$  plain by a pair of functions  $[x(t), y(t)]$ , then the corresponding differential of the length  $s$  has the form  $ds = \sqrt{(x'(t))^2 + (y'(t))^2} \, dt$ . Thus we obtain

$$A = 2\pi \int_a^b y(t) \sqrt{(y'(t))^2 + (x'(t))^2} \, dt.$$

**6.B.37.** Prove that

$$\frac{\sqrt{2}}{20} \leq \int_0^1 \frac{x^9}{\sqrt{1+x}} dx \leq \frac{1}{10}.$$

**Solution.** Because

$$0 \leq \frac{x^9}{\sqrt{2}} \leq \frac{x^9}{\sqrt{1+x}} \leq x^9, \quad x \in [0, 1],$$

the geometric meaning of the definite integral implies

$$\frac{\sqrt{2}}{20} = \int_0^1 \frac{x^9}{\sqrt{2}} dx \leq \int_0^1 \frac{x^9}{\sqrt{1+x}} dx \leq \int_0^1 x^9 dx = \frac{1}{10}.$$

□

**6.B.38.** Without symbols of differentiation and integration, express

$$\left( \int_x^0 t^5 \ln(t+1) dt \right)', \quad x \in (-1, 1),$$

if the differentiation is done with respect to  $x$ .

**Solution.** Integration is often thought of as the inverse operation to differentiation. In this problem, we'll use this "inverse-ness". The function

$$F(x) := \int_0^x t^5 \ln(t+1) dt, \quad x \in (-1, 1)$$

is clearly the antiderivative of function  $f(x) := x^5 \ln(x+1)$  on interval  $(-1, 1)$ , i.e. by differentiating it, we'll get exactly  $f$ . Hence

$$\left( \int_x^0 t^5 \ln(t+1) dt \right)' = - \left( \int_0^x t^5 \ln(t+1) dt \right)' = -x^5 \ln(x+1).$$

**Improper integrals.**

**6.B.39.** Decide if

$$\int_1^{+\infty} \frac{\operatorname{arctg} x}{x\sqrt{x}} dx \in \mathbb{R}.$$

**Solution.** The improper integral represents the area of the figure between the graph of a positive function

$$y = \frac{\operatorname{arctg} x}{x\sqrt{x}}, \quad x \geq 1$$

and the  $x$  axis (from the left, the figure is bounded by the line  $x = 1$ ). Hence the integral is a positive real number, or equals  $+\infty$ . We know that

$$\frac{\pi}{4} \leq \operatorname{arctg} x \leq \frac{\pi}{2}, \quad x \in [1, +\infty).$$

But that implies

$$\frac{\pi}{2} = \frac{\pi}{4} \int_1^{+\infty} x^{-\frac{3}{2}} dx \leq \int_1^{+\infty} \frac{\operatorname{arctg} x}{x\sqrt{x}} dx \leq \frac{\pi}{2} \int_1^{+\infty} x^{-\frac{3}{2}} dx = \pi,$$

When computing the volume of the same solid, then the increase of  $\Delta x$  causes the volume increase by a multiple of this increment and the area of the circle with radius  $f(x)$ . Hence it is given by the formula

$$V(f) = \pi \int_a^b (f(x))^2 dx.$$

As an example of using the formulas for surface and volume, we derive the well known formulas for the surface of the sphere and volume of the ball with diameter  $r$ .

$$\begin{aligned} A_r &= 2\pi \int_{-r}^r r \sqrt{1 - (x/r)^2} \frac{1}{\sqrt{1 - (x/r)^2}} dt \\ &= 2\pi r \int_{-r}^r dt = 4\pi r^2 \end{aligned}$$

$$\begin{aligned} V_r &= \pi \int_{-r}^r (r^2 - x^2) dx \\ &= \pi \left[ r^2 x - \frac{1}{3} x^3 \right]_{-r}^r = \frac{4}{3} \pi r^3. \end{aligned}$$

Similarly to the circle, the ball is also the object which has the smallest surface area among all with a given volume. That is the reason why soap bubbles almost always assume this shape.

**6.2.22. Integral criterion for series.** Using the improper integral, we can also decide the question of convergence for a class of infinite series:

**Theorem.** Let  $\sum_{n=1}^{\infty} f(n)$  be a series such that the function  $f : \mathbb{R} \rightarrow \mathbb{R}$  is positive and nonincreasing on the interval  $(1, \infty)$ . Then this series converges if and only if the integral

$$\int_1^{\infty} f(x) dx.$$

converges.

□

**PROOF.** If the integral is interpreted as the area of a region under the curve, the criterion is clear.

Indeed, notice that the given series diverges or converges if and only if the same is true for the same series without the first summand. Moreover, by the monotonicity of  $f(x)$ , there are the following estimates

$$s'_k = \sum_{n=2}^k f(n) \leq \int_1^k f(x) dx \leq \sum_{n=1}^{\infty} f(n) = s_k,$$

because  $s'_k$  is the lower sum of the Riemann integral while  $s_k$  is the upper sum. Thus, the integral converges if and only if the series does, as expected. □

### 3. Sequences, series and limit processes

While building a menagerie of functions, we encountered power series, which extend the collection of all polynomials in a natural way, see 5.4.3. We obtain a class of analytic functions in this way. But we have yet to prove that power series are continuous functions. We show below that not only

i.e. in particular

$$\int_1^{+\infty} \frac{\operatorname{arctg} x}{x\sqrt{x}} dx \in \mathbb{R}.$$

□

The formula (1) can be also used in a case when the function  $f$  is unbounded or the interval  $(a, b)$  is unbounded. We speak of the so called improper integrals. For the improper integrals, the limits on the right hand side may be improper and may not exist at all. If one of the limits doesn't exist or we receive an expression  $\infty - \infty$ , it means that the integral doesn't exist ( $\infty - \infty$  doesn't have a character of an indefinite expression in this case). We say the integral oscillates. In every other case, we have the result (recall that  $\infty + \infty = +\infty$ ,  $-\infty - \infty = -\infty$ ,  $\pm\infty + a = \pm\infty$  for  $a \in \mathbb{R}$ ).

**6.B.40.** Determine

- (a)  $\int_1^{\infty} \sin x dx$ ;
- (b)  $\int_1^{\infty} \frac{dx}{x^4+x^2}$ ;
- (c)  $\int_0^4 \frac{dx}{\sqrt{x}}$ ;
- (d)  $\int_{-1}^1 \frac{dx}{x^2}$ .

**Solution.** Case (a). We can immediately determine

$$\int_1^{\infty} \sin x dx = [-\cos x]_1^{\infty} = \lim_{x \rightarrow \infty} (-\cos x) + \cos 1.$$

Because the limit on the right hand side doesn't exist, the integral oscillates.

Cases (b), (c). Analogously, we can easily compute

$$\begin{aligned} \int_1^{\infty} \frac{dx}{x^4+x^2} &= \int_1^{\infty} \frac{dx}{x^2(x^2+1)} = \int_1^{\infty} \frac{1}{x^2} - \frac{1}{1+x^2} dx = \\ &[-\frac{1}{x} - \operatorname{arctg} x]_1^{\infty} = \lim_{x \rightarrow \infty} (-\frac{1}{x} - \operatorname{arctg} x) + \frac{1}{1} + \operatorname{arctg} 1 = \\ &0 - \frac{\pi}{2} + 1 + \frac{\pi}{4} = 1 - \frac{\pi}{4} \end{aligned}$$

and even more easily

$$\int_0^4 \frac{dx}{\sqrt{x}} = [2\sqrt{x}]_0^4 = 4 - 0 = 4,$$

where the primitive function is continuous from the right side at the origin (thus the limit equals the value of the function).

Case (d). If we'd mindlessly compute

$$\int_{-1}^1 \frac{dx}{x^2} = [-\frac{1}{x}]_{-1}^1 = -1 - 1 = -2,$$

we'd receive an obviously wrong result (a negative value while integrating a positive function). The reason why the Newton-Leibniz formula cannot be applied in this way is the

are they continuous but it is possible to differentiate and integrate a power series term by term.

Moreover, functions often depend on further parameters which are dummy when differentiating or integrating, but we need to understand how the result behaves with respect to these parameters. For instance, what about the differentiability of the Gamma function introduced above? Or, when computing volume or area depending on a free parameter, how to minimize it?

Finally, in the end of this chapter we briefly introduce some more advanced concepts of integration.

**6.3.1. How well behaved is a sequence of functions?** We

return to the discussion of the limits of sequences of functions and the sum of series of functions in view of the methods of differential and integral calculus. Consider a convergent series of functions

$$S(x) = \sum_{n=1}^{\infty} f_n(x)$$

on an interval  $[a, b]$ . Natural questions include:

- If all functions  $f_n(x)$  are continuous at some point  $x_0 \in [a, b]$ , is the function  $S(x)$  also continuous at the point  $x_0$ ?
- If all functions  $f_n(x)$  are differentiable at some point  $a \in [a, b]$ , is the function  $S(x)$  also differentiable there and does the equality  $S'(x) = \sum_{n=1}^{\infty} f'_n(x)$  hold?
- If all functions  $f_n(x)$  are Riemann integrable on an interval  $[a, b]$ , is the function  $S(x)$  also integrable there and does the equality  $\int_a^b S(x)dx = \sum_{n=1}^{\infty} \int_a^b f_n(x)dx$  hold?

Notice, it does not matter whether we discuss series or sequences, since the former ones are just limits of the sequences of the partial sums. First, we demonstrate by examples that the answers to all three questions above are "NO!". Then we find additional conditions on the convergence of the series (or sequences) which guarantees the validity of all three statements. Later we shall mention alternative concepts of integration which are more satisfactory than the Riemann integral for an even wider classes of functions.

**6.3.2. Examples of nasty sequences.** (1) Consider the functions

$$f_n(x) = (\sin x)^n$$

on the interval  $[0, \pi]$ . The values of these functions are non-negative and smaller than one at all points  $0 \leq x \leq \pi$ , except for  $x = \frac{\pi}{2}$ , where the value is 1. Hence on the whole interval  $[0, \pi]$ , these functions converge to the function

$$f(x) = \lim_{n \rightarrow \infty} f_n(x) = \begin{cases} 0 & \text{for all } x \neq \frac{\pi}{2} \\ 1 & \text{for } x = \frac{\pi}{2}. \end{cases}$$

point by point. The limit of the sequence of functions  $f_n$  is a discontinuous function, even though all functions  $f_n(x)$  are continuous. The problematic point is an inner point of the interval.

discontinuity of the given function at the origin. But if we use the additivity rule

$$\int_a^b f(x) dx = \int_a^c f(x) dx + \int_c^b f(x) dx,$$

which always holds, if the integrals on the right hand side are sensible, we'll find the correct result

$$\int_{-1}^1 \frac{dx}{x^2} = \int_{-1}^0 \frac{dx}{x^2} + \int_0^1 \frac{dx}{x^2} = \left[-\frac{1}{x}\right]_{-1}^0 + \left[-\frac{1}{x}\right]_0^1 = \lim_{x \rightarrow 0^-} \left(-\frac{1}{x}\right) - 1 - 1 - \lim_{x \rightarrow 0^+} \left(-\frac{1}{x}\right) = \infty - 2 + \infty = +\infty.$$

Note that the even character of function  $y = x^{-2}$  also implies

$$\int_{-1}^1 \frac{dx}{x^2} = 2 \int_0^1 \frac{dx}{x^2} = 2 \cdot \infty = +\infty.$$

### 6.B.41. Compute the definite integrals

- $\int_0^\infty \frac{1}{(x+2)^5} dx;$
- $\int_{-2}^2 \ln|x| dx;$
- $\int_1^\infty \frac{e^{-\sqrt{x}}}{\sqrt{x}} dx;$
- $\int_{-1}^0 \frac{e^{1/x}}{x^3} dx;$
- $\int_1^2 \frac{1}{x \ln x} dx.$

**Solution.** We have

$$(a) \int_0^\infty \frac{dx}{(x+2)^5} = -\frac{1}{4} [(x+2)^{-4}]_0^\infty = -\frac{1}{4} \left( \lim_{x \rightarrow \infty} (x+2)^{-4} - 2^{-4} \right) = -\frac{1}{4} \left( 0 - \frac{1}{16} \right) = \frac{1}{64};$$

$$(b) \int_{-2}^2 \ln|x| dx = \int_{-2}^0 \ln|x| dx + \int_0^2 \ln|x| dx = 2 \int_0^2 \ln x dx = \left| \begin{array}{l} F(x) = \ln x \\ G'(x) = 1 \end{array} \right| \left| \begin{array}{l} F'(x) = \frac{1}{x} \\ G(x) = x \end{array} \right| = 2 \left( [x \ln x]_0^2 - \int_0^2 1 dx \right) = 2 \left( [x \ln x]_0^2 - [x]_0^2 \right) = 2 \left( 2 \ln 2 - \lim_{x \rightarrow 0^+} (x \ln x) - 2 + 0 \right) = 4 \ln 2 - 4;$$

$$(c) \int_1^\infty \frac{e^{-\sqrt{x}}}{\sqrt{x}} dx = \left| \begin{array}{l} t = \sqrt{x} \\ dt = \frac{1}{2\sqrt{x}} dx \end{array} \right| = 2 \int_1^\infty e^{-t} dt = 2 [-e^{-t}]_1^\infty = -2 \left( \lim_{t \rightarrow \infty} e^{-t} - e^{-1} \right) = \frac{2}{e};$$

$$(d) \int_{-1}^0 \frac{e^{1/x}}{x^3} dx = \left| \begin{array}{l} u = 1/x \\ du = -\frac{1}{x^2} dx \end{array} \right| = - \int_{-1}^{-\infty} u e^u du = \int_{-\infty}^{-1} u e^u du = \left| \begin{array}{l} F(u) = u \\ G'(u) = e^u \end{array} \right| \left| \begin{array}{l} F'(u) = 1 \\ G(u) = e^u \end{array} \right| =$$

The same phenomenon occurs for a series of functions, because the sum is the limit of partial sums. Hence in the previous example, it suffices to express  $f_n$  as the  $n$ -th partial sum. For example,  $f_1(x) = \sin x$ ,  $f_2(x) = (\sin x)^2 - \sin x$ , etc. The figure plots the functions  $f_m(x)$  for  $m = n^3$ ,  $n = 1, \dots, 10$ .

- (2) We look at the second question, i.e. badly behaving derivatives. A natural idea on the same principle as above is to construct a sequence of functions which has the same nonzero derivative at one point, but becomes smaller and smaller. So they converge pointwise to the identically zero function.

The next figure plots the functions

$$f_n(x) = x(1-x^2)^n$$

on the interval  $[-1, 1]$  for values  $n = m^2$ ,  $m = 1, \dots, 10$ .

It is immediate that  $\lim_{n \rightarrow \infty} f_n(x) = 0$  and that all functions  $f_n(x)$  are smooth. Their derivative at  $x = 0$  is

$$f'_n(0) = ((1-x^2)^n - 2nx^2(1-x^2)^{n-1})|_{x=0} = 1$$

for all  $n$ . But the limit function for the sequence  $f_n$  has a zero derivative at every point.

(3) The counterexample to the third statement is in 6.2.18 already. The characteristic function  $\chi_{\mathbb{Q}}$  of rational numbers can be expressed as a sum of countably many functions, which are numbered exactly by rational numbers. They are zero everywhere except for the single point after which they are named for, where the value is 1. Riemann integrals of all such functions are zero, but the sum is not a Riemann integrable function.

This example illustrates the fundamental flaw of the Riemann integral, to which we return later.

We present an example where the limit function  $f$  is integrable, all functions  $f_n$  are continuous, but the value of the integral is not the limit of the integrals of  $f_n$ . We modify the

$$[u e^u]_{-\infty}^{-1} - \int_{-\infty}^{-1} e^u du = [u e^u]_{-\infty}^{-1} - [e^u]_{-\infty}^{-1} = -\frac{1}{e} - \lim_{u \rightarrow -\infty} u e^u - \frac{1}{e} + \lim_{u \rightarrow -\infty} e^u = -\frac{2}{e};$$

(e)

$$\int_1^2 \frac{dx}{x \ln x} = \left| \begin{array}{l} r = \ln x \\ dr = \frac{1}{x} dx \end{array} \right| = \int_0^{\ln 2} \frac{dr}{r} = [\ln r]_0^{\ln 2} = \ln(\ln 2) - \lim_{r \rightarrow 0^+} \ln r = \ln(\ln 2) + \infty = +\infty.$$

□

**6.B.42.** Compute the improper integrals

$$\int_0^{\infty} x^2 e^{-x} dx; \quad \int_{-\infty}^{\infty} \frac{dx}{e^x + e^{-x}}.$$

**Solution.** Because the improper integral is a special case of a definite integral, we have at our disposal the basic methods to compute them. By integration by parts, we obtain

$$\begin{aligned} \int_0^{\infty} x^2 e^{-x} dx &= \left| \begin{array}{l} F(x) = x^2 \\ G'(x) = e^{-x} \end{array} \right| \begin{array}{l} F'(x) = 2x \\ G(x) = -e^{-x} \end{array} \Big| = \\ &[-x^2 e^{-x}]_0^{\infty} + 2 \int_0^{\infty} x e^{-x} dx = \\ &\left| \begin{array}{l} F(x) = x \\ G'(x) = e^{-x} \end{array} \right| \begin{array}{l} F'(x) = 1 \\ G(x) = -e^{-x} \end{array} \Big| = \\ &-\lim_{x \rightarrow \infty} \frac{x^2}{e^x} + 2[-x e^{-x}]_0^{\infty} + 2 \int_0^{\infty} e^{-x} dx = \end{aligned}$$

$$0 - 2 \lim_{x \rightarrow \infty} \frac{x}{e^x} + 2[-e^{-x}]_0^{\infty} = 0 + 2 \left( \lim_{x \rightarrow \infty} -e^{-x} + 1 \right) = 2.$$

The substitution method then yields

$$\int_{-\infty}^{\infty} \frac{dx}{e^x + e^{-x}} = \int_{-\infty}^{\infty} \frac{e^x}{e^{2x} + 1} dx = \left| \begin{array}{l} y = e^x \\ dy = e^x dx \end{array} \right| = \int_0^{\infty} \frac{dy}{y^2 + 1} = [\arctg y]_0^{\infty} = \lim_{y \rightarrow \infty} \arctg y = \frac{\pi}{2},$$

when the new limits of the integral are derived from the limits

$$\lim_{x \rightarrow -\infty} e^x = 0, \quad \lim_{x \rightarrow \infty} e^x = +\infty.$$

□

**6.B.43.** Compute

$$\int_0^{\infty} x^{2n+1} e^{-x^2} dx, \quad n \in \mathbb{N}.$$

**Solution.** We'll first solve this problem by the substitution method and then repeatedly apply integration by parts, yielding

$$\begin{aligned} \int_0^{\infty} x^{2n+1} e^{-x^2} dx &= \left| \begin{array}{l} y = x^2 \\ dy = 2x dx \end{array} \right| = \frac{1}{2} \int_0^{\infty} y^n e^{-y} dy = \\ &\left| \begin{array}{l} F(y) = y^n \\ G'(y) = e^{-y} \end{array} \right| \begin{array}{l} F'(y) = ny^{n-1} \\ G(y) = -e^{-y} \end{array} \Big| = \\ &\frac{1}{2} \left( [-y^n e^{-y}]_0^{\infty} + n \int_0^{\infty} y^{n-1} e^{-y} dy \right) = \\ &\frac{n}{2} \int_0^{\infty} y^{n-1} e^{-y} dy = \end{aligned}$$

sequence of the functions  $x(1-x^2)^n$  used above. They integrate to  $\int_0^1 x(1-x^2)^n dx = \frac{1}{2(n+1)}$ . Thus, we consider the functions

$$f_n(x) = 2(n+1)x(1-x^2)^n.$$

These functions with  $n = m^2, m = 1, \dots, 10$  are on the next diagram.

We verify that the values of these functions converge to zero for every  $x \in [0, 1]$  (for example  $\ln(f_n(x)) \rightarrow -\infty$ ). But for all  $n$

$$\int_0^1 f_n(x) dx = 1 \neq 0.$$

**6.3.3. Uniform convergence.** A reason of failure in all three previous examples is the fact that the speed of pointwise convergence of values  $f_n(x) \rightarrow f(x)$  varies dramatically point from point. Hence a natural idea is to confine the problem to cases where the convergence will have roughly the same speed over all the interval:

#### UNIFORM CONVERGENCE

**Definition.** We say that the sequence of functions  $f_n(x)$  converges uniformly on interval  $[a, b]$  to the limit  $f(x)$ , if for every positive number  $\varepsilon$ , there exists a natural number  $N \in \mathbb{N}$  such that for all  $n \geq N$  and all  $x \in [a, b]$  the inequality

$$|f_n(x) - f(x)| < \varepsilon$$

holds.

A series of functions converges uniformly on an interval, if the sequence of its partial sums converges uniformly.

Albeit the choice of the number  $N$  depends on the chosen  $\varepsilon$ , it is independent on the point  $x \in [a, b]$ . This is the difference from pointwise convergence, where  $N$  depends on both  $\varepsilon$  and  $x$ . We visualise the definition graphically in this way: if we consider a zone created by a translation of the limit function  $f(x)$  to  $f(x) \pm \varepsilon$  for arbitrarily small, but fixed positive  $\varepsilon$ , all of the functions  $f_n(x)$  will fall into this zone, except for finitely many of them. The first and the last of the nasty examples above do not have this property; In the second example, the sequence of derivatives  $f'_n$  lacked it.

provide a picture here!!!

**6.3.4.** The three claims in the following theorem say that all three generally false properties discussed in 6.3.1 are true for uniform convergence (but beware the subtleties when differentiating).

$$\begin{aligned} & \left| \begin{array}{l} F(y) = y^{n-1} \\ G'(y) = e^{-y} \end{array} \right| \left| \begin{array}{l} F'(y) = (n-1)y^{n-2} \\ G(y) = -e^{-y} \end{array} \right| = \\ & \frac{n}{2} \left( [-y^{n-1} e^{-y}]_0^\infty + (n-1) \int_0^\infty y^{n-2} e^{-y} dy \right) = \\ & \frac{n(n-1)}{2} \int_0^\infty y^{n-2} e^{-y} dy = \dots = \frac{n(n-1)\dots 2}{2} \int_0^\infty y e^{-y} dy = \\ & \left| \begin{array}{l} F(y) = y \\ G'(y) = e^{-y} \end{array} \right| \left| \begin{array}{l} F'(y) = 1 \\ G(y) = -e^{-y} \end{array} \right| = \\ & \frac{n!}{2} \left( [-y e^{-y}]_0^\infty + \int_0^\infty e^{-y} dy \right) = \frac{n!}{2} [-e^{-y}]_0^\infty = \frac{n!}{2}. \end{aligned}$$

□

**6.B.44.** In dependency on  $a \in \mathbb{R}^+$  determine the integral  $\int_0^1 \frac{1}{x^a} dx$ . ○

**Lengths, areas, surfaces, volumes.**

**6.B.45.** Determine the length of the curve given parametrically:

$$x = \sin^2 t, \quad y = \cos^2 t,$$

$$\text{for } t \in [0, \frac{\pi}{2}].$$

**Solution.** According to ??, the length of a curve is given by the integral

$$\begin{aligned} & \int_0^{\frac{\pi}{2}} \sqrt{(x'(t))^2 + (y'(t))^2} dt \\ & = \int_0^{\frac{\pi}{2}} \sqrt{(\sin 2t)^2 + (-\sin 2t)^2} dt \\ & = \int_0^{\frac{\pi}{2}} \sqrt{2} \sin 2t dt = \sqrt{2}. \end{aligned}$$

If we realize that the given curve is a part of the line  $y = 1 - x$  (since  $\sin^2 t + \cos^2 t = 1$ ) and moreover the segment with boundary points  $[0, 1]$  (for  $t = 0$ ) and  $[1, 0]$  (for  $t = \frac{\pi}{2}$ ), we can immediately write its length  $\sqrt{2}$ . □

**6.B.46.** Determine the length of a curve given parametrically:

$$x = t^2, \quad y = t^3$$

$$\text{for } t \in [0, \sqrt{5}].$$

**Solution.** We'll again determine the length  $l$  by using the formula ??:

$$\begin{aligned} l & = \int_0^{\sqrt{5}} \sqrt{4t^2 + 9t^4} dt = \int_0^{\sqrt{5}} t \sqrt{9t^2 + 4} dt \\ & = \frac{1}{2} \int_0^5 \sqrt{9u + 4} du = \frac{2}{27} [(9u + 4)^{\frac{3}{2}}]_0^5 = \frac{335}{27} \end{aligned}$$

□

CONSEQUENCES OF UNIFORM CONVERGENCE

**Theorem.** (1) Let  $f_n(x)$  be a sequence of functions continuous on a closed interval  $[a, b]$  and converging uniformly to the function  $f(x)$  on this interval. Then  $f(x)$  is also continuous on the interval  $[a, b]$ .

(2) Let  $f_n(x)$  be a sequence of Riemann integrable functions on a finite closed interval  $[a, b]$  which converge uniformly to the function  $f(x)$  on this interval. Then  $f(x)$  is Riemann integrable, and

$$\int_a^b f(x) dx = \int_a^b \left( \lim_{n \rightarrow \infty} f_n(x) \right) dx = \lim_{n \rightarrow \infty} \int_a^b f_n(x) dx.$$

**6.B.47.** Determine the area to the right of the line  $x = 3$  and bounded by the graph of a function  $y = \frac{1}{x^3-1}$  and the  $x$  axis.

**Solution.** The area is given by the improper integral  $\int_3^\infty \frac{1}{x^3-1} dx$ . We'll compute it using decomposition into partial fractions:

$$\frac{1}{x^3-1} = \frac{Ax+B}{x^2+x+1} + \frac{C}{x-1},$$

$$1 = (Ax+B)(x-1) + C(x^2+x+1),$$

$$x = 1 \implies C = \frac{1}{3},$$

$$x^0 : 1 = C - B \implies B = -\frac{2}{3},$$

$$x^2 : 0 = A + C \implies A = -\frac{1}{3}$$

and we can write

$$\int_3^\infty \frac{1}{x^3-1} dx = \frac{1}{3} \int_3^\infty \left( \frac{1}{x-1} - \frac{x+2}{x^2+x+1} \right) dx.$$

Now we'll separately determine the indefinite integral  $\int \frac{x+2}{x^2+x+1} dx$ :

$$\int \frac{x+2}{x^2+x+1} dx$$

$$= \int \frac{x + \frac{1}{2}}{(x + \frac{1}{2})^2 + \frac{3}{4}} dx + \frac{3}{2} \int \frac{1}{(x + \frac{1}{2})^2 + \frac{3}{4}} dx$$

$$\left| \begin{array}{l} \text{substitution at the first integral} \\ t = x^2 + x + 1 \\ dt = 2(x + \frac{1}{2}) dx \end{array} \right|$$

$$= \frac{1}{2} \int \frac{1}{t} dt + \frac{3}{2} \int \frac{1}{(x + \frac{1}{2})^2 + \frac{3}{4}}$$

$$= \left| \begin{array}{l} \text{substitution at the first integral} \\ s = x + \frac{1}{2} \\ ds = dx \end{array} \right|$$

$$= \frac{1}{2} \ln(x^2 + x + 1) + \frac{3}{2} \int \frac{1}{s^2 + \frac{3}{4}} ds$$

$$= \frac{1}{2} \ln((x^2 + x + 1) + \frac{3\sqrt{3}}{2} \int \frac{1}{(\frac{2}{\sqrt{3}}s)^2 + 1} ds$$

$$\left| \begin{array}{l} \text{substitution at the second integral} \\ u = \frac{2}{\sqrt{3}}s \\ du = \frac{2}{\sqrt{3}}s ds \end{array} \right|$$

$$= \frac{1}{2} \ln(x^2 + x + 1) + 2 \frac{\sqrt{3}}{2} \int \frac{1}{u^2 + 1} du$$

$$= \frac{1}{2} \ln(x^2 + x + 1) + \sqrt{3} \arctan(u)$$

$$= \frac{1}{2} \ln(x^2 + x + 1) + \sqrt{3} \arctan\left(\frac{2x+1}{\sqrt{3}}\right).$$

(3) Let  $f_n(x)$  be a sequence of functions differentiable on a closed interval  $[a, b]$  and assume  $f_n(x_0) \rightarrow f(x_0)$  at some point  $x_0 \in [a, b]$ . Moreover, assume all derivatives  $g_n(x) = f'_n(x)$  are continuous and converge uniformly to the function  $g(x)$  on the same interval. Then the function  $f(x) = \int_{x_0}^x g(t) dt$  is differentiable on the interval  $[a, b]$ , the functions  $f_n(x)$  converge to  $f(x)$  and  $f'(x) = g(x)$ . In other words,

$$\frac{d}{dx} f(x) = \frac{d}{dx} \left( \lim_{n \rightarrow \infty} f_n(x) \right) = \lim_{n \rightarrow \infty} \left( \frac{d}{dx} f_n(x) \right)$$

**PROOF OF THE FIRST CLAIM.** Fix an arbitrary fixed point  $x_0 \in [a, b]$  and let  $\varepsilon > 0$  be given. It is required to show that

$$|f(x) - f(x_0)| < \varepsilon$$

for all  $x$  close enough to  $x_0$ . From the definition of uniform convergence,

$$|f_n(x) - f(x)| < \varepsilon$$

for all  $x \in [a, b]$  and all sufficiently large  $n$ . Choose some  $n$  with this property and consider  $\delta > 0$  such that

$$|f_n(x) - f_n(x_0)| < \varepsilon$$

for all  $x$  in  $\delta$ -neighbourhood of  $x_0$ . That is possible because  $f_n(x)$  are continuous for all  $n$ . Then

$$|f(x) - f(x_0)| \leq |f(x) - f_n(x)| + |f_n(x) - f_n(x_0)| + |f_n(x_0) - f(x_0)| < 3\varepsilon$$

for all  $x$  in the  $\delta$ -neighbourhood of  $x_0$ . This is the desired inequality with the bound  $3\varepsilon$ .  $\square$

**Remark.** In fact, the arguments in the proof show a more general claim. Indeed, if the functions  $f_n(x)$  converge uniformly to  $f(x)$  on  $[a, b]$ , and the individual functions  $f_n(x)$  have the limits (or one-sided limits)  $\lim_{x \rightarrow x_0} f_n(x) = a_n$ , then the limit  $\lim_{x \rightarrow x_0} f(x)$  exists if and only if the limit  $\lim_{n \rightarrow \infty} a_n = a$  exists. Then they are equal, that is,

$$a = \lim_{n \rightarrow \infty} \left( \lim_{x \rightarrow x_0} f_n(x) \right) = \lim_{x \rightarrow x_0} \left( \lim_{n \rightarrow \infty} f_n(x) \right).$$

The reader should be able to modify the above proof for this situation.

**6.3.5. Proof of the second claim.** The proof of this part of the theorem is based upon a generalization of the properties of Cauchy sequences of numbers to uniform convergence of functions. In this way we can work with the existence of the limit of a sequence of integrals without needing to know the limit.

In total, for the improper integral we can write:

$$\begin{aligned} & \int_3^\infty \frac{1}{x^3-1} dx \\ &= \frac{1}{3} \lim_{\delta \rightarrow \infty} \left[ \ln|x-1| \right. \\ & \quad \left. - \frac{1}{2} \ln(x^2+x+1) - \sqrt{3} \arctan\left(\frac{2x+1}{\sqrt{3}}\right) \right]_3^\delta \\ &= \frac{1}{3} \lim_{\delta \rightarrow \infty} \left( \frac{1}{3} \ln|\delta-1| \right. \\ & \quad \left. - \frac{1}{2} \ln(\delta^2+\delta+1) - \sqrt{3} \arctan\left(\frac{2\delta+1}{\sqrt{3}}\right) \right) \\ & \quad - \frac{1}{3} \ln 2 + \frac{1}{6} \ln 13 + \frac{\sqrt{3}}{3} \arctan \frac{7}{\sqrt{3}} \\ &= \frac{1}{6} \ln 13 + \frac{1}{\sqrt{3}} \arctan \frac{7}{\sqrt{3}} - \frac{1}{3} \ln 2 - \frac{\sqrt{3}}{6} \pi. \end{aligned}$$

**6.B.48.** Determine the surface and volume of a circular paraboloid created by rotating a part of the parabola  $y = 2x^2$  for  $x \in [0, 1]$  around the  $y$  axis.

**Solution.** The formulas stated in the texts are true for rotating the curves around the  $x$  axis! Hence it's necessary either to integrate the given curve with respect to variable  $y$ , or to transform.

$$\begin{aligned} V &= \int_0^2 \frac{x}{2} dx = \pi \\ S &= 2\pi \int_0^2 \sqrt{\frac{x}{2}} \sqrt{1 + \frac{1}{8x}} dx = 2\pi \int_0^2 \sqrt{\frac{x}{2} + \frac{1}{16}} dx \\ &= \pi \frac{17\sqrt{17}-1}{24}. \end{aligned}$$

**6.B.49.** Compute the area  $S$  of a figure composed of two parts of plane bounded by lines  $x = 0$ ,  $x = 1$ ,  $x = 4$ , the  $x$  axis and the graph of a function

$$y = \frac{1}{\sqrt[3]{x-1}}.$$

**Solution.** First realize that

$$\frac{1}{\sqrt[3]{x-1}} < 0, \quad x \in [0, 1), \quad \frac{1}{\sqrt[3]{x-1}} > 0, \quad x \in (1, 4]$$

and

$$\lim_{x \rightarrow 1^-} \frac{1}{\sqrt[3]{x-1}} = -\infty, \quad \lim_{x \rightarrow 1^+} \frac{1}{\sqrt[3]{x-1}} = +\infty.$$

The first part of the figure (below the  $x$  axis) is thus bounded by the curves

$$y = 0, \quad x = 0, \quad x = 1, \quad y = \frac{1}{\sqrt[3]{x-1}}$$

with an area given by the improper integral

UNIFORMLY CAUCHY SEQUENCES

**Definition.** The sequence of functions  $f_n(x)$  on interval  $[a, b]$  is *uniformly Cauchy*, if for every (small) positive number  $\varepsilon$ , there exists a large natural number  $N$  such that for all  $x \in [a, b]$  and all  $n \geq N$ ,

$$|f_n(x) - f_m(x)| < \varepsilon.$$

Every uniformly convergent sequence of function on interval  $[a, b]$  is also uniformly Cauchy on the same interval. To see this, it suffices to notice the usual bound

$$|f_n(x) - f_m(x)| \leq |f_n(x) - f(x)| + |f(x) - f_m(x)|$$

based on the triangle inequality.

Before coming to the proof 6.3.4(2), we mention the following:

**Proposition.** Every uniformly Cauchy sequence of functions  $f_n(x)$  on the interval  $[a, b]$  uniformly converges to some function  $f$  on this interval.

**PROOF.** Of course, the condition for a sequence of functions to be uniform Cauchy implies that also for all  $x \in [a, b]$ , the sequence of values  $f_n(x)$  is a Cauchy sequence of real (or complex) numbers. Hence the sequence of functions  $f_n(x)$  converges pointwise to some function  $f(x)$ .

Choose  $N$  large enough so that

$$|f_n(x) - f_m(x)| < \varepsilon$$

for some small positive  $\varepsilon$  chosen beforehand and all  $n \geq N$ ,  $x \in [a, b]$ . Now choose one such  $n$  and fix it, then

$$|f_n(x) - f(x)| = \lim_{m \rightarrow \infty} |f_n(x) - f_m(x)| \leq \varepsilon$$

for all  $x \in [a, b]$ . Hence the sequence  $f_n(x)$  converges to its limit uniformly.  $\square$

**PROOF OF THE SECOND CLAIM IN 6.3.4.** Recall that every uniformly convergent sequence of functions is also uniformly Cauchy and that the Riemann sums of all single terms  $f_n(x)$  of the sequence converge to  $\int_a^b f_n(x) dx$  independently of the choice of the partition and the representatives. Hence, if

$$|f_n(x) - f_m(x)| < \varepsilon$$

for all  $x \in [a, b]$ , then also

$$\left| \int_a^b f_n(x) dx - \int_a^b f_m(x) dx \right| \leq \varepsilon|b-a|.$$

Therefore the sequence of numbers  $\int_a^b f_n(x) dx$  is Cauchy, and hence convergent.

The Riemann sums of the limit function  $f(x)$  can be made arbitrarily close to those of  $f_n(x)$  for large  $n$ , by the same argument as above. So  $f(x)$  is integrable. Moreover,

$$\left| \int_a^b f_n(x) dx - \int_a^b f(x) dx \right| \leq \varepsilon|b-a|,$$

so the limit value is as expected.  $\square$

$$S_1 = -\int_0^1 \frac{1}{\sqrt[3]{x-1}} dx;$$

while the second part (above the  $x$  axis), which is bounded by the curves

$$y = 0, \quad x = 1, \quad x = 4, \quad y = \frac{1}{\sqrt[3]{x-1}},$$

has an area of

$$S_2 = \int_1^4 \frac{1}{\sqrt[3]{x-1}} dx.$$

Since

$$\int \frac{1}{\sqrt[3]{x-1}} dx = \frac{3}{2} \sqrt[3]{(x-1)^2} + C,$$

the sum  $S_1 + S_2$  can be gotten as

$$S = -\lim_{x \rightarrow 1^-} \left( \frac{3}{2} \sqrt[3]{(x-1)^2} - \frac{3}{2} \right) + \lim_{x \rightarrow 1^+} \left( \frac{3}{2} \sqrt[3]{9} - \frac{3}{2} \sqrt[3]{(x-1)^2} \right) = \frac{3}{2} (1 + \sqrt[3]{9}).$$

We have shown among other things, that the given figure has a finite area, even though it's unbounded (both from the top and the bottom). (If we approach  $x = 1$  from the right, eventually from the left, its altitude grows beyond measure.) Recall here the indefinite expression of type  $0 \cdot \infty$ . Namely, the figure is bounded if we limit ourselves to  $x \in [0, 1 - \delta] \cup [1 + \delta, 4]$  for an arbitrarily small  $\delta > 0$ .  $\square$

**6.B.50.** Determine the average velocity  $v_p$  of a solid in the time interval  $[1, 2]$ , if its velocity is

$$v(t) = \frac{t}{\sqrt{1+t^2}}, \quad t \in [1, 2].$$

Omit the units.

**Solution.** To solve the problem, it suffices to realize that the sought average velocity is the mean value of function  $v$  on interval  $[1, 2]$ . Hence

$$v_p = \frac{1}{2-1} \int_1^2 \frac{t}{\sqrt{1+t^2}} dt = \int_2^5 \frac{1}{\sqrt{x}} dx = \sqrt{5} - \sqrt{2},$$

with  $1 + t^2 = x$ ,  $t dt = dx/2$ .  $\square$

**6.B.51.** Compute the length  $s$  of a part of the curve called tractrix given by the parametric description

$$f(t) = r \cos t + r \ln \left( \operatorname{tg} \frac{t}{2} \right), \quad g(t) = r \sin t, \quad t \in [\pi/2, a],$$

where  $r > 0$ ,  $a \in (\pi/2, \pi)$ .

**Solution.** Since

$$f'(t) = -r \sin t + \frac{r}{2 \operatorname{tg} \frac{t}{2} \cdot \cos^2 \frac{t}{2}} = -r \sin t + \frac{r}{\sin t} = \frac{r \cos^2 t}{\sin t},$$

$$g'(t) = r \cos t \text{ on interval } [\pi/2, a],$$

for the length  $s$  we get

**6.3.6. Proof of the third claim.** For the corresponding result about derivatives, extra care is needed regarding the assumptions: If the functions  $\tilde{f}_n(x) = f_n(x) - f_n(x_0)$  are considered instead of  $f_n(x)$ , the derivatives do not change. Hence without loss of generality it can be assumed that all functions satisfy  $f_n(x_0) = 0$ .

Then one of the assumptions of the theorem is satisfied automatically. For all  $x \in [a, b]$ , we can write

$$f_n(x) = \int_{x_0}^x g_n(t) dt.$$

Because the functions  $g_n$  converge uniformly to  $g$  on all of  $[a, b]$ , the functions  $f_n(x)$  converge to

$$f(x) = \int_{x_0}^x g(t) dt.$$

$g$  is a uniform limit of continuous functions, thus  $g$  is again continuous. By 6.2.8, for the relations between the Riemann integral and the primitive function, the proof is finished.

**6.3.7. Uniform convergence of series.** For infinite series, the corresponding results follow as a corollary in this way:

CONSEQUENCES FOR UNIFORM CONVERGENCE OF SERIES

**Theorem.** Consider a sequence of functions  $f_n(x)$  on interval  $[a, b]$ .

(1) If all the functions  $f_n(x)$  are continuous on  $[a, b]$  and the series

$$S(x) = \sum_{n=1}^{\infty} f_n(x)$$

converges uniformly to the function  $S(x)$ , then  $S(x)$  is continuous on  $[a, b]$ .

(2) If all the functions  $f_n(x)$  are Riemann integrable on  $[a, b]$  and the series

$$S(x) = \sum_{n=1}^{\infty} f_n(x)$$

uniformly converges to  $S(x)$  on  $[a, b]$ , then  $S(x)$  is integrable on  $[a, b]$  and

$$\int_a^b \left( \sum_{n=1}^{\infty} f_n(x) \right) dx = \sum_{n=1}^{\infty} \int_a^b f_n(x) dx.$$

(3) If all the functions  $f_n(x)$  are continuously differentiable on the interval  $[a, b]$ , if the series  $S(x) = \sum_{n=1}^{\infty} f_n(x)$  converges for some  $x_0 \in [a, b]$ , and if the series  $T(x) = \sum_{n=1}^{\infty} f'_n(x)$  converges uniformly on  $[a, b]$ , then the series  $S(x)$  converges.  $S(x)$  is continuously differentiable on  $[a, b]$  and  $S'(x) = T(x)$ . That is:

$$\frac{d}{dx} \left( \sum_{n=1}^{\infty} f_n(x) \right) = \sum_{n=1}^{\infty} \frac{d}{dx} f_n(x).$$

$$s = \int_{\pi/2}^a \sqrt{\frac{r^2 \cos^4 t}{\sin^2 t} + r^2 \cos^2 t} dt = \int_{\pi/2}^a \sqrt{\frac{r^2 \cos^2 t}{\sin^2 t}} dt = -r \int_{\pi/2}^a \frac{\cos t}{\sin t} dt = -r [\ln(\sin t)]_{\pi/2}^a = -r \ln(\sin a).$$

□

**6.B.52.** Compute the volume of a solid created by rotation of a bounded surface, whose boundary is the curve  $x^4 - 9x^2 + y^4 = 0$ , around the  $x$  axis.

**Solution.** If  $[x, y]$  is a point on the  $x^4 - 9x^2 + y^4 = 0$ , clearly this curve also intersects points  $[-x, y]$ ,  $[x, -y]$ ,  $[-x, -y]$ . Thus is symmetric with respect to both axes  $x, y$ . For  $y = 0$ , we have  $x^2(x - 3)(x + 3) = 0$ , i.e. the  $x$  axis is intersected by the boundary curve at points  $[-3, 0]$ ,  $[0, 0]$ ,  $[3, 0]$ . In the first quadrant, it can then be expressed as a graph of the function

$$f(x) = \sqrt[4]{9x^2 - x^4}, \quad x \in [0, 3].$$

The sought volume is thus a double (here we consider  $x > 0$ ) of the integral

$$\int_0^3 \pi f^2(x) dx = \pi \int_0^3 \sqrt{9x^2 - x^4} dx.$$

Using the substitution  $t = \sqrt{9 - x^2}$  ( $x dx = -t dt$ ), we can easily compute

$$\int_0^3 \sqrt{9x^2 - x^4} dx = \int_0^3 x \cdot \sqrt{9 - x^2} dx = -\int_3^0 t^2 dt = 9,$$

and receive the result  $18\pi$ . □

**6.B.53. Torricelli's trumpet, 1641.** Let a part of a branch of the hyperbola  $xy = 1$  for  $x \geq a$ , where  $a > 0$ , rotate around the  $x$  axis. Show that the solid of revolution created in this manner has a finite volume  $V$  and simultaneously an infinite surface  $S$ .

**Solution.** We know that

$$V = \pi \int_a^{+\infty} \left(\frac{1}{x}\right)^2 dx = \pi \int_a^{+\infty} \frac{1}{x^2} dx = \pi \left( \lim_{x \rightarrow +\infty} -\frac{1}{x} - \left(-\frac{1}{a}\right) \right) = \frac{\pi}{a}$$

and

$$S = 2\pi \int_a^{+\infty} \frac{1}{x} \cdot \sqrt{1 + \left(-\frac{1}{x^2}\right)^2} dx = 2\pi \int_a^{+\infty} \frac{\sqrt{x^4 + 1}}{x^3} dx \geq 2\pi \int_a^{+\infty} \frac{1}{x} dx = 2\pi \left( \lim_{x \rightarrow +\infty} \ln x - \ln a \right) = +\infty.$$

The fact that the given solid (the so called Torricelli's trumpet) cannot be painted with a finite amount of color, but can be filled with a finite amount of fluid, is called Torricelli's paradox. But realize that a real color painting has a

**6.3.8. Test of uniform convergence.** A simple way to test that a sequence of functions converges uniformly is to use a comparison with the absolute convergence of a suitable sequence of numbers. This is often called the *Weierstrass test*.

Suppose a sequence of functions  $f_n(x)$  is given on an interval  $I = [a, b]$  satisfying

$$|f_n(x)| \leq a_n \in \mathbb{R}$$

for suitable real constants  $a_n$  and for all  $x \in [a, b]$ . Let

$$s_k(x) = \sum_{n=1}^k f_n(x)$$

for distinct indices  $k$ . For  $k > m$ ,

$$\begin{aligned} |s_k(x) - s_m(x)| &= \left| \sum_{n=m+1}^k f_n(x) \right| \\ &\leq \sum_{n=m+1}^k |f_n(x)| \leq \sum_{n=m+1}^k a_n. \end{aligned}$$

If the series of the (nonnegative) constants  $\sum_{n=1}^{\infty} a_n$  is convergent, then the sequence of its partial sums is a Cauchy sequence. But then the sequence of partial sums  $s_n(x)$  is uniformly Cauchy.

By 6.3.5 the following is verified:

THE WEIERSTRASS TEST

**Theorem.** Let  $f_n(x)$  be a sequence of functions defined on interval  $[a, b]$  with  $|f_n(x)| \leq a_n \in \mathbb{R}$ .

If the series of numbers  $\sum_{n=1}^{\infty} a_n$  is convergent, then the series  $S(x) = \sum_{n=1}^{\infty} f_n(x)$  converges uniformly.

**6.3.9. Consequences for power series.** The Weierstrass test has important results for power series

$$S(x) = \sum_{n=0}^{\infty} a_n (x - x_0)^n$$

centered at a point  $x_0$ .

We saw earlier in 5.4.8, that each power series converges on an entire interval  $(x_0 - \delta, x_0 + \delta)$ . The radius of convergence  $\delta \geq 0$  can be zero or  $\infty$ . (see 5.4.12).

In the proof of theorem 5.4.8, a comparison with a suitable geometric series is used to verify the convergence of the series  $S(x)$ . By the Weierstrass test, the series  $S(x)$  converges uniformly on every compact (i.e. bounded closed) interval  $[a, b]$  contained in the interval  $(x_0 - \delta, x_0 + \delta)$ . Thus the following crucial result is proved:

nonzero width, which the computation doesn't take into account. For example, if we would paint it from the inside, a single drop of color would undoubtedly "block" the trumpet of infinite length.  $\square$

### C. Power series

**6.C.1.** Expand the function  $\ln(1+x)$  into a power series at point 0 and 1 and determine all  $x \in \mathbb{R}$  for which these series converge.

**Solution.** First we'll determine the expansion at point 0. To expand a function into a power series at a given point is the same as to determine its Taylor expansion at that point. We can easily see that

$$[\ln(x+1)]^{(n)} = (-1)^{n+1} \frac{(n-1)!}{(x+1)^n},$$

so after computing the derivatives at zero, we have  $\ln(x+1) = \ln 1 + \sum_{n=1}^{\infty} a_n x^n$ , where

$$a_n = \frac{(-1)^{n+1}(n-1)!}{n!} = \frac{(-1)^{n+1}}{n}.$$

Thus we can write

$$\begin{aligned} \ln(x+1) &= x - \frac{1}{2}x^2 + \frac{1}{3}x^3 - \frac{1}{4}x^4 + \dots \\ &= \sum_{n=1}^{\infty} \frac{(-1)^{n+1}}{n} x^n. \end{aligned}$$

For the radius of convergence, we can then use the limit of the quotient of the following coefficients of terms of the power series

$$r = \frac{1}{\lim_{n \rightarrow \infty} \left| \frac{a_{n+1}}{a_n} \right|} = \frac{1}{\lim_{n \rightarrow \infty} \frac{\frac{1}{n+1}}{\frac{1}{n}}} = 1.$$

Hence the series converges for arbitrary  $x \in (-1, 1)$ . For  $x = -1$  we get the harmonic series (with a negative sign), for  $x = 1$  we get the alternating harmonic series, which converges by the Leibniz criterion. Thus the given series converges exactly for  $x \in (-1, 1]$ .

Analogously, for the expansion at point 1, by computing the above derivatives from 6.C.1, we get

$$\begin{aligned} \ln(x+1) &= \ln(2) + \frac{1}{2}(x-1) - \frac{1}{8}(x-1)^2 \\ &\quad + \frac{1}{3 \cdot 2^3}(x-1)^3 - \dots \\ &= \ln(2) + \sum_{n=1}^{\infty} \frac{(-1)^{n+1}}{n \cdot 2^n} (x-1)^n, \end{aligned}$$

### DIFFERENTIATION AND INTEGRATION OF POWER SERIES

**Theorem.** Every power series  $S(x)$  is continuous and is continuously differentiable at all points inside its interval of convergence. The function  $S(x)$  is Riemann integrable and can be differentiated or integrated done term by term.

Abel's theorem states that power series are continuous even at the boundary points of their domain when they converge there (including eventual infinite limits). We do not prove it here.

The pleasant properties of power series also reveal limitations on the use in practical modelling. In particular, it is not possible to approximate piece-wise continuous or non-differentiable functions very well by using power series. Of course, it should be possible to find better sets of functions  $f_n(x)$  than just the values  $f_n(x) = x^n$ , up to constants. The best known examples are Fourier series and wavelets discussed in the next chapter.

**6.3.10. Laurent series.** We return to the smooth function  $f(x) = e^{-1/x^2}$  from paragraph 6.1.5 in the context of Taylor series expansions. It is not analytic at the origin, because all its derivatives are zero there and the function is strictly positive at all other points. At all points  $x_0 \neq 0$  this function is given by its convergent Taylor series with radius of convergence  $r = |x_0|$ . At the origin the Taylor series converges only at the one point 0.

Replace  $x$  with the expression  $-1/x^2$  into the power series for  $e^x$ . The result is the series of functions

$$S(x) = \sum_{n=0}^{\infty} \frac{1}{n!} (-1)^n x^{-2n} = \sum_{n=-\infty}^0 \frac{(-1)^{|n|}}{|n|!} x^{2n}.$$

The series converges at all points  $x \neq 0$ . It gives a good idea about the behaviour near the exceptional point  $x = 0$ .

Thus we consider the following series similar to power series but more general:

#### LAURENT<sup>6</sup> SERIES

A series of functions of the form

$$S(x) = \sum_{n=-\infty}^{\infty} a_n (x-x_0)^n$$

is called a *Laurent series centered at  $x_0$* . The series is convergent if both its parts with positive and negative exponents converge separately.

The importance of Laurent series can be seen with rational functions. Consider such a function  $S(x) = f(x)/g(x)$  with coprime polynomials  $f$  and  $g$  and consider a root  $x_0$  of

<sup>6</sup>Pierre Alphonse Laurent (1813-1854) was a French engineer and military officer. He submitted his generalization of the Taylor series into the Grand Prix competition of the French Académie des Sciences. For formal reasons it was not considered. It was published much later, after the author's death.

and for the radius of convergence of this series, we get

$$r = \frac{1}{\lim_{n \rightarrow \infty} \left| \frac{a_{n+1}}{a_n} \right|} = \frac{1}{\lim_{n \rightarrow \infty} \frac{1}{\frac{2^{n+1}(n+1)}{2^n n}}} = 1.$$

The first series converges for  $-1 < x \leq 1$ , the second for  $-1 < x \leq 3$ .  $\square$

**6.C.2.** Expand the function  $\cos^2(x)$  into a power series (i.e. determine its Taylor expansion) at point 0 and determine for which real numbers this series converges.  $\circ$

**6.C.3.** Expand the function  $\sin^2(x)$  into a power series at point 0 and determine for which real numbers this series converges.  $\circ$

**6.C.4.** Expand the function  $\ln(x^3 + 3x^2 + 3x + 1)$  into a power series at point 0 and determine for which  $x \in \mathbb{R}$  it converges.  $\circ$

**6.C.5.** Expand the function  $\ln \sqrt{x}$  into a power series at point 1 and determine for which  $x \in \mathbb{R}$  it converges.  $\circ$

**6.C.6.** On the interval of convergence  $(-1, 1)$ , determine the sum of the series

$$\sum_{n=1}^{\infty} n(n+1)x^n.$$

**Solution.** We have

$$\begin{aligned} \sum_{n=1}^{\infty} n(n+1)x^n &= \sum_{n=1}^{\infty} n(x^{n+1})' = \left( \sum_{n=1}^{\infty} n x^{n+1} \right)' = \\ &= \left( \sum_{n=1}^{\infty} n x^{n-1} x^2 \right)' = \left[ x^2 \sum_{n=1}^{\infty} (x^n)' \right]' = \\ &= \left[ x^2 \left( \sum_{n=1}^{\infty} x^n \right)' \right]' = \left[ x^2 \left( -1 + \sum_{n=0}^{\infty} x^n \right)' \right]' = \\ &= \left[ x^2 \left( -1 + \frac{1}{1-x} \right)' \right]' = \left[ x^2 \cdot \frac{1}{(1-x)^2} \right]' = \frac{2x}{(1-x)^3} \end{aligned}$$

for all  $x \in (-1, 1)$ .  $\square$

**6.C.7.** For a convergent series

$$\sum_{n=0}^{\infty} \frac{(-1)^n}{\sqrt{n+100}},$$

estimate the error of the approximation of its sum by the partial sum  $s_{9999}$ .  $\circ$

**6.C.8.** With an error lesser than  $1/10$ , approximately compute

$$\int_1^2 \left( x - \frac{\cos^{10} x}{10} \right) \ln x \, dx.$$

**6.C.9.** Compute

$$\lim_{n \rightarrow \infty} \frac{\sqrt{1+\frac{1}{n}} + \sqrt{1+\frac{2}{n}} + \dots + \sqrt{1+1}}{n}.$$

polynomial  $g(x)$ . If the multiplicity of this root is  $s$ , then after multiplication we obtain the function  $\tilde{S}(x) = S(x)(x-x_0)^s$ , which is analytic on some neighbourhood of  $x_0$ . Therefore we can write

$$\begin{aligned} S(x) &= \frac{a_{-s}}{(x-x_0)^r} + \dots + \frac{a_{-1}}{x-x_0} + a_0 + a_1(x-x_0) + \dots \\ &= \sum_{n=-s}^{\infty} a_n(x-x_0)^n. \end{aligned}$$

Consider the two parts of the Laurent series separately:

$$S(x) = S_- + S_+ = \sum_{n=-\infty}^{-1} a_n(x-x_0)^n + \sum_{n=0}^{\infty} a_n(x-x_0)^n.$$

For the series  $S_+$ , Theorem 5.4.8 implies that its radius of convergence  $R$  is given by  $R^{-1} = \limsup_{n \rightarrow \infty} \sqrt[n]{|a_n|}$ . Apply the same idea to the series  $S_-$  with  $1/x$  substituted for  $x$ . It is then apparent that the series  $S_-(x)$  converges for  $|x-x_0| > r$ , where  $r = \limsup_{n \rightarrow \infty} \sqrt[n]{|a_{-n}|}$ .

Notice that the conclusions about convergence remain true even for complex values of  $x$  substituted into the expression. Laurent series can be considered as functions defined on a domain in the complex plain. We return to this in chapter 9. The following theorem is proved already.

CONVERGENCE OF THE LAURENT SERIES ON THE ANNULUS

**Theorem.** The Laurent series  $S(x)$  centered at  $x_0$  converges for all  $x \in \mathbb{C}$  satisfying  $r < |x-x_0| < R$  and diverges for all  $x$  satisfying  $|x-x_0| < r$  or  $|x-x_0| > R$ , where

$$r = \limsup_{n \rightarrow \infty} \sqrt[n]{|a_{-n}|}, \quad R^{-1} = \limsup_{n \rightarrow \infty} \sqrt[n]{|a_n|}.$$

The Laurent series need not converge at any point, because possibly  $R < r$ . If we look for an example of the above case of rational functions expanded to Laurent series at some of the roots of the denominator, then clearly  $r = 0$  and therefore, as expected, it converges in the punctured neighbourhood of this point  $x_0$ .  $R$  is given by the distance to the closest root of the denominator. In the case of the first example, the function  $e^{-1/x^2}$ ,  $r = 0$  and  $R = \infty$ .

**6.3.11. Numerical approximation of integration.** Just

as in paragraph 6.1.16, we use the Taylor expansion to propose simple approximations of integration. We deal with an integral  $I = \int_a^b f(x) \, dx$  of an analytic function  $f(x)$  and a uniform partition of the interval  $[a, b]$  using points  $a = x_0, x_1, \dots, x_n = b$  with distances  $x_i - x_{i-1} = h > 0$ . Denote the points in the middle of the intervals in the partitions by  $x_{i+1/2}$  and the values of the function at the points of the partition by  $f(x_i) = f_i$ .

Compute the contribution of one segment of the partition to the integral by the Taylor expansion and the previous theorem. Integrate symmetrically around the middle values so

**6.C.10. Applications of the integral criterion of convergence.** Now let's get back to (number) series. Thanks to the integral criterion of convergence (see 6.2.19), we can decide the question of convergence for a wider class of series: Decide, whether the following sums converge or diverge:

- a)  $\sum_{n=1}^{\infty} \frac{1}{n \ln n}$ ,  
 b)  $\sum_{n=1}^{\infty} \frac{1}{n^2}$ .

**Solution.** First notice, that we cannot decide the convergence of none of these series by using the ratio or root test (all limits  $\lim_{n \rightarrow \infty} \left| \frac{a_{n+1}}{a_n} \right|$  and  $\lim_{n \rightarrow \infty} \sqrt[n]{a_n}$  equal 1). Using the integral criterion for convergence of series, we obtain:

a) 
$$\int_1^{\infty} \frac{1}{x \ln(x)} dx = \int_0^{\infty} \frac{1}{t} dt = \lim_{\delta \rightarrow \infty} [\ln(t)]_0^{\delta} = \infty,$$
 hence the given series diverges.

b) 
$$\int_1^{\infty} \frac{1}{x^2} dx = \lim_{\delta \rightarrow \infty} \left[ -\frac{1}{x} \right]_1^{\delta} = 1,$$
 hence the given series converges.

**6.C.11.** Using the integral criterion, decide the convergence of series

$$\sum_{n=1}^{\infty} \frac{1}{(n+1) \ln^2(n+1)}.$$

**Solution.** The function

$$f(x) = \frac{1}{(x+1) \ln^2(x+1)}, \quad x \in [1, +\infty)$$

is clearly positive and nonincreasing on its whole domain, thus the given series converges if and only if the integral  $\int_1^{+\infty} f(x) dx$  converges. By using the substitution  $y = \ln(x+1)$  (where  $dy = dx/(x+1)$ ), we can compute

$$\int_1^{+\infty} \frac{1}{(x+1) \ln^2(x+1)} dx = \int_{\ln 2}^{+\infty} \frac{1}{y^2} dy = \frac{1}{\ln 2}.$$

Hence the series converges.

**Uniform convergence.**

**6.C.12.** Does the sequence of functions

$$y_n = e^{\frac{x^4}{4n^2}}, \quad x \in \mathbb{R}, \quad n \in \mathbb{N}$$

converge uniformly on  $\mathbb{R}$ ?

**Solution.** The sequence  $\{y_n\}_{n \in \mathbb{N}}$  converges pointwise to the constant function  $y = 1$  on  $\mathbb{R}$ , since

that the derivatives of odd orders cancel each other out while integrating:

$$\begin{aligned} \int_{-h/2}^{h/2} f(x_{i+1/2} + t) dt &= \int_{-h/2}^{h/2} \left( \sum_{n=0}^{\infty} \frac{1}{n!} f^{(n)}(x_{i+1/2}) t^n \right) dt \\ &= \sum_{k=0}^{\infty} \left( \int_{-h/2}^{h/2} \frac{1}{k!} f^{(k)}(x_{i+1/2}) t^k dt \right) \\ &= \sum_{k=0}^{\infty} \frac{h^{2k+1}}{2^{2k}(2k+1)!} f^{(2k)}(x_{i+1/2}). \end{aligned}$$

A simple numerical approximation of integration on one segment of the partition is the *trapezoidal rule*. This uses the area of a trapezoid given by the points  $[x_i, 0]$ ,  $[x_i, f_i]$ ,  $[0, x_{i+1}]$ ,  $[x_{i+1}, f_{i+1}]$  for approximation. This area is

$$P_i = \frac{1}{2}(f_i + f_{i+1})h$$

In total, the integral  $I$  is approximated by

$$I_{\text{trap}} = \sum_{i=0}^{n-1} P_i = \frac{h}{2}(f_0 + 2f_1 + \dots + 2f_{n-1} + f_n).$$

Compare  $I_{\text{trap}}$  to the exact value of  $I$  computed by contributions over individually segments of the partition. Express the values  $f_i$  by the middle values  $f_{i+1/2}$  and the derivatives  $f_{i+1/2}^{(k)}$  in the following way:

$$\begin{aligned} f_{i+1/2 \pm 1/2} &= f_{i+1/2} \pm \frac{h}{2} f'_{i+1/2} + \frac{h^2}{2!2^2} f''(i+1/2) \\ &\quad \pm \frac{h^3}{3!2^3} f^{(3)}(i+1/2) + \dots \end{aligned}$$

Thus, the contribution  $P_i$  to the approximation is

$$P_i = \frac{1}{2}(f_i + f_{i+1})h = h(f_{i+1/2} + \frac{h^2}{2!2^2} f''(i+1/2)) + O(h^5).$$

Estimate the error  $\Delta_i = I - I_{\text{trap}}$  over one segment of the partition:

$$\begin{aligned} \Delta_i &= h(f_{i+1/2} + \frac{h^2}{24} f''_{i+1/2} - f_{i+1/2} - \frac{h^2}{8} f''_{i+1/2} + O(h^4)) \\ &= -\frac{h^3}{12} f''_{i+1/2} + O(h^5). \end{aligned}$$

The total error is thus estimated as

$$\begin{aligned} |I - I_{\text{trap}}| &= \frac{1}{12} n h^3 |f''| + n O(h^5) \\ &= \frac{1}{12} (b-a) h^2 |f''| + O(h^4) \end{aligned}$$

□ where  $|f''|$  represents an upper estimate for  $|f''(x)|$  of  $f$  over the integral of integration.

If the linear approximation of the function over the individual segments does not suffice, we can try approximations by quadratic polynomials. To do so, three values are always needed, so work with segments of the partition in pairs. Suppose  $n = 2m$  and consider  $x_i$  with odd indices. We choose

$$\begin{aligned} f_{i+1} &= f(x_i + h) = f_i + \alpha_i h + \beta_i h^2 \\ f_{i-1} &= f(x_i - h) = f_i - \alpha_i h + \beta_i h^2 \end{aligned}$$

$$\lim_{n \rightarrow \infty} e^{\frac{x^4}{4n^2}} = e^0 = 1, \quad x \in \mathbb{R}.$$

But the computation

$$y_n(\sqrt{2n}) = e > 2 \quad \text{for all } n \in \mathbb{N}$$

implies that it's not a uniform convergence. (In the definition of uniform convergence, it suffices to consider  $\varepsilon \in (0, 1)$ .)  $\square$

**6.C.13.** Decide whether the series

$$\sum_{n=1}^{\infty} \frac{\sqrt{x} \cdot n}{n^4 + x^2}$$

converges uniformly on the interval  $(0, +\infty)$ .

**Solution.** Using the denotation

$$f_n(x) = \frac{\sqrt{x} \cdot n}{n^4 + x^2}, \quad x > 0, \quad n \in \mathbb{N},$$

we have

$$f'_n(x) = \frac{n(n^4 - 3x^2)}{2\sqrt{x}(n^4 + x^2)^2}, \quad x > 0, \quad n \in \mathbb{N}.$$

From now on, let  $n \in \mathbb{N}$  be arbitrary. The inequalities  $f'_n(x) > 0$  for  $x \in (0, n^2/\sqrt{3})$  and  $f'_n(x) < 0$  for  $x \in (n^2/\sqrt{3}, +\infty)$  imply that the maximum of function  $f_n$  is attained exactly at the point  $x = n^2/\sqrt{3}$ . Since

$$f_n\left(\frac{n^2}{\sqrt{3}}\right) = \frac{\sqrt[4]{27}}{4n^2} \quad \text{a} \quad \sum_{n=1}^{\infty} \frac{\sqrt[4]{27}}{4n^2} = \frac{\sqrt[4]{27}}{4} \sum_{n=1}^{\infty} \frac{1}{n^2} < +\infty,$$

according to the Weierstrass test, the series  $\sum_{n=1}^{\infty} f_n(x)$  converges uniformly on the interval  $(0, +\infty)$ .  $\square$

**6.C.14.** For  $x \in [-1, 1]$ , add

$$\sum_{n=1}^{\infty} \frac{(-1)^{n+1}}{n(n+1)} x^{n+1}.$$

**Solution.** First notice that by the symbol for an indefinite integral, we'll denote one specific primitive function (while preserving the variable), which should be understood as a so called function of the upper limit, while the lower limit is zero. Using the theorem about integration of a power series for  $x \in (-1, 1)$ , we'll obtain

$$\begin{aligned} \sum_{n=1}^{\infty} \frac{(-1)^{n+1}}{n(n+1)} x^{n+1} &= \sum_{n=1}^{\infty} \left( \frac{(-1)^{n+1}}{n} \int x^n dx \right) \\ &= \int \sum_{n=1}^{\infty} \left( \frac{(-1)^{n+1}}{n} x^n \right) dx \\ &= \int \sum_{n=1}^{\infty} ((-1)^{n+1} \int x^{n-1} dx) dx \\ &= \int \left( \int \sum_{n=1}^{\infty} (-x)^{n-1} dx \right) dx = \int \left( \int (1 - x + x^2 - x^3 + \dots) dx \right) dx \\ &= \int \left( \int \frac{1}{1+x} dx \right) dx = \int \ln(1+x) + C_1 dx. \end{aligned}$$

Since

$$\int \sum_{n=1}^{\infty} \left( \frac{(-1)^{n+1}}{n} x^n \right) dx = \int \ln(1+x) + C_1 dx,$$

we know from the continuity of the given functions that

which implies

$$\beta_i = \frac{1}{2h^2}(f_{i+1} + f_{i-1} - 2f_i).$$

The approximation of the integral over two segments of the partition between  $x_{i-1}$  and  $x_{i+1}$  is now estimated by the expression (notice we integrate the quadratic polynomial with the requested values  $f_{i-1}$ ,  $f_i$ ,  $f_{i+1}$  in the points  $x_{i-1}$ ,  $x_i$ ,  $x_{i+1}$ , respectively. It is not necessary to know the constant  $\alpha_i$ )

$$\begin{aligned} P_i &= \int_{-h}^h f_i + \alpha_i t + \beta_i t^2 dt = 2hf_i + \frac{2}{3}\beta_i h^3 \\ &= 2hf_i + \frac{2h}{6}(f_{i+1} + f_{i-1} - 2f_i) \\ &= \frac{h}{3}(f_{i+1} + f_{i-1} + 4f_i). \end{aligned}$$

This procedure is called *Simpson's rule*<sup>7</sup>. The entire integral is now approximated by

$$I_{\text{Simp}} = \frac{1}{3}h(f_0 + 4 \sum_{m=0}^{n-1} f_{2m+1} + 2 \sum_{m=1}^{n-1} f_{2m} + f_{2n}).$$

As with the trapezoidal rule above, the total error is estimated by

$$|I - I_{\text{Simp}}| = \frac{1}{180}(b-a)h^4|f^{(4)}| + O(h^5),$$

where  $|f^{(4)}|$  represents the upper bound for  $|f^{(4)}(x)|$  over the interval of integration.

**6.3.12. Integrals dependent on parameters.** When integrating a function  $f(x, y_1, \dots, y_n)$  of 1 real variable  $x$  depending on further real parameters  $y_1, \dots, y_n$  with respect to the single variable  $x$ , the result is a function  $F(y_1, \dots, y_n)$  depending on all the parameters. Such a function  $F$  often occurs in practice. For instance, we can look for the volume or area of a body which depends on parameters, and determine the minimal and maximal values (with additional constraints as well). Often it is desirable to interchange the operations of differentiation and integration. That this can be done is proved below. We begin with an examination of continuous dependency on the parameters.

For sake of simplicity, we shall deal with functions  $f(x, y)$  depending on two variables,  $x \in [a, b]$ ,  $y \in [c, d]$ . We say  $f$  is *continuous* on  $I = [a, b] \times [c, d] \subset \mathbb{R}^2 = \mathbb{C}$  if for each  $z = (x, y)$  from the domain of  $f$  and  $\varepsilon > 0$  there is some  $\delta > 0$  such  $|f(w) - f(z)| < \varepsilon$  if  $w \in \mathcal{O}_\delta(z)$ . (Notice the definition is the same as with the univariate functions, just we use the distance in the plane.)

The function  $f(x, y)$  is called *uniformly continuous* if for each  $\varepsilon > 0$ , there is  $\delta > 0$  such that for any two points  $z, w$  in  $I \subset \mathbb{R}^2 = \mathbb{C}$ ,  $|z - w| < \delta$  implies  $|f(z) - f(w)| < \varepsilon$ . Exactly the same argument as with univariate functions, based on the fact that every open cover of a compact set in the complex

<sup>7</sup>This way of approximating the integral is attributed to the English mathematician and inventor Thomas Simpson (1710-1761).

$$\sum_{n=1}^{\infty} \frac{(-1)^{n+1}}{n} x^n = \ln(1+x) + C_1, \quad x \in (-1, 1).$$

The choice  $x = 0$  then yields  $0 = \ln 1 + C_1$ , i.e.  $C_1 = 0$ .

Next,

$$\begin{aligned} \int \ln(1+x) dx &= \text{per partes} \\ &= \left| \begin{array}{ll} u = \ln(1+x) & u' = \frac{1}{1+x} \\ v' = 1 & v = x \end{array} \right| \\ &= x \ln(1+x) - \int \frac{x}{1+x} dx = x \ln(1+x) - \int 1 - \frac{1}{1+x} dx \\ &= x \ln(1+x) - x + \ln(1+x) + C_2 \\ &= (x+1) \ln(x+1) - x + C_2. \end{aligned}$$

Since the given series converges at the point  $x = 0$  with a sum of 0, analogously as for  $C_1$ ,

$$0 = 1 \cdot \ln 1 - 0 + C_2$$

implies that  $C_2 = 0$ . In total, we have for  $x \in (-1, 1)$ :

$$\sum_{n=1}^{\infty} \frac{(-1)^{n+1}}{n(n+1)} x^{n+1} = (x+1) \ln(x+1) - x.$$

Moreover, according to Abel's theorem (see 6.3.9), the sum of the given series equals the (potentially improper) limit of the function  $(x+1) \ln(x+1) - x$  at points  $-1$  and  $1$ . In our case, both limits are proper (at point  $1$ , the function is even continuous and the value of the limit at point  $1$  then equals the value of the function  $2 \ln 2 - 1$ .) For computing the value of the limit at point  $-1$ , we'll use L'Hospital's rule:

$$\begin{aligned} \lim_{x \rightarrow -1^+} (x+1) \ln(x+1) - x &= \lim_{t \rightarrow 0^+} t \ln t + 1 \\ &= \lim_{t \rightarrow 0^+} \frac{\ln t}{\frac{1}{t}} + 1 = \lim_{t \rightarrow 0^+} \frac{\frac{1}{t}}{-\frac{1}{t^2}} + 1 \\ &= \lim_{t \rightarrow 0^+} -t + 1 = 1. \end{aligned}$$

Of course, the convergence of the series at points  $\pm 1$  can be verified directly. It's even possible to directly deduce that  $\sum_{n=1}^{\infty} \frac{1}{n(n+1)} = 1$  (by writing out  $\frac{1}{n(n+1)} = \frac{1}{n} - \frac{1}{n+1}$ ).  $\square$

**6.C.15. Sum of a series.** Using theorem 6.3.5 "about the interchange of a limit and an integral of a sequence of uniformly convergent functions", we'll now add the number series

$$\sum_{n=1}^{\infty} \frac{1}{n2^n}.$$

We'll use the fact that  $\int_2^{\infty} \frac{dx}{x^{n+1}} = \frac{1}{n2^n}$ .

**Solution.** On interval  $(2, \infty)$ , the series of functions  $\sum_{n=1}^{\infty} \frac{1}{x^{n+1}}$  converges uniformly. That is implied for example by the Weierstrass test: each of the function  $\frac{1}{x^{n+1}}$  is decreasing on interval  $(2, \infty)$ , thus their values are at most  $\frac{1}{2^{n+1}}$ ; the series  $\sum_{n=1}^{\infty} \frac{1}{2^{n+1}}$  is convergent though (it's a geometric series with quotient  $\frac{1}{2}$ ). Hence according

plane contains a finite subcover, cf. Theorem 5.2.8(5), provides the following lemma (cf. the proof of Theorem 6.2.11).

**Lemma.** Each continuous function  $f(x, y)$  on  $I = [a, b] \times [c, d]$  is uniformly continuous.

Now we are ready for the following important claim:

**Theorem.** Assume  $f(x, y)$  is a function defined for all  $x$  lying in a bounded interval  $[a, b]$  and all  $y$  in a bounded interval  $[c, d]$ , continuous on  $I = [a, b] \times [c, d]$ . Consider the (Riemann) integral

$$F(y) = \int_a^b f(x, y) dx.$$

Then the function  $F(y)$  is continuous on  $[c, d]$ .

**PROOF.** Fix a point  $y \in [c, d]$ , small  $\varepsilon > 0$ , and choose a neighbourhood  $W$  of  $y$  such that for all  $\bar{y} \in W \subset [c, d]$  and all  $x \in [a, b]$  (remember  $f$  is uniformly continuous)

$$|f(x, \bar{y}) - f(x, y)| < \varepsilon.$$

The Riemann integral of continuous functions is evaluated by approximations of finite sums (equivalently: upper, lower, or Riemann sums with arbitrary representatives  $\xi_i$ , see paragraph 6.2.9).

The goal is to establish that the Riemann sums for the integrals with parameters  $y$  and  $\bar{y}$  cannot differ much. In the following estimate for any partition with  $k$  intervals and representatives  $\xi_i$ , first use the standard properties of the absolute value and then exploit the choice of  $W$ :

$$\begin{aligned} & \left| \sum_{i=0}^{k-1} f(\xi_i, \bar{y})(x_{i+1} - x_i) - \sum_{i=0}^{k-1} f(\xi_i, y)(x_{i+1} - x_i) \right| \\ & \leq \sum_{i=0}^{k-1} |f(\xi_i, \bar{y}) - f(\xi_i, y)|(x_{i+1} - x_i) \\ & < \varepsilon(b-a). \end{aligned}$$

It follows that the limit values for any sequences of the partitions and representatives  $F(y)$  and  $F(\bar{y})$  cannot differ by more than  $\varepsilon(b-a)$  either, so the function  $F$  is continuous.  $\square$

**6.3.13. Integrating twice.** The fact that the integral  $F(y) = \int_a^b f(x, y) dx$  of a continuous function  $f : [a, b] \times [c, d] \rightarrow \mathbb{R}$  in the plane is again a continuous function  $F : [c, d] \rightarrow \mathbb{R}$  allows us to repeat the integration and write

$$(1) \quad I = \int_c^d \int_a^b f(x, y) dx dy = \int_c^d \left( \int_a^b f(x, y) dx \right) dy.$$

The next theorem is the simplest version of the claim known as *Fubini theorem*.

to the Weierstrass test, the series of functions  $\sum_{n=1}^{\infty} \frac{1}{x^{n+1}}$  converges uniformly. We can even write the resulting function explicitly. Its value at any  $x \in (2, \infty)$  is the value of the geometric series with quotient  $\frac{1}{x}$ , so if we denote the limit by  $f(x)$ , we have

$$f(x) = \sum_{n=1}^{\infty} \frac{1}{x^{n+1}} = \frac{1}{x^2} \frac{1}{1 - \frac{1}{x}} = \frac{1}{x(x-1)}.$$

By using (6.3.7) (3), we get

$$\begin{aligned} \sum_{n=1}^{\infty} \frac{1}{n2^n} &= \sum_{n=1}^{\infty} \int_2^{\infty} \frac{dx}{x^{n+1}} = \int_2^{\infty} \left( \sum_{n=1}^{\infty} \frac{1}{x^{n+1}} \right) dx \\ &= \int_2^{\infty} \frac{1}{x(x-1)} dx = \lim_{\delta \rightarrow \infty} \int_2^{\delta} \frac{1}{x-1} - \frac{1}{x} dx \\ &= \lim_{\delta \rightarrow \infty} [(\ln(\delta-1) - \ln(\delta)) - \ln(1) + \ln 2] \\ &= \lim_{\delta \rightarrow \infty} \left[ \ln \left( \frac{\delta-1}{\delta} \right) \right] + \ln(2) \\ &= \ln \left( \lim_{\delta \rightarrow \infty} \frac{\delta-1}{\delta} \right) + \ln 2 = \ln 2 \end{aligned}$$

□

**6.C.16.** Consider function  $f(x) = \sum_{n=1}^{\infty} ne^{-nx}$ . Determine

$$\int_{\ln 2}^{\ln 3} f(x) dx.$$

**Solution.** Similarly as in the previous case, the Weierstrass test for uniform convergence implies that the series of functions  $\sum_{n=1}^{\infty} ne^{-nx}$  converges uniformly on interval  $(\ln 2, \ln 3)$ , since each of the functions  $ne^{-nx}$  is lesser than  $\frac{n}{2^n}$  on  $(\ln 2, \ln 3)$  and the series  $\sum_{n=1}^{\infty} \frac{n}{2^n}$  converges, which can be seen for example from the ratio test for convergence of series:

$$\lim_{n \rightarrow \infty} \left| \frac{a_{n+1}}{a_n} \right| = \lim_{n \rightarrow \infty} \frac{(n+1)2^{-(n+1)}}{n2^n} = \lim_{n \rightarrow \infty} \frac{1}{2} \frac{n+1}{n} = \frac{1}{2}.$$

In total, according to (6.3.7) (3), we have

$$\begin{aligned} \int_{\ln 2}^{\ln 3} f(x) dx &= \int_{\ln 2}^{\ln 3} \sum_{n=1}^{\infty} ne^{-nx} dx = \sum_{n=1}^{\infty} \int_{\ln 2}^{\ln 3} ne^{-nx} dx \\ &= \sum_{n=1}^{\infty} [-e^{-nx}]_{\ln 2}^{\ln 3} = \sum_{n=1}^{\infty} \left( \frac{1}{2^n} - \frac{1}{3^n} \right) = 1 - \frac{1}{2} = \frac{1}{2}. \end{aligned}$$

□

**6.C.17.** Determine the following limit (give reasons for the procedure of computation):

$$\lim_{n \rightarrow \infty} \int_0^{\infty} \frac{\cos\left(\frac{x}{n}\right)}{\left(1 + \frac{x}{n}\right)^n} dx.$$

FUBINI THEOREM

**Theorem.** Consider a continuous function  $f : [a, b] \times [c, d] \rightarrow \mathbb{R}$  in the plane  $\mathbb{R}^2$ . The multiple integration (1) is well defined and does not depend on the order of integration, i.e.,

$$I = \int_c^d \left( \int_a^b f(x, y) dx \right) dy = \int_a^b \left( \int_c^d f(x, y) dy \right) dx..$$

**PROOF.** We know  $f$  is uniformly continuous on the product of intervals  $[a, b] \times [c, d]$  in the plane. Thus, for each  $\varepsilon > 0$  there is  $\delta > 0$  such that  $|f(x_1, y_1) - f(x_2, y_2)| < \varepsilon$  whenever  $|x_1 - x_2| < \delta$  and  $|y_1 - y_2| < \delta$ .

We know both Riemann integrals in (1) exist, thus we may fix a sequence  $\Xi_k$  of partitions of the interval  $[a, b]$  into  $k$  subinterval  $[x_{i-1}, x_i]$  of equal size  $1/k$  and with representatives  $\xi_{i,k}$ ,  $i = 1, \dots, k$ , and similarly for the interval  $[c, d]$  with the subintervals  $[y_{j-1}, y_j]$  and representatives  $\eta_{j,k}$ ,  $j = 1, \dots, k$ . Then we may write

$$I = \int_c^d \lim_{k \rightarrow \infty} \left( \sum_{i=1}^k f(\xi_{i,k}, y) \frac{1}{k} (b-a) \right) dy$$

If  $\frac{1}{k} < \delta$ , then

$$\begin{aligned} & \left| \int_a^b f(x, y) dy - \sum_{i=1}^k f(\xi_{i,k}, y) \frac{1}{k} (b-a) \right| \\ & \leq \sum_{i=1}^k \left| \int_{x_{i-1}}^{x_i} f(x, y) dx - f(\xi_{i,k}, y) \frac{1}{k} (b-a) \right| \\ & \leq \sum_{i=1}^k \int_{x_{i-1}}^{x_i} |f(x, y) - f(\xi_{i,k}, y)| dx \\ & \leq \varepsilon (b-a). \end{aligned}$$

Thus, the convergence of

$$\lim_{k \rightarrow \infty} \sum_{i=1}^k f(\xi_{i,k}, y) \frac{1}{k} (b-a) = F(y) = \int_a^b f(x, y) dx$$

is uniform on  $[c, d]$ . In particular, we may swap the integral and the limit to obtain

$$\begin{aligned} I &= \lim_{k \rightarrow \infty} \int_c^d \left( \sum_{i=1}^k f(\xi_{i,k}, y) \frac{1}{k} (b-a) \right) dy \\ &= \lim_{k \rightarrow \infty} \sum_{i=1}^k \left( \int_c^d f(\xi_{i,k}, y) dy \right) \frac{1}{k} (b-a) \\ &= \lim_{k, \ell \rightarrow \infty} \sum_{i=1}^k \sum_{j=1}^{\ell} f(\xi_i, \eta_j) \frac{1}{k} \frac{1}{\ell} (b-a)(d-c). \end{aligned}$$

Clearly, the same result will appear if we swap the order of the integration. □

**Solution.** First we'll determine  $\lim_{n \rightarrow \infty} \frac{\cos(\frac{x}{n})}{(1+\frac{x}{n})^n}$ . The sequence of these functions converges pointwise and we have

$$\lim_{n \rightarrow \infty} \frac{\cos(\frac{x}{n})}{(1+\frac{x}{n})^n} = \frac{1}{\lim_{n \rightarrow \infty} (1+\frac{x}{n})^n} \stackrel{(?)}{=} \frac{1}{e^x}$$

It can be shown that the given sequence converges uniformly. Then according to (6.3.5),

$$\begin{aligned} \lim_{n \rightarrow \infty} \int_0^\infty \frac{\cos(\frac{x}{n})}{(1+\frac{x}{n})^n} dx &= \int_0^\infty \left[ \lim_{n \rightarrow \infty} \frac{\cos(\frac{x}{n})}{(1+\frac{x}{n})^n} \right] dx \\ &= \int_0^\infty \frac{1}{e^x} dx = 1 \end{aligned}$$

We leave the verification of uniform convergence to the reader (we only point out that the discussion is more complicated than in the previous cases). □

**6.C.23.** Express the function  $y = e^x$  defined on the whole real axis as an infinite polynomial with terms of the form  $a_n(x-1)^n$  and express the function  $y = 2^x$  defined on  $\mathbb{R}$  as an infinite polynomial with terms  $a_n x^n$ . ○

**6.C.24.** Find a function  $f$  such that for  $x \in \mathbb{R}$ , the sequence of functions

$$f_n(x) = \frac{n^2 x^3}{n^2 x^2 + 1}, \quad n \in \mathbb{N}$$

**6.3.14. Differentiation in the integrals.** We are ready to discuss the differentiation of integrals with respect to parameters. The following result is extremely useful. For instance we shall use it in the next chapter when examining integral transforms.

DIFFERENTIATION WITH RESPECT TO PARAMETERS

**Theorem.** Consider a continuous function  $f(x, y)$  defined for all  $x$  from a finite interval  $[a, b]$  and for all  $y$  in another finite interval  $[c, d]$ , a point  $c \in [c, d]$ , and the integral

$$F(y) = \int_a^b f(x, y) dx.$$

If there exists the continuous derivative  $\frac{d}{dy} f$  on a neighbourhood of the point  $c$ , then  $\frac{d}{dy} F(c)$  exists as well and

$$\frac{d}{dy} F(c) = \int_a^b \frac{d}{dy} f(x, y)|_{y=c} dx.$$

**PROOF.** By the assumed continuity of all functions and the already known continuous dependence of integrals on parameters, some knowledge about univariate antiderivatives can be used. The result is then a simple consequence of the Fubini theorem. □

Denote

$$G(y) = \int_a^b \frac{d}{dy} f(x, y) dx, \quad F(y) = \int_a^b f(x, y) dx$$

and compute, invoking Fubini theorem, the antiderivative

$$\begin{aligned} H(y) &= \int_{y_0}^y G(z) dz = \int_{y_0}^y \left( \int_a^b \frac{d}{dz} f(x, z) dx \right) dz \\ &= \int_a^b \left( \int_{y_0}^y \frac{d}{dz} f(x, z) dz \right) dx \\ &= \int_a^b (f(x, y) - f(x, y_0)) dx \\ &= F(y) - F(y_0). \end{aligned}$$

Finally, differentiating with respect to  $y$  yields

$$G(y) = \frac{d}{dy} H(y) = \frac{dF}{dy}(y),$$

as desired. □

**6.3.15. The Riemann–Stieltjes integral.** To end this chapter, we mention briefly some other concepts of integration. Mostly we confine ourselves to remarks and comments. Readers interested in a thorough explanation can find another source.

First, a modification of the Riemann integral, which is useful when discussing probability and statistics. In the discussion of integration, we summed infinitely many linearized (infinitely) small increments of the area given by a function  $f(x)$ . We omitted the possibility that for different values of  $x$  we could take the increments with different weights. This

to it. Is this convergence uniform on  $\mathbb{R}$ ?

6.C.25. Does the series

$$\sum_{n=1}^{\infty} \frac{nx}{n^4+x^2}, \quad \text{kde } x \in \mathbb{R},$$

converge uniformly on the whole real axis?

6.C.26. By using differentiation, obtain the Taylor expansion of function  $y = \cos x$  from the Taylor expansion of function  $y = \sin x$  centered at the origin.

6.C.27. Approximate

- (a) cosine of ten degrees with a precision of at least  $10^{-5}$ ;
- (b) the definite integral  $\int_0^{1/2} \frac{dx}{x^4+1}$  with a precision of at least  $10^{-3}$ .

6.C.28. Determine the power expansion centered at  $x_0 = 0$  of function

$$f(x) = \int_0^x e^{t^2} dt, \quad x \in \mathbb{R}.$$

6.C.29. Find the analytic function whose Taylor series is

$$x - \frac{1}{3}x^3 + \frac{1}{5}x^5 - \frac{1}{7}x^7 + \dots,$$

for  $x \in [-1, 1]$ .

6.C.30. From the knowledge of the sum of a geometric series, derive the Taylor series of function

$$y = \frac{1}{5+2x}$$

centered at the origin. Then determine its radius of convergence.

6.C.31. Use the derivatives of functions  $y = \operatorname{tg} x$  and  $y = \operatorname{cotg} x$  to find the indefinite integrals of functions

- (a)  $y = \operatorname{cotg}^2 x, \quad x \in (0, \pi)$ ;
- (b)  $y = \frac{1}{\sin^2 x \cos^2 x}, \quad x \in (0, \frac{\pi}{2})$ .

6.C.32. By repeated use of integration by parts, for all  $x \in \mathbb{R}$  determine

- (a)  $\int x^2 \sin x dx$ ;
- (b)  $\int x^2 e^x dx$ .

6.C.33. For example by using integration by parts, determine

can be arranged at the infinitesimal level by exchanging the differential  $dx$  for  $\varphi(x)dx$  for some suitable function  $\varphi$ .

Imagine that at some point  $x_0$ , the increment of the integrated quantity is given by  $\alpha f(x_0)$  independently of the size of the increment of  $x$ . For example, we may observe the probability that the amount of alcohol per mille in the blood of a driver at a test will be at most  $x$ . We might like to integrate over the possible values in the interval  $[0, x]$ . With quite a large probability the value is 0. Thus for any integral sum, the segment containing zero contributes by a constant nonzero contribution, independent of the norm of the partition. We cannot simulate such behaviour by multiplying the differential  $dx$  by some real function. Instead we generalize the Riemann integral in the following way:

#### RIEMANN-STIELTJES INTEGRAL

Choose a real nondecreasing function  $g$  on a finite interval  $[a, b]$ . For every partition  $\Xi$  with representative  $\xi_i$  and points of the partition

$$a = x_0, x_1, \dots, x_n = b$$

the Riemann–Stieltjes integral sum of function  $f(x)$  as

$$S_{\Xi} = \sum_{i=1}^n f(\xi_i)(g(x_i) - g(x_{i-1})).$$

The Riemann–Stieltjes integral

$$I = \int_a^b f(x)dg(x)$$

exists and its value is  $I$ , if for every real  $\varepsilon > 0$  there exists a norm of the partition  $\delta > 0$  such that for all partitions  $\Xi$  with norm smaller than  $\delta$ ,

$$|S_{\Xi} - I| < \varepsilon.$$

For example, choose  $g(x)$  on interval  $[0, 1]$  as a piecewise constant function with finitely many discontinuities  $c_1, \dots, c_k$  and “jumps”

$$\alpha_i = \lim_{x \rightarrow c_i+} g(x) - \lim_{x \rightarrow c_i-} g(x),$$

then the Riemann–Stieltjes integral exists for every continuous  $f(x)$  and equals

$$I = \int_0^1 f(x)dg(x) = \sum_{i=1}^k \alpha_i f(c_i).$$

By the same technique as used for the Riemann integral, we define upper and lower sums and upper and lower Riemann–Stieltjes integral. For bounded functions they always exist, and their values coincide if and only if the Riemann–Stieltjes integral in the above sense exists.

We have already encountered problems with the Riemann integration of functions that are “too jumpy”. For a

$$\int x \ln^2 x \, dx$$

for  $x > 0$ .

**6.C.34.** Using integration by parts, determine

$$\int (2 - x^2) e^x \, dx$$

on the whole real line.

**6.C.35.** Integrate

- (a)  $\int (2x + 5)^{10} \, dx, \quad x \in \mathbb{R};$
- (b)  $\int \frac{1}{x \ln^2 x} \, dx, \quad x > 0;$
- (c)  $\int e^{-x^3} x^2 \, dx, \quad x \in \mathbb{R};$
- (d)  $\int 15 \frac{\arcsin^2 x}{\sqrt{1-x^2}} \, dx, \quad x \in (-1, 1);$
- (e)  $\int \frac{\ln x}{x} \, dx, \quad x > 0;$
- (f)  $\int \frac{\operatorname{arctg} \sqrt{x}}{\sqrt{x(1+x)}} \, dx, \quad x > 0;$
- (g)  $\int \frac{e^x}{e^{2x} + 3} \, dx, \quad x \in \mathbb{R};$
- (h)  $\int \sin \sqrt{x} \, dx, \quad x > 0$

by using the substitution method.

**6.C.36.** For  $x \in (0, 1)$ , by using suitable substitutions, reduce the integrals

$$\int x^2 \sqrt{\frac{x}{1-x}} \, dx; \quad \int \frac{dx}{(x-1)\sqrt{x^2+x+1}}$$

to integrals of rational functions.

**6.C.37.** For  $x \in (-\pi/2, \pi/2)$  compute

$$\int \frac{dx}{1 + \sin^2 x}$$

using the substitution  $t = \operatorname{tg} x$ .

**6.C.38.** How many distinct primitive functions to function  $y = \cos(\ln x)$  does there exist on the interval  $(0, 10)$ ?

**6.C.39.** Give an example of a function  $f$  on the interval  $I = [0, 1]$  that doesn't have a primitive function on  $I$ .

**6.C.40.** Using the Newton integral, compute

- (a)  $\int_0^\pi \sin x \, dx;$
- (b)  $\int_0^1 \operatorname{arctg} x \, dx;$
- (c)  $\int_{-\pi/4}^{3\pi/4} \frac{\cos x}{1 + \sin x} \, dx;$
- (d)  $\int_{1/e}^e |\ln x| \, dx.$

**6.C.41.** Compute

$$\int_1^2 \frac{x}{\sqrt{1+x^2}} \, dx.$$

function  $g(x)$  on a finite interval  $[a, b]$  define its *variation* by

$$\operatorname{var}_a^b g = \sup_{\Xi} \sum_{i=1}^n |g(x_i) - g(x_{i-1})|,$$

where the supremum is taken over all partitions  $\Xi$  of the interval  $[a, b]$ . If the supremum is infinite, we say that  $g(x)$  has unbounded variation on  $[a, b]$ . Otherwise we say that  $g$  is a function with bounded variation on  $[a, b]$ . A function is of bounded variation if and only if it can be written as the difference of two monotonic functions.

As in the discussion of the Riemann integral, we derive the following theorem. We invite the reader to add the details of its proof. The main tools are the mean theorem, the uniform continuity of continuous functions on closed bounded intervals. The variation of  $g$  over the interval  $[a, b]$  plays the role of the length of the interval in the earlier proofs dealing with Riemann integration.

PROPERTIES OF THE RIEMANN-STIELTJES INTEGRAL

**Theorem.** Let  $f(x)$  and  $g(x)$  be real functions on a finite interval  $[a, b]$ .

- (1) Suppose  $g(x)$  is non-decreasing and continuously differentiable. Then the Riemann integral on the left hand side and the Riemann-Stieltjes integral on the right hand side either both exist or do not exist. In the former case, their values are equal

$$\int_a^b f(x)g'(x)dx = \int_a^b f(x)dg(x)$$

- (2) If  $f(x)$  is continuous and  $g(x)$  is a function with finite variation, then the integral  $\int_a^b f(x)dg(x)$  exists.

**6.3.16. Kurzweil-Henstock integral.** The last topic in this chapter is a modification of the Riemann integral, which fixes the unfortunate behaviour at the third point in the paragraph 6.3.1. That is, the limits of the non-decreasing sequences of integrable functions are again integrable. Then we can interchange the order of the limit process and integration in these cases, just as with uniform convergence.

Notice what is the essence of the problem. Intuitively we assume that very small sets must have zero size. Thus the changes of values of the functions on such sets should not change the integral. Moreover, a countable union of such sets which are "negligible for the purpose of integration" should also have zero size. We would expect for example that the set of rational numbers inside a finite interval would have this property, hence its characteristic function should be integrable and the value of such an integral should be zero.

We say that a set  $A \subset \mathbb{R}$  has *zero measure*, if for every  $\varepsilon > 0$  there is a covering of the set  $A$  by a countable system

6.C.42. For arbitrary real numbers  $a < b$  determine

$$\int_a^b \operatorname{sgn} x \, dx.$$

Recall that  $\operatorname{sgn} x = 1$ , for  $x > 0$ ;  $\operatorname{sgn} x = -1$ , for  $x < 0$ ; and  $\operatorname{sgn} 0 = 0$ .

6.C.43. Compute the definite integral

$$\int_0^1 \frac{x^3}{1+x^4} \, dx.$$

6.C.44. For example by repeated integration by parts, compute

$$\int_0^{\pi/2} e^{2x} \cos x \, dx.$$

6.C.45. Determine

$$\int_{-1}^1 x^2 e^{-x} \, dx.$$

6.C.46. Compute the integral

$$\int_{-1}^1 \frac{x}{\sqrt{5-4x}} \, dx$$

using the substitution method.

6.C.47. Compute

(a)  $\int_1^{e^8} \frac{dx}{x\sqrt{1+\ln x}}$ ;  
 (b)  $\int_0^{\ln 2} \frac{x}{e^x} \, dx.$

6.C.48. Which of the positive numbers

$$p := \int_0^{\pi/2} \cos^7 x \, dx, \quad q := \int_0^{\pi} \cos^2 x \, dx$$

is bigger?

6.C.49. Determine the signs of these three numbers (values of integrals)

$$a := \int_{-2}^2 x^3 2^x \, dx; \quad b := \int_0^{\pi} \cos x \, dx; \quad c := \int_0^{2\pi} \frac{\sin x}{x} \, dx.$$

6.C.50. Order the numbers

of open intervals  $J_i, i = 1, 2, \dots$  such that

$$\sum_{i=1}^{\infty} m(J_i) < \varepsilon.$$

$m(J_i)$  means the length of the interval  $J_i$ .

In the sequel, the statement “function  $f$  has the given property on a set  $B$  almost everywhere” means that  $f$  has this property at all points except for a subset  $A \subset B$  of zero measure. For example, the characteristic function of rational numbers is zero almost everywhere. A piece-wise continuous function is continuous almost everywhere.

Now we modify the definition of the Riemann integral so that restrictions on the Riemann sums are permitted, eliminating the effect of the values of the integrated function on sets of measure zero. This is achieved by a finer control of the size of the segments in the partition in the vicinity of problematic points.

A positive real function  $\delta$  on a finite interval  $[a, b]$  is called a *gauge*. A partition  $\Xi$  of interval  $[a, b]$  with representatives  $\xi_i$  is  $\delta$ -gauged, if

$$\xi_i - \delta(\xi_i) < x_{i-1} \leq \xi_i \leq x_i < \xi_i + \delta(\xi_i)$$

for all  $i$ .

The norm  $\delta$  of the partition used in the Riemann integration is a special case of constant gauges  $\delta(x) = \delta > 0$ . In order to restrict the Riemann sums to a gauged partition with representatives in the definition of the integral, it is necessary to know that for every gauge  $\delta$ , a  $\delta$ -gauged partition with representatives exist. Otherwise the condition in the definition could be satisfied in a vacuous way. This statement is called *Cousin's lemma*. It is proved by exploiting the standard properties of suprema:

For a given gauge  $\delta$  on  $[a, b]$ , denote by  $M$  the set of all points  $x \in [a, b]$  such that a  $\delta$ -gauged partition with representatives can be found on  $[a, x]$ .  $M$  is nonempty and bounded, thus it has a supremum  $s$ . If  $s \neq b$ , then there is a gauged partition with representatives at  $s$ , where  $s$  is in the interior of the last segment. This leads to a contradiction. Thus the supremum is  $b$ , but then the gauge  $\delta(b) > 0$  and thus  $b$  itself belongs to the set  $M$ .

Now we can state the following generalization of the Riemann integral.

Call it the *K-integral*<sup>8</sup>.

<sup>8</sup>There are many equivalent definitions and thus also names for this K-integral. A complicated approach was coined by Arnaud Denjoy around 1912. Thus the space of real functions integrable on an interval  $[a, b]$  in this sense is often called *Denjoy space*. Other people involved were Nikolai Luzin and Oskar Perron. We can find the integral under their names. The simple and beautiful definition was introduced by Jaroslav Kurzweil, a Czech mathematician still living in 1957. Much of the theory was developed by Ralph Henstock (1923-2007), an English mathematician.

$$A := \int_0^{\pi/2} \cos x \sin^2 x \, dx, \quad B := \int_0^{\pi/2} \sin^2 x \, dx, \quad C := \int_{-1}^1 -x^5 5^x \, dx,$$

$$D := \int_{2\pi}^{10} \frac{x^2+2}{x^6+4} \, dx + \int_{\pi}^{2\pi} \frac{x^2+2}{x^6+4} \, dx + \int_{10}^{\pi} \frac{x^2+2}{x^6+4} \, dx$$

by size. ○

**6.C.51.** By considering the geometric meaning of the definite integral, determine

- (a)  $\int_{-2}^2 |x - 1| \, dx;$
- (b)  $\int_{-0,10}^{0,10} \operatorname{tg} x \, dx;$
- (c)  $\int_0^{2\pi} \sin x \, dx.$

**6.C.52.** Compute  $\int_{-1}^1 |x| \, dx.$

**6.C.53.** Determine

$$\int_{-1}^1 x^5 \sin^2 x \, dx.$$

**6.C.54.** Without using the symbols of differentiating and integrating, express

$$\left( \int_{x^2}^a 3t^2 \cos t \, dt \right)'$$

with variable  $x \in \mathbb{R}$  and a real constant  $a$ , if we differentiate with respect to  $x$ . ○

KURZWEIL-HENSTOCK INTEGRAL

**Definition.** A function  $f$  defined on a finite interval  $[a, b]$  has a *Kurzweil-Henstock* integral

$$I = \int_a^b f(x) \, dx,$$

if for every  $\varepsilon > 0$ , there exists a gauge  $\delta$  such that for every  $\delta$ -gauged partition with representatives  $\Xi$ , the inequality  $|S_{\Xi} - I| < \varepsilon$  is true for the corresponding Riemann sum  $S_{\Xi}$ .

**6.3.17. Basic properties.** When defining the K-integral, only the set of all partitions is bounded, for which the Riemann sums are taken into account. Hence if the function is Riemann integrable, then it is K-integrable, and the two integrals are equal.

For the same reason, the argumentation in Theorem 6.2.8 about simple properties of the Riemann integral applies. This verifies that the K-integral behaves in the same way. In particular, a linear combination of integrable function  $cf(x) + dg(x)$  is again integrable and its integral is  $c \int_a^b f(x)dx + d \int_a^b g(x)dx$  etc. To prove this, it suffices only to think through some modifications when discussing the refined partitions, which moreover should be  $\delta$ -gauged.

The Kurweil integral behaves as anticipated with respect to the sets of zero measure:

**Theorem.** Let the function  $f$ , which is zero almost everywhere be defined on the interval  $[a, b]$ . Then the K-integral  $\int_a^b f(x)d(x)$  exists and is zero.

**PROOF.** The proof is an illustration of the idea that the influence of values on a “small” set can be removed by a suitable choice of gauge. Denote by  $M$  the corresponding set of zero measure, outside of which  $f(x) = 0$  and write  $M_k \subset [a, b]$ ,  $k = 1, \dots$ , for the subset of the points for which  $k - 1 < |f(x)| \leq k$ . Because all the sets  $M_k$  have zero measure, each of them can be covered by a countable system of pairwise disjoint open intervals  $J_{k,i}$  such that the sum of their lengths is arbitrarily small.

Define the gauge  $\delta(x)$  for  $x \in J_{k,i}$  so that the intervals  $(x - \delta(x), x + \delta(x))$  are still contained in  $J_{k,i}$ . Outside of  $M$ ,  $\delta$  is defined arbitrarily.

For any  $\delta$ -gauged partition  $\Xi$  of the interval  $[a, b]$  the bound on the corresponding Riemann sum is given as

$$\left| \sum_{j=0}^{n-1} f(\xi_n)(x_{i+1} - x_i) \right| = \left| \sum_{\substack{j=0 \\ \xi_i \in M}}^{n-1} f(\xi_n)(x_{i+1} - x_i) \right|$$

$$\leq \sum_{k=1}^{\infty} \sum_{\substack{j=0 \\ \xi_i \in M_k}}^{n-1} |f(\xi_n)|(x_{i+1} - x_i)$$

$$\leq \sum_{k=1}^{\infty} k \left( \sum_{\substack{j=0 \\ \xi_i \in M_k}}^{n-1} m(J_{k,j}) \right).$$

To guarantee that this bound is smaller than a given  $\varepsilon$ , it suffices to choose the covering by the intervals  $J_{k,j}$  so that

$$\sum_{j=1}^{\infty} m(J_{k,j}) \leq \frac{\varepsilon}{k2^k}.$$

Since  $\sum_{k=1}^{\infty} 2^{-k} = 1$ , the result follows.  $\square$

**Corollary.** *If the values of  $f(x)$  are changed on a set of zero measure, the K-integrability of  $f(x)$  is not changed, and neither is the value of its integral.*

**6.3.18. The fundamental theorems of Calculus.** We conclude this chapter with a few remarks on the properties of integration procedures from the point of view of expectations and reality.<sup>9</sup>

In 6.2.9, we deal with the relation between the derivatives  $f'(t)$  and the antiderivatives (integrals)  $F(t)$ . Since  $f(t)$  is assumed continuous, two essential claims collapse into one, resulting in

$$F(t) = \int_{t_0}^t f(x) dx$$

up to the choice of the value of  $F(t_0)$ . In particular,

$$\int_{t_0}^t F'(dx) dx = F(t) - f(t_0)$$

for all choices of  $F$ .

More generally, this can be split into two claims which hold for the K-integral under much milder conditions:

#### 1ST AND 2ND FUNDAMENTAL THEOREMS OF CALCULUS

**Theorem.** (1) *Suppose the K-integral  $\int_a^b f(x) dx$  exists. Then  $F(t) = \int_a^t f(x) dx$  is continuous. The derivative  $F'(t)$  exists and equals  $f(t)$  almost everywhere.*  
 (2) *Suppose  $F(t)$  is a continuous function on  $[a, b]$  and suppose  $f(t) = F'(t)$  exists for all but countably many exceptional points  $t$  in  $[a, b]$ . If  $f(t)$  is defined arbitrarily at those points, then  $F(t) = \int_a^t f(x) dx$  exists for all  $t \in [a, b]$  and equals to  $F(t) - F(a)$ .*

**6.3.19. K-integrability and Lebesgue measure.** We illustrate the claims in the latter theorem on the indicator function  $\chi_{\mathbb{Q}}$  of the rational numbers. Clearly its K-integral

$$F(t) = \int_a^t \chi_{\mathbb{Q}}(x) dx$$

exists ( $\chi_{\mathbb{Q}}$  is zero almost everywhere) and equals zero. Its derivative  $F'(t)$  is identically zero, and equals  $\chi_{\mathbb{Q}}$  nearly everywhere. This is a good example of a bounded function which is

<sup>9</sup>A very good and elementary exposition of the K-integral can be found in the short paper *Return to the Riemann Integral*. The American Mathematical Monthly, Vol. 103, No. 8 (1996), 625-632. by Robert G. Bartle.

not Riemann integrable, but is integrable in the more general sense.

There are many more K-integrable functions than Riemann integrable functions. There is no difference between proper and improper integrals. More precisely, the K-integral  $\int_a^b f(x) dx$  exists if and only if the one-sided limit

$$\lim_{t \rightarrow a^-} \int_t^b f(x) dx$$

is well defined and their values coincide, and similarly for the upper limit  $b$ . This is due to the freedom in the choice of the gauges.

There is only an indirect proof that there are bounded functions on a compact interval which are not K-integrable, based on some set-theoretic arguments, but there are no explicit constructions of such functions available.

We say that a set of real numbers  $M$  is measurable if the K-integral of its indicator function  $\chi_M$  exists. The assignment  $m : M \mapsto \int_a^b \chi_M(x) dx$  for all sets  $M \subset [a, b]$  has the properties of a *measure*. The set of such measurable sets  $M$  is closed under finite intersections and countable unions. The measure  $m$  is additive with respect to unions of at most countable systems of pairwise disjoint sets.

This measure coincides with the *Lebesgue measure*. This measure is used in another concept of integration, which is extremely useful in higher dimensional applications, the *Lebesgue integral*. We do not go into more details here. We remark that a real function  $f$  is Lebesgue integrable if and only if its absolute value is K-integrable.

A big advantage of the K-integral compared to other concepts is the possibility of integrating many functions which are not integrable in absolute value. Compare the concepts of convergence and absolute convergence of series.

A typical example is the sinus integral over all reals. The K-integral of the sinc function  $\int_0^\infty \frac{\sin x}{x} dx$  exists, while the absolute value  $g(x) = |\text{sinc}(x)|$  is not Lebesgue integrable. Such integrals are important in models for signal processing where it is necessary to aggregate potentially infinite many interferences canceling each other by different signs.

**6.3.20. The convergence theorems.** We have dealt with uniform convergence and Riemann integrability. With the K-integral, there is a much nicer and stronger theorem available. A special case is the monotone convergence theorem for uniformly bounded functions  $f_0(x) \leq f_1(x) \leq \dots$ .

## DOMINATED CONVERGENCE THEOREM

**Theorem.** Suppose  $f_0, f_1, f_2, \dots$  are all  $K$ -integrable functions on an interval  $[a, b]$ , converging pointwise to the limit function  $f$ . If there are two  $K$ -integrable functions  $g$  and  $h$  satisfying

$$g(x) \leq f_n \leq h(x),$$

for all  $n \in \mathbb{N}$  and  $x \in [a, b]$ , then  $f$  is  $K$ -integrable too, and

$$\int_a^b f(t) dt = \lim_{n \rightarrow \infty} \int_a^b f_n(t) dt.$$

For monotone convergence, there is a stronger result saying that a sufficient and necessary condition for the  $K$ -integrability of the pointwise limit is  $\sup_n \int_a^b f_n(x) dx < \infty$ .

This theorem could not be applied in our third example in 6.3.2. There the functions  $f_n$  have a "bump" which gets larger but narrower when close to the origin. The functions cannot be dominated by an integrable function.

With the Riemann integral, a similar dominated convergence theorem can be proved, except that we have to guarantee the integrability of the pointwise limit  $f$ .

**D. Extra examples for the whole chapter**

**6.D.1.** Determine the significant properties of the function

$$f(x) = -\frac{x^2}{x+1}, \quad x \in \mathbb{R} \setminus \{-1\}.$$

By "significant properties" is meant items such as domain, range, zeros, extrema, stationary and inflection points, points of discontinuity, intervals of increasing, decreasing, convexity, concavity, and asymptotes if applicable. Briefly, all the relevant information required to sketch a graph.

**6.D.2.** Determine the significant properties of the function

$$f(x) = \frac{1-x^3}{x^2}.$$

**6.D.3.** Determine the significant properties of the function

$$f(x) = \frac{x^3 - 3x^2 + 3x + 1}{x - 1}.$$

**6.D.4.** Determine the significant properties of the function

$$f(x) = \sqrt[3]{x} e^{-x}.$$

**6.D.5.** Determine the significant properties of the function

$$f(x) = \operatorname{arctg} \frac{x}{2-x}.$$

**6.D.6.** Determine the significant properties of the function

$$\frac{\ln x}{x}.$$

Epecially, find the extremes, the points of inflection and the asymptotes and sketch its graph.

**6.D.7.** Determine the significant properties of the function

$$\ln(x^2 - 3x + 2) + x.$$

In particular, find the extremes, the points of inflection and the asymptotes:

**6.D.8.** Determine the significant properties of the function

$$(x^2 - 2)e^{x^2 - 1}.$$

In particular, find the extremes, the points of inflection and the asymptotes:

**6.D.9.** Determine the significant properties of the function

$$\ln(2x^2 - x - 1).$$

Among other things, find the extremes, the points of inflection and the asymptotes.

**6.D.10.** Determine the significant properties of the function

$$\frac{x^2 - 2}{x - 1}.$$

Among other things, find the extremes, the points of inflection and the asymptotes.

**6.D.11.** Using any basic formulas, determine a primitive function for the function

- (a)  $y = \sqrt{x \sqrt{x \sqrt{x}}}$ ,  $x \in (0, +\infty)$ ;  
 (b)  $y = (2^x + 3^x)^2$ ,  $x \in \mathbb{R}$ ;  
 (c)  $y = \frac{1}{\sqrt{4-4x^2}}$ ,  $x \in (-1, 1)$ ;  
 (d)  $y = \frac{\cos x}{1+\sin x}$ ,  $x \in \left(-\frac{\pi}{2}, \frac{3\pi}{2}\right)$ .

**6.D.12.** Find a primitive function for the function

$$y = e^x + \frac{3}{\sqrt{4-x^2}}$$

on the interval  $(-2, 2)$ .

**6.D.13.** Determine

$$\int \frac{x^3}{1+x^4} dx, \quad x \in \mathbb{R}.$$

**6.D.14.** Determine

$$\int \frac{4}{x^2-2x+3} dx, \quad x \in \mathbb{R}.$$

**6.D.15.** For  $x \in (0, 1)$ , compute

$$\int \left( \frac{x^2+1}{x(x^2-1)} + \frac{3}{\sqrt{4-4x^2}} + 4 \sin x - 5 \cos x \right) dx.$$

**6.D.16.** Determine the indefinite integrals

- (a)  $\int \operatorname{arctg} x dx$ ,  $x \in \mathbb{R}$ ;  
 (b)  $\int \frac{\ln x}{x} dx$ ,  $x > 0$

using integration by parts.

**6.D.17.** Determine

$$\int \frac{\sqrt{x}}{\sqrt{x+1}} dx, \quad x > 0.$$

**6.D.18.** Compute

- (a)  $\int x^n \ln x dx$ ,  $x > 0$ ,  $n \neq -1$ ;  
 (b)  $\int \frac{x}{1+x^4} dx$ ,  $x \in \mathbb{R}$ .

**6.D.19.** Determine

$$\int \frac{3x+5}{x^2+4x+8} dx, \quad x \in \mathbb{R}.$$

**6.D.20.** Compute the indefinite integral of the function

$$y = \frac{1}{(x^2+x+1)^2}, \quad x \in \mathbb{R}.$$

**6.D.21.** Determine

$$\int \frac{dx}{x^3+1}, \quad x \neq -1.$$

**6.D.22.** Integrate

$$\int \frac{1}{x^3-1} dx, \quad x \neq 1.$$

**6.D.23.** Compute the integral

$$\int \frac{x^3}{(x-1)(x-2)^2} dx, \quad x \in \mathbb{R} \setminus \{1, 2\}.$$

**6.D.24.** For  $x \in (0, \frac{\pi}{2})$ , compute

(a)  $\int \sin^3 x \cos^4 x dx$ ;

(b)  $\int \frac{1+\cos^2 x}{1+\cos 2x} dx$ ;

(c)  $\int 2 \sin^2 \frac{x}{2} dx$ ;

(d)  $\int \cos^2 x dx$ ;

(e)  $\int \cos^5 x \sqrt{\sin x} dx$ ;

(f)  $\int \frac{dx}{\sin^2 x \cos^4 x}$ ;

(g)  $\int \frac{dx}{\sin^3 x}$ ;

(h)  $\int \frac{dx}{\sin x}$ .

6.D.25. Compute the indefinite integral

$$\int \frac{1}{x^4 + 3x^3 + 5x^2 + 4x + 2} dx.$$

6.D.26. Compute the integral

$$\int_{\frac{\pi}{4}}^{\frac{\pi}{2}} \frac{\sin t}{1 - \cos^2 t} dt.$$

6.D.27. Compute the integral

$$\int_0^{\ln 2} \frac{dx}{e^{2x} - 3e^x}.$$

6.D.28. Compute:

(i)  $\int_0^{\frac{\pi}{2}} \sin x \sin 2x dx,$

(ii)  $\int \sin^2 x \sin 2x dx.$

6.D.29. Compute the improper integral

(a)  $\int_{-\infty}^{+\infty} \frac{dx}{1+x^2};$

(b)  $\int_0^{+\infty} \frac{dx}{x};$

(c)  $\int_0^4 \frac{2x^2 + \sqrt{x}}{x} dx;$

(d)  $\int_{-1}^1 \ln |x| dx.$

6.D.30. Determine

$$\int_0^{3\pi/2} \frac{\cos x}{1 + \sin x} dx.$$

6.D.31. Compute the improper integrals

$$\int_{-\infty}^{+\infty} \frac{1}{x^2 + x + 1} dx.$$

6.D.32. Compute

$$\int_{-\infty}^{+\infty} \frac{e^x}{e^{2x} + e^x + 1} dx.$$

6.D.33. By using the substitution method, compute

$$\int_{-\infty}^0 x e^{-x^2} dx; \quad \int_0^{\infty} \frac{e^{-(1/x)}}{x^2} dx.$$

**6.D.34.** Compute the integrals

$$\int_0^1 \frac{e^{-\sqrt{x}}}{\sqrt{x}} dx; \quad \int_1^4 \frac{e^{-\sqrt{x}}}{\sqrt{x}} dx; \quad \int_4^{+\infty} \frac{e^{-\sqrt{x}}}{\sqrt{x}} dx.$$

**6.D.35.** Find the values of  $\alpha \in \mathbb{R}$ , for which

- (a)  $\int_1^{+\infty} \frac{dx}{x^\alpha} \in \mathbb{R}$ ;  
 (b)  $\int_0^1 \frac{dx}{x^\alpha} \in \mathbb{R}$ ;  
 (c)  $\int_{-\infty}^{+\infty} \sin(\alpha x) dx \in \mathbb{R}$ .

**6.D.36.** For which  $p, q \in \mathbb{R}$  is the integral

$$\int_2^{+\infty} \frac{dx}{x^p (\ln x)^q}$$

finite?

**6.D.37.** Decide if the following is true:

- (a)  $\int_{-\infty}^{+\infty} \frac{dx}{x^2+3} \in \mathbb{R}$ ;  
 (b)  $\int_{-\infty}^{+\infty} \frac{dx}{x^2-3} \in \mathbb{R}$ ;  
 (c)  $\int_1^{+\infty} \frac{1+2\sin^3 x}{x^5+x^3+1} dx \in \mathbb{R}$ .

## Solutions of the exercises

**6.A.4.**  $\frac{2 \sin x}{\cos^3 x}$ .

**6.A.5.**  $p^{(5)}(x) = 12 \cdot 5!; p^{(6)}(x) = 0$ .

**6.A.6.**  $2^{12} e^{2x} + \cos x$ .

**6.A.7.**  $f^{(26)}(x) = -\sin x + 2^{26} e^{2x}$ .

**6.A.8.** All of them.

**6.A.9.** (a)  $v(0) = 6$  m/s; (b)  $t = 3$  s,  $s(3) = 16$  m; (c)  $v(4) = -2$  m/s,  $a(4) = -2$  m/s<sup>2</sup>.

**6.A.12.**  $\frac{\pi}{4} + \frac{1}{2}(x-1) - \frac{1}{4}(x-1)^2 + \frac{1}{12}(x-1)^3$ .

**6.A.13.** (a)  $1 + \frac{x^2}{2}$ ; (b)  $1 - \frac{x^2}{2}$ ; (c)  $x - \frac{x^3}{3}$ ; (d)  $x + \frac{x^3}{3}$ ; (e)  $x + x^2 + \frac{x^3}{3}$ .

**6.A.14.**  $2(x-1) - (x-1)^2 + \frac{2}{3}(x-1)^3 - \frac{1}{2}(x-1)^4$ .

**6.A.15.**  $\frac{-x^3}{3(1+x)^3}$ .

**6.A.16.**  $x - \frac{x^3}{6}; \sin 1^\circ \approx \frac{\pi}{180} - \frac{\pi^3}{6 \cdot 180^3}; \lim_{x \rightarrow 0^+} \frac{x \sin x - x^2}{x^4} = -\frac{1}{6}$ .

**6.A.17.**  $\sum_{k=0}^n \frac{2^k}{k!} x^k, n \geq 8, n \in \mathbb{N}$ .

**6.A.18.**  $(x-1)^3 + 3(x-1)^2 + (x-1) + 4$ .

**6.A.26.**  $1 - \frac{\pi^2}{10^2 \cdot 2} + \frac{\pi^4}{10^4 \cdot 4!}$ .

**6.A.27.**  $1 - 3x + \frac{7}{24}x^4$ ; above the tangent line.

**6.A.29.**  $\left(-\frac{\sqrt{2}}{2}, \frac{\sqrt{2}}{2}\right)$ .

**6.A.30.** It's convex on intervals  $(-\infty, 0)$  and  $(0, 1/2)$ ; concave on interval  $(1/2, +\infty)$ . It has only one asymptote, the line  $y = \pi/4$  ( $v \pm \infty$ ).

**6.A.31.** (a)  $y = 0$  at  $-\infty$ ; (b)  $x = 2$  - horizontal,  $y = 1$   $v \pm \infty$ .

**6.A.32.**  $y = 0$  for  $x \rightarrow \pm \infty$ .

**6.A.33.**  $y = \ln 10, y = x + \ln 3$ .

**6.B.1.**  $S_{\varepsilon_n, \sup} = \frac{n+1}{n}, S_{\varepsilon_n, \inf} = \frac{n-1}{n}$ ; yes, it is.

**6.B.15.**  $2x^3 + 3x^2 - 2x - 13 + \frac{-19x+53}{x^2-2x+4}$ .

**6.B.16.**  $x^3 - \frac{1}{3}x + \frac{2}{9} + \frac{5}{9(3x+2)}$ .

**6.B.17.** (a)  $\frac{2}{x-2} + \frac{3}{x+2} - \frac{1}{x+3}$ ; (b)  $\frac{2}{x} - \frac{1}{x^2} + \frac{1}{x^2+1} + \frac{x}{(x^2+1)^2}$ .

**6.B.18.**  $\frac{5}{x-2} + \frac{3}{x^3} - \frac{3}{x}$ .

**6.B.19.**  $\frac{3}{x+1} + \frac{4x-2}{x^2-4x+13}$ .

**6.B.20.**  $\frac{1}{x^2} - \frac{2}{x} + \frac{2x-3}{x^2-x+2}$ .

**6.B.21.**  $\frac{1}{x} - \frac{1}{x^2} + \frac{1}{x^3} - \frac{1}{x+1}$ .

**6.B.22.**  $\frac{A}{x-2} + \frac{B}{x^2} + \frac{C}{x} + \frac{Dx+E}{(3x^2+x+4)^2} + \frac{Fx+G}{3x^2+x+4}$ .

**6.B.23.**  $1 + \frac{1}{x^3} - \frac{3}{x} + \frac{5}{x-2}$ .

**6.B.24.** (a)  $3 \ln |x-2|$ ; (b)  $\frac{1}{(x-2)^2}$ .

**6.B.44.**  $\frac{1}{1-a}$  for  $a \in (0, 1)$ ,  $\infty$  else.

**6.C.2.**

$$\sum_{i=0}^{\infty} (-1)^i \frac{2^{2n-1}}{(2n)!} x^{2n},$$

 converges for all real  $x$ .

**6.C.3.**

$$\sum_{n=1}^{\infty} (-1)^{n+1} \frac{2^{2n-1}}{(2n)!} x^{2n},$$

 converges for all real  $x$ .

6.C.4.

$$f(x) = \sum_{n=1}^{\infty} \frac{3(-1)^{n+1}}{n} x^n,$$

converges for  $x \in (-1, 1]$ .

6.C.5. It's good to realize we're expanding  $\frac{1}{2} \ln(x)$ .

$$f(x) = \sum_{i=0}^{\infty} (-1)^{i+1} \frac{1}{2^i} (x-1)^i,$$

Converges on interval  $(0, 2]$ .

6.C.7. The error belongs to the interval  $(0, 1/200)$ .

$$6.C.8. 0 < \int_1^2 \frac{\cos^{10} x}{10} \ln x \, dx < \frac{1}{10}, \int_1^2 x \ln x \, dx = \ln 4 - \frac{3}{4}.$$

$$6.C.9. \int_1^2 \sqrt{x} \, dx = \frac{2}{3} (2\sqrt{2} - 1).$$

$$6.C.18. \sum_{n=0}^{\infty} \frac{(-1)^n}{(2n)!} x^{2n}.$$

6.C.19.  $y = \arctg x$ .

6.C.20. Exactly for  $x \in (-\frac{5}{2}, \frac{5}{2})$ , we have

$$\frac{1}{5+2x} = \frac{1}{5} \sum_{n=0}^{\infty} \left(-\frac{2}{5}\right)^n x^n.$$

$$6.C.21. \frac{1}{3} \sum_{n=0}^{\infty} \frac{2^n}{3^n} x^n.$$

6.C.22.

$$f(x) = 1/2 + \sum_{i=0}^{\infty} \frac{(-1)^{i+1} 2^{2i}}{(2i+1)!} \left(x - \frac{\pi}{4}\right)^{2i+1}.$$

The series converges for all  $x \in \mathbb{R}$ .

$$6.C.23. \sum_{n=0}^{\infty} \frac{e}{n!} (x-1)^n; \sum_{n=0}^{\infty} \frac{\ln^n 2}{n!} x^n.$$

6.C.24.  $f(x) = x$ ,  $x \in \mathbb{R}$ ; yes.

6.C.25. No.

$$6.C.26. \sum_{n=0}^{\infty} \frac{(-1)^n}{(2n)!} x^{2n}.$$

$$6.C.27. (a) 1 - \frac{\pi^2}{18^2 \cdot 2!} + \frac{\pi^4}{18^4 \cdot 4!}; (b) \frac{1}{2} - \frac{1}{5 \cdot 2^5}.$$

$$6.C.28. \sum_{n=0}^{\infty} \frac{1}{(2n+1)n!} x^{2n+1}.$$

6.C.29.  $y = \arctg x$ .

6.C.30. Exactly for  $x \in (-\frac{5}{2}, \frac{5}{2})$ , we have

$$\frac{1}{5+2x} = \frac{1}{5} \sum_{n=0}^{\infty} \left(-\frac{2}{5}\right)^n x^n.$$

6.C.31. (a)  $-\cotg x - x + C$ ; (b)  $\tg x - \cotg x + C$ .

6.C.32. (a)  $-x^2 \cos x + 2x \sin x + 2 \cos x + C$ ; (b)  $e^x (x^2 - 2x + 2) + C$ .

6.C.33.  $\frac{x^2}{4} (2 \ln^2 x - 2 \ln x + 1) + C$ .

6.C.34.  $(2x - x^2) e^x + C$ .

6.C.35. (a)  $\frac{(2x+5)^{11}}{22} + C$ ; (b)  $-\frac{1}{\ln x} + C$ ; (c)  $-\frac{1}{3} e^{-x^3} + C$ ; (d)  $5 \arcsin^3 x + C$ ; (e)  $\frac{\ln^2 x}{2} + C$ ;

(f)  $\arctg^2 \sqrt{x} + C$ ; (g)  $\frac{\sqrt{3}}{3} \arctg \left(\frac{\sqrt{3}}{3} e^x\right) + C$ ; (h)  $2 \sin \sqrt{x} - 2\sqrt{x} \cos \sqrt{x} + C$ .

6.C.36. For example  $1 - x = t^2 x$  gives  $\int \frac{-2}{(1+t^2)^4} dt$ ; and  $\sqrt{x^2 + x + 1} = x + y$  leads to  $\int \frac{2 dy}{y^2 + 2y - 2}$ .

6.C.37.  $\frac{\sqrt{2}}{2} \arctg (\sqrt{2} \tg x) + C$ .

6.C.38. Infinitely many.

6.C.39. For example,  $f$  can attain a value of 1 at rational points of the interval and be zero at irrational points.

6.C.40. (a) 2; (b)  $\frac{\pi}{4} - \frac{\ln 2}{2}$ ; (c)  $2 \ln(1 + \sqrt{2})$ ; (d)  $2 - \frac{2}{e}$ .

6.C.41.  $\sqrt{5} - \sqrt{2}$ .

$$6.C.42. |b| - |a|.$$

$$6.C.43. \frac{1}{4} \ln 2.$$

$$6.C.44. \frac{1}{5} (e^\pi - 2).$$

$$6.C.46. \frac{1}{6}.$$

$$6.C.47. (a) 4; (b) \frac{1 - \ln 2}{2}.$$

$$6.C.48. p < q.$$

$$6.C.49. a > 0; b = 0; c > 0.$$

$$6.C.50. C < D = 0 < A < B.$$

$$6.C.51. (a) 5; (b) 0; (c) 0.$$

$$6.C.52. 1.$$

$$6.C.53. 0.$$

$$6.C.54. -6x^5 \cos x^2.$$

**6.D.1.** The range is  $(-\infty, 0] \cup [4, +\infty)$ . Function  $f$  is not odd, even nor periodic. It has a single discontinuity  $x_0 = -1$  with

$$\lim_{x \rightarrow -1^+} f(x) = -\infty, \quad \lim_{x \rightarrow -1^-} f(x) = +\infty.$$

The function intersects the  $x$  axis only at the origin. It is positive for  $x < -1$  and not positive for  $x > -1$ . It can be shown easily that

$$\begin{aligned} \lim_{x \rightarrow -\infty} f(x) &= +\infty, & \lim_{x \rightarrow +\infty} f(x) &= -\infty; \\ f'(x) &= -\frac{x^2 + 2x}{(x+1)^2}, & f''(x) &= -\frac{2}{(x+1)^3}, \quad x \in \mathbb{R} \setminus \{-1\}. \end{aligned}$$

This implies that  $f$  is increasing on the intervals  $[-2, -1)$ ,  $(-1, 0]$  and decreasing on the intervals  $(-\infty, -2]$ ,  $[0, +\infty)$ . At the stationary point  $x_1 = 0$  it reaches a strict local maximum and at the stationary point  $x_2 = -2$  it has a local minimum  $y_2 = 4$ . It is convex on the interval  $(-\infty, -1)$  and concave on the interval  $(-1, +\infty)$ . It does not have a point of inflection. The line  $x = -1$  is a horizontal asymptote, the inclined asymptote at  $\pm\infty$  is the line  $y = -x + 1$ . For example,  $f(-3) = 9/2$ ,  $f'(-3) = -3/4$ ,  $f(1) = -1/2$ ,  $f'(1) = -3/4$ .

**6.D.1.** The function is defined and continuous on  $\mathbb{R} \setminus \{0\}$ . It is not odd, even, nor periodic. It is negative on the interval  $(1, +\infty)$ . The only point of intersection of the graph with the axes is the point  $[1, 0]$ . At the origin,  $f$  has a discontinuity of the second kind and its range is  $\mathbb{R}$ , because

$$\lim_{x \rightarrow 0} f(x) = +\infty, \quad \lim_{x \rightarrow +\infty} f(x) = -\infty, \quad \lim_{x \rightarrow -\infty} f(x) = +\infty.$$

Moreover,

$$\begin{aligned} f'(x) &= -\frac{x^3 + 2}{x^3}, \quad x \in \mathbb{R} \setminus \{0\}, \\ f''(x) &= \frac{6}{x^4}, \quad x \in \mathbb{R} \setminus \{0\}. \end{aligned}$$

The only stationary point is  $x_1 = -\sqrt[3]{2}$ . The function  $f$  is increasing on the interval  $[x_1, 0)$ , decreasing on the intervals  $(-\infty, x_1]$ ,  $(0, +\infty)$ . Hence at  $x_1$  it has a local minimum  $y_1 = 3/\sqrt[3]{4}$ . It has no points of inflection. It is convex on its whole domain. The line  $x = 0$  is a horizontal asymptote and the line  $y = -x$  is an inclined asymptote at  $\pm\infty$ .

**6.D.3.** The function is defined and continuous on  $\mathbb{R} \setminus \{1\}$ . It is not odd, even nor periodic. The points of intersection of the graph of  $f$  with the axes are the points  $[1 - \sqrt[3]{2}, 0]$  and  $[0, -1]$ . At  $x_0 = 1$ , the function has a discontinuity of the second kind and its range is  $\mathbb{R}$ , which follows from the limits

$$\lim_{x \rightarrow 1^-} f(x) = -\infty, \quad \lim_{x \rightarrow 1^+} f(x) = +\infty, \quad \lim_{x \rightarrow \pm\infty} f(x) = +\infty.$$

After the arrangement

$$f(x) = (x-1)^2 + \frac{2}{x-1}, \quad x \in \mathbb{R} \setminus \{1\},$$

it is not difficult to compute

$$\begin{aligned} f'(x) &= 2 \frac{(x-1)^3 - 1}{(x-1)^2}, \quad x \in \mathbb{R} \setminus \{1\}, \\ f''(x) &= 2 \frac{(x-1)^3 + 2}{(x-1)^3}, \quad x \in \mathbb{R} \setminus \{1\}. \end{aligned}$$

The only stationary point is  $x_1 = 2$ . The function  $f$  is increasing on the interval  $[2, +\infty)$ , decreasing on the intervals  $(-\infty, 1)$ ,  $(1, 2]$ . Hence at the point  $x_1$  it attains the local minimum  $y_1 = 3$ . It is convex on the intervals  $(-\infty, 1 - \sqrt[3]{2})$ ,  $(1, +\infty)$  and concave on the intervals  $(1 - \sqrt[3]{2}, 1)$ . The point  $x_2 = 1 - \sqrt[3]{2}$  is a point of inflection. The line  $x = 1$  is a horizontal asymptote. The function does not have any inclined asymptotes.

**6.D.4.** The function is defined and continuous on  $\mathbb{R}$ . It is not odd, even nor periodic. It attains positive values on the positive half-axis, negative values on the negative half-axis. The point of intersection of the graph of  $f$  with the axes is only at the point  $[0, 0]$ . The derivative is:

$$f'(x) = \frac{e^{-x}}{3\sqrt[3]{x^2}} - \sqrt[3]{x}e^{-x}, \quad x \in \mathbb{R} \setminus \{0\}, \quad f'(0) = +\infty,$$

$$f''(x) = \sqrt[3]{x}e^{-x} - \frac{2e^{-x}}{3\sqrt[3]{x^2}} - \frac{2e^{-x}}{9\sqrt[3]{x^5}}, \quad x \in \mathbb{R} \setminus \{0\}.$$

The only zero point of the first derivative is the point  $x_0 = 1/3$ . The function  $f$  is increasing on the interval  $(-\infty, 1/3]$  and decreasing on the interval  $[1/3, +\infty)$ . Hence at the point  $x_0$ , it has an absolute maximum  $y_0 = 1/\sqrt[3]{3e}$ . Since  $\lim_{x \rightarrow -\infty} f(x) = -\infty$ , its range is  $(-\infty, y_0]$ . The points of inflection are

$$x_1 = \frac{1-\sqrt{3}}{3}, \quad x_2 = 0, \quad x_3 = \frac{1+\sqrt{3}}{3}.$$

It is convex on the intervals  $(x_1, x_2)$  and  $(x_3, +\infty)$ , concave on the intervals  $(-\infty, x_1)$ ,  $(x_2, x_3)$ . The only asymptote is the line  $y = 0$  at  $+\infty$ , i.e.  $\lim_{x \rightarrow +\infty} f(x) = 0$ .

**6.D.5.** The function is defined and continuous on  $\mathbb{R} \setminus \{2\}$ . It is not odd, even nor periodic. It's positive exactly on the interval  $(0, 2)$ . The only point of intersection of the graph of  $f$  with the axes is the point  $[0, 0]$ . At  $x_0 = 2$ , the jump of size  $\pi$  is observed, as follows from the limits

$$\lim_{x \rightarrow 2^-} f(x) = \frac{\pi}{2}, \quad \lim_{x \rightarrow 2^+} f(x) = -\frac{\pi}{2}.$$

We have

$$f'(x) = \frac{1}{x^2 - 2x + 2}, \quad x \in \mathbb{R} \setminus \{2\},$$

$$f''(x) = \frac{2(1-x)}{(x^2 - 2x + 2)^2}, \quad x \in \mathbb{R} \setminus \{2\}.$$

The first derivative does not have a zero point. The function  $f$  is therefore increasing at every point of its domain. Since

$$\lim_{x \rightarrow -\infty} f(x) = -\frac{\pi}{4}, \quad \lim_{x \rightarrow +\infty} f(x) = -\frac{\pi}{4},$$

its range is the set  $(-\pi/2, \pi/2) \setminus \{-\pi/4\}$ . The function  $f$  is convex on the interval  $(-\infty, 1)$ , concave on the intervals  $(1, 2)$ ,  $(2, +\infty)$ . Thus the point  $x_1 = 1$  is a point of inflection with  $f(1) = \pi/4$ . The only asymptote is the line  $y = -\pi/4$  at  $\pm\infty$ .

**6.D.6.** Domain  $\mathbb{R}^+$ , global maximum  $x = e$ , point of inflection

$$x = \sqrt{e^3}$$

, increasing on  $(0, e)$ , decreasing on  $(e, \infty)$ , concave on  $(0, \sqrt{e^3})$ , convex on  $(\sqrt{e^3}, \infty)$ , asymptotes  $x = 0$  and  $y = 0$ ,  $\lim_{x \rightarrow 0} f(x) = -\infty$ ,  $\lim_{x \rightarrow \infty} f(x) = 0$ .

**6.D.7.** Domain  $\mathbb{R} \setminus [1, 2]$ . Local maximum  $x = \frac{1-\sqrt{5}}{2}$ , concave on the whole domain, asymptotes  $x = 1$ ,  $x = 2$ .

**6.D.8.** Domain  $\mathbb{R}$ . Local minimas  $-1, 1$ , maximum at  $0$ . Even function. Points of inflection  $\pm \frac{1}{\sqrt{2}}$ , no asymptotes.

**6.D.9.** Domain  $\mathbb{R} \setminus [-\frac{1}{2}, 1]$ . No global extremes. No inflection points, asymptotes  $x = -\frac{1}{2}$ ,  $x = 1$ .

**6.D.10.** Domain  $\mathbb{R} \setminus \{1\}$ . No extremes. No points of inflection, convex on  $(-\infty, 1)$ , concave on  $(1, \infty)$ . Horizontal asymptote  $x = 1$ . Inclined asymptote  $y = x + 1$ .

**6.D.11.** (a)  $\frac{8}{15} x^{\frac{8}{7}} x^{\frac{7}{7}}$ ; (b)  $\frac{4^x}{\ln 4} + 2 \frac{6^x}{\ln 6} + \frac{9^x}{\ln 9}$ ; (c)  $\frac{\arcsin x}{2}$ ; (d)  $\ln(1 + \sin x)$ .

## Continuous tools for modelling

*How do we manage non-linear objects?  
– mainly by linear tools again...*

### A. Orthogonal systems of functions

If we want to understand three-dimensional objects, we often use (one or more) two-dimensional plane projections of them. The orthogonal projections are special in providing the closest images of the points of the objects in the chosen plane.

Similarly, we can understand complicated functions in terms of simpler ones. We consider their projections into the (real) vector space generated by those chosen functions. Perhaps we recall from Chapter 2 that the orthogonal projections

In this chapter, we mainly deal with applications of the tools of differential and integral calculus. We consider a variety of problems related to functions of one real variable.

The tools and procedures are similar to the ones shown in Chapter 3, i.e. we consider linear combinations of selected generators and linear transformations.

This chapter serves also as a useful consolidation of background material before considering functions of several variables, differential equations, and the calculus of variations.

We begin by asking how to approximate a given function by linear combinations from a given set of generators. Approximation considerations lead to the general concept of distance. We illustrate the concepts on rudiments of the Fourier series. Our intuition from the Euclidean spaces of low dimensions is extended to infinite dimensional spaces, particularly the concept of orthogonal projections.

The next part of this chapter focuses on integral operators. These are linear mappings on functions which are defined in terms of integrals. Especially, we pay attention to convolutions and Fourier analysis. Throughout all these considerations, we work with real or complex valued functions of one variable.

Only then do we introduce the elements of the theory of metric spaces. This should enlighten the concepts of convergence and approximation on infinite dimensional spaces of functions. It will also cover our needs in analysis on Euclidean spaces  $\mathbb{R}^n$  in the next chapter.

### 1. Fourier series

**7.1.1. Spaces of functions.** As usual, we begin by choosing appropriate sets of functions to use. We want enough functions so that our models can conveniently be applied in practice. At the same time, the functions must be sufficiently “smooth” so that we can integrate and differentiate as needed.

All functions are defined on an interval  $I = [a, b] \subset \mathbb{R}$ , where  $a < b$ . The interval may be bounded, (i.e., both  $a$  and  $b$  are finite), or unbounded (i.e., either  $a = -\infty$ , or  $b = +\infty$ , or both).

were easily computed in terms of inner products. Now we do the same for the infinite dimensional spaces of functions.

The inner product mimics the product of scalars. Actually, the simplest way is to introduce the inner product to suitable vector spaces of functions on a given interval  $I = [a, b] \subset \mathbb{R}$  in this way:

$$\langle f, g \rangle = \int_a^b f(x)g(x) \, dx.$$

We refer to this inner product as  $L_2$ , see 7.1.3 for more information, including the complex valued functions.

Such a scalar product allows us to calculate the projections to finite dimensional subspaces in the same way as we did in finite dimensional vector spaces.

**7.A.1.** Given the vector subspace  $\langle x^2, 1/x \rangle$  of the space of real-valued functions on the interval  $[1, 2]$ , with the  $L_2$  product, complete the function  $1/x$  to an orthogonal basis of the subspace. Determine the orthogonal projection of the function  $x$  onto it, and compute the distance of the function  $x$  from this subspace.

**Solution.** First, consider the basis. It is required that the function  $1/x$  be one of the vectors of the basis. The vector space in question is generated by two linearly independent functions, thus its dimension is 2. All of the vectors in it are of the form  $a \cdot \frac{1}{x} + b \cdot x^2$  for some  $a, b \in \mathbb{R}$ . It remains to find one more vector of the basis which is orthogonal to the function  $f_1 = 1/x$ . According to the Gram–Schmidt process, we seek it in the form  $f_2 = x^2 + k \cdot \frac{1}{x}$ ,  $k \in \mathbb{R}$ . The real constant  $k$  can be determined from the condition of orthogonality:

$$0 = \left\langle \frac{1}{x}, x^2 + k \cdot \frac{1}{x} \right\rangle = \left\langle \frac{1}{x}, x^2 \right\rangle + k \left\langle \frac{1}{x}, \frac{1}{x} \right\rangle.$$

Therefore,

$$k = -\frac{\langle \frac{1}{x}, x^2 \rangle}{\langle \frac{1}{x}, \frac{1}{x} \rangle} = -\frac{\int_1^2 \frac{1}{x} \cdot x^2 \, dx}{\int_1^2 \frac{1}{x} \cdot \frac{1}{x} \, dx} = -3.$$

Thus, the requested orthogonal basis is  $(\frac{1}{x}, x^2 - \frac{3}{x})$ .

Next, we calculate the projection  $p_x$  of the function  $x$  onto this subspace (see (1) on page 110). We find

$$\begin{aligned} p_x &= \frac{\langle x, \frac{1}{x} \rangle}{\langle \frac{1}{x}, \frac{1}{x} \rangle} \cdot \frac{1}{x} + \frac{\langle x, x^2 - \frac{3}{x} \rangle}{\langle x^2 - \frac{3}{x}, x^2 - \frac{3}{x} \rangle} \cdot (x^2 - \frac{3}{x}) \\ &= \frac{2}{x} + \frac{15}{34} \left(x^2 - \frac{3}{x}\right). \end{aligned}$$

SPACES OF PIECEWISE SMOOTH FUNCTIONS

We denote by  $\mathcal{S}^0 = \mathcal{S}^0[a, b]$  the set of all piecewise continuous functions on  $I = [a, b]$  with real or complex values. Otherwise put, all functions  $f$  in  $\mathcal{S}^0 = \mathcal{S}^0[a, b]$  have only finitely many points of discontinuity on bounded intervals. Moreover,  $f$  has finite one-sided left and right limits at every point in  $[a, b]$ . In particular,  $f$  is bounded on all bounded subintervals.

For every natural number  $k \geq 1$ , we consider the set of all piecewise continuous functions  $f$  such that all their derivatives up to order  $k$  (inclusive) lie in  $\mathcal{S}^0$ . We denote this set by  $\mathcal{S}^k[a, b]$ , or briefly  $\mathcal{S}^k$ . Note that the derivatives of functions in  $\mathcal{S}^k$  need not exist at all points, but their one-sided limits must exist.

If the interval  $I$  is unbounded, we often consider only those functions with compact support. A function with compact support means that it is identically zero outside some bounded interval of the real line. For unbounded intervals, we denote by  $\mathcal{S}_c^k$  the subset of those functions in  $\mathcal{S}^k$  which have compact support.

Functions in  $\mathcal{S}^0$  are always Riemann integrable on the bounded interval  $I = [a, b]$ , with both

$$\int_a^b |f(x)| \, dx < \infty, \quad \text{and} \quad \int_a^b |f(x)|^2 \, dx < \infty.$$

Both integrals are finite for unbounded intervals if the function  $f$  has compact support.

**7.1.2. Distance between functions.** The properties of limits and derivatives ensure that  $\mathcal{S}^k$  and  $\mathcal{S}_c^k$  are vector spaces. In finite-dimensional spaces, the distance between vectors can be expressed by means of the differences of the coordinate components. In spaces of functions, we proceed analogously and utilize the absolute value of real or complex numbers and the Euclidean distance in the following way:

THE  $L_1$  DISTANCE OF FUNCTIONS

The  $L_1$ -distance between functions  $f$  and  $g$  in  $\mathcal{S}_c^0$  is defined by

$$\|f - g\|_1 = \int_a^b |f(x) - g(x)| \, dx.$$

If  $g = 0$ , then the distance from  $f$  to the zero function, namely  $\|f\|_1$ , is called the  $L_1$ -norm (ie. length, or size) of  $f$ .

The  $L_1$ -distance between functions  $f$  and  $g$  (when both are real valued) expresses the area enclosed by the graphs of these functions, regardless of which function takes greater values. We observe that  $\|f - g\|_1 \geq 0$ .

Since  $f$  and  $g$  are both piecewise continuous functions,  $\|f - g\|_1 = 0$  only if  $f$  and  $g$  differ in their values at most at the points of discontinuity, and hence at only finitely many points on any bounded interval. Recall that we can change

Finally, the distance of a vector from the subspace is given by the norm of the difference between this vector and its projection. In this case:

$$\begin{aligned} \|x - p_x\|_2 &= \left( \int_1^2 \left( x - \frac{2}{x} - \frac{15}{34} \left( x^2 - \frac{3}{x} \right) \right)^2 dx \right)^{\frac{1}{2}} \\ &= \frac{1}{\sqrt{408}} \doteq 0.0495. \end{aligned} \quad \square$$

**7.A.2.** Consider the real vector space of functions on the interval  $[1, 2]$  generated by the functions  $\frac{1}{x}, \frac{1}{x^2}, \frac{1}{x^3}$  with the  $L_2$  product. Complete the function  $\frac{1}{x}$  to an orthogonal basis of this space. Determine also the projection of the functions  $\frac{1}{x^4}$  and  $x$  onto the above vector space. Then find their distances from this vector space.

**Solution.** As in the previous exercise, use the Gram–Schmidt orthogonalization process (with the given scalar product). Successively,

$$\begin{aligned} f_1(x) &= \frac{1}{x}, \\ f_2(x) &= \frac{1}{x^2} - \frac{3}{4x}, \\ f_3(x) &= \frac{1}{x^3} - \frac{3}{2x^2} + \frac{13}{24x}. \end{aligned}$$

The projection of  $\frac{1}{x^4}$  is  $\frac{15}{32}f_1 + \frac{69}{40}f_2 + \frac{9}{4}f_3$  while the distance is  $\frac{\sqrt{14}}{2240} = 0.00167$ .

The projection of  $x$  is  $2f_1 + 96(-\frac{3}{4} + \ln(2))f_2 + 5760(-\frac{3}{2}\ln(2) + \frac{25}{24})f_3$ , while the distance is approximately 0.035.

The illustrations show the functions  $x$  and  $1/x^4$  and their approximations. We can see that the function  $\frac{1}{x^4}$ , which is the one whose shape is similar to that of one or more generators, is approximated much better by the projection.  $\square$

But there are plenty of inner products on functions. We mention two of them in the following exercises.

**7.A.3.** Verify that for each interval  $I = [a, b] \subset \mathbb{R}$  and positive continuous function  $\omega$  on  $I$ , the formula

the value of any function at a finite number of points, without changing the value of the integral.

If in particular,  $f$  and  $g$  are both continuous on  $[a, b]$ , then  $\|f - g\|_1 = 0$  implies  $f(x) = g(x)$  for all  $x \in [a, b]$ . Indeed, if  $f(x_0) \neq g(x_0)$  at a point  $x_0, a \leq x_0 \leq b$ , and if  $f$  and  $g$  are both continuous at  $x_0$ , then  $f$  and  $g$  also differ on some small neighbourhood of  $x_0$ , and this neighbourhood, in turn, contributes a non-zero value into the integral, so that then  $\|f - g\|_1 > 0$ .

If we have three functions  $f, g$ , and  $h$ , then, of course,

$$\begin{aligned} \int_a^b |f(x) - g(x)| dx &= \int_a^b |f(x) - h(x) + h(x) - g(x)| dx \\ &\leq \int_a^b |f(x) - h(x)| dx + \int_a^b |h(x) - g(x)| dx, \end{aligned}$$

so the usual triangle inequality

$$\|f - g\|_1 \leq \|f - h\|_1 + \|h - g\|_1$$

holds. To derive this inequality, we used only the triangle inequality for the scalars; thus it is valid for functions  $f, g \in \mathcal{S}_c^0$  with complex values as well.

$\|f - g\|_1$  is not the only way to measure distance between two functions  $f$  and  $g$ . For another way:

THE  $L_2$ -DISTANCE

The  $L_2$ -distance between functions  $f$  and  $g$  in  $\mathcal{S}_c^0$  is defined by

$$\|f - g\|_2 = \left( \int_a^b |f(x) - g(x)|^2 dx \right)^{1/2}.$$

If  $g = 0$ , then  $\|f\|_2$ , the distance from  $f$  to the zero function, is called the  $L_2$  norm of  $f$ .

Clearly  $\|f\|_2 \geq 0$ . Moreover,  $\|f\|_2 = 0$ , implies that  $f(x) = 0$  for all  $x$  except for a finite set of points in any bounded interval. As above for the  $L_1$  norm,  $\|f - g\|_2 = 0$  only if  $f$  and  $g$  differ in their values at most at the points of discontinuity, and hence at only finitely many points on any bounded interval. In particular, if  $f$  and  $g$  are both continuous for all  $x$ , then  $\|f - g\|_2 = 0$  implies  $f(x) = g(x)$  for all  $x$ .

The square of  $\|f\|_2$  for a function  $f$  is

$$\|f\|_2^2 = \int_a^b |f(x)|^2 dx$$

and it is related to the well-defined symmetric bilinear mapping of real or complex functions to scalars

$$\langle f, g \rangle = \int_a^b f(x)\overline{g(x)} dx$$

since

$$\langle f, f \rangle = \int_a^b f(x)\overline{f(x)} dx = \int_a^b |f(x)|^2 dx = \|f\|_2^2.$$

We can use therefore all the properties of inner products in unitary spaces as described in Chapter 3. In particular, the

$$\langle f, g \rangle_\omega = \int_a^b f(x)g(x)\omega(x) dx$$

defines an inner product on the continuous functions on  $I$ . Verify that choosing  $I = (-1, 1)$  and  $\omega(x) = (1 - x^2)^{-1/2}$ , the functions

$$T_k(x) = \cos(k \arccos(x)), \quad k \in \mathbb{N},$$

form an orthogonal system of polynomials with respect to this inner product. These polynomials are called *Chebyshev polynomials*.

**Solution.** We compare the defining formula with the  $L_2$  inner product above: Consider the substitution  $x = \varphi(z)$ , where  $\varphi$  is the inverse function to  $z = \int_a^x \omega(t) dt$ . The inverse exists, since  $\omega$  is positive and so  $z$  is a strictly increasing function of  $x$ . Thus,  $dz = \omega(x)dx$  and

$$\begin{aligned} \langle f, g \rangle_\omega &= \int_a^b f(x)g(x)\omega(x) dx \\ &= \int_0^{\varphi^{-1}(b)} f(\varphi(z))g(\varphi(z)) dz. \end{aligned}$$

In particular, the “coordinate change”  $x = \varphi(z)$  identifies the vector space of continuous functions on  $I$  with the space of continuous function on another interval equipped with the  $L_2$  inner product and so  $\langle \cdot, \cdot \rangle_\omega$  is an inner product. Of course, the properties of the inner product can be checked directly.

In this special case,  $\omega(x) = \frac{d}{dx}(\arccos(x))$ , and thus the above substitution yields

$$\langle T_r, T_s \rangle_\omega = \int_0^\pi \cos(rz) \cos(sz) dz.$$

We are dealing with improper Riemann integrals (integrating the unbounded function  $\omega$ ), but this does not cause any problem. By using the well known trigonometric formula

$$\cos(rz) \cos(sz) = \frac{1}{2}(\cos((r - s)z) + \cos((r + s)z))$$

the integral is easily evaluated. It vanishes for all  $r \neq s$ .

The remaining task is to show that  $T_k(x)$  is a polynomial.

The definition itself shows directly that

$$T_0(x) = 1, \quad T_1(x) = x.$$

By the above trigonometric formula,

$$\begin{aligned} T_{n+1}(x) + T_{n-1}(x) &= \cos((n + 1) \arccos(x)) + \cos((n - 1) \arccos(x)) \\ &= 2 \cos(n \arccos(x)) \cos(\arccos(x)) = 2xT_n(x) \end{aligned}$$

so that for all positive  $n$ ,

$$T_{n+1}(x) = 2xT_n(x) - T_{n-1}(x).$$

inner product satisfies both linearity in the first argument and the Hermitian symmetry

$$\langle f, g \rangle = \overline{\langle g, f \rangle}.$$

It is a symmetric bilinear mapping in the real case.

**7.1.3. Orthogonality.** In Chapters 2 and 3, we dealt with finite-dimensional real or complex vector spaces. Most properties derived there concerned pairs or finite sets of vectors. Now, we can do just the same with functions. We restrict our definition of the inner product to any vector subspace generated by only finitely many functions  $f_1, \dots, f_k$  (over real or complex numbers, according to our need). We again obtain a well-defined inner product on this finite-dimensional vector subspace and so all our considerations from the finite dimensional linear algebra apply again.

As an example, consider the monomial functions  $f_i(x) = x^i$ ,  $i = 0, \dots, k$ . In  $\mathcal{S}^0$ , these generate the  $(k + 1)$ -dimensional vector subspace  $\mathbb{R}_k[x]$  of all polynomials of degree at most  $k$ . The inner product of two such polynomials is given by integration. Every polynomial of degree at most  $k$  is uniquely expressed as a linear combination of the generators  $f_0, \dots, f_k$ . Moreover, if we can arrange the choice of generators to satisfy

$$(1) \quad \langle f_i, f_j \rangle = \begin{cases} 0 & \text{for } i \neq j, \\ 1 & \text{for } i = j, \end{cases}$$

then the computations become much easier than they would otherwise.

Recall the Gram–Schmidt orthogonalization procedure, see 2.3.20. This procedure transforms any system of linearly independent generators  $f_i$  into new (again linearly independent) orthogonal generators  $g_i$  of the same subspace, i.e.  $\langle g_i, g_j \rangle = 0$  for all  $i \neq j$ . We can calculate them step by step. Put  $g_1 = f_1$ , and

$$g_{\ell+1} = f_{\ell+1} + a_1 g_1 + \dots + a_\ell g_\ell, \quad a_i = -\frac{\langle f_{\ell+1}, g_i \rangle}{\|g_i\|^2}$$

for  $\ell \geq 1$ .

To illustrate, we apply this procedure to the three polynomials  $1, x, x^2$  on the interval  $[-1, 1]$ . Put  $g_1 = 1$ , and generate the sequence

$$\begin{aligned} g_1 &= 1 \\ g_2 &= x - \frac{1}{\|g_1\|^2} \left( \int_{-1}^1 x \cdot 1 dx \right) \cdot g_1 = x - 0 = x \\ g_3 &= x^2 - \frac{1}{\|g_1\|^2} \left( \int_{-1}^1 x^2 \cdot 1 dx \right) \cdot g_1 - \\ &\quad \frac{1}{\|g_2\|^2} \left( \int_{-1}^1 x^2 \cdot x dx \right) \cdot g_2 = x^2 - \frac{1}{3}. \end{aligned}$$

The corresponding orthogonal basis of the space  $\mathbb{R}_2[x]$  of all polynomials of degree less than three on the interval  $[-1, 1]$  is  $1, x, x^2 - 1/3$ . Rescaling by appropriate numbers so that

This is the recurrent definition of Chebyshev polynomials. That all  $T_k(x)$  are polynomials now follows by induction.

□

**7.A.4.** Show that the choice of the weight function  $\omega(x) = e^{-x}$  and the interval  $I = [0, \infty)$  in the previous example leads to an inner product for which the *Laguerre polynomials*

$$L_n(x) = \sum_{k=0}^n \binom{n}{k} \frac{(-1)^k}{k!} x^k$$

form an orthonormal system. ○

**7.A.5.** Check that the orthonormal systems obtained in the previous two examples coincide with the result of the corresponding Gram-Schmidt orthogonalisation procedure applied to the system  $1, x, x^2, \dots, x^n, \dots$ , using the inner products  $\langle \cdot, \cdot \rangle_\omega$ , possibly only up to signs. ○

Given a finite-dimensional vector (sub)space of functions, calculate first the orthogonal (or orthonormal) basis of this subspace by the Gram-Schmidt orthogonalization process (see 2.3.20). Then determine the orthogonal projection as before. See the formula (1) at page 110.

**7.A.6.** Given the vector subspace  $\langle \sin(x), x \rangle$  of the space of real-valued functions on the interval  $[0, \pi]$ , complete the function  $x$  to an orthogonal basis of the subspace and determine the orthogonal projection of the function  $\frac{1}{2} \sin(x)$  onto it. ○

**7.A.7.** Given the vector subspace  $\langle \cos(x), x \rangle$  of the space of real-valued functions on the interval  $[0, \pi]$ , complete the function  $\cos(x)$  to an orthogonal basis of the subspace and determine the orthogonal projection of the function  $\sin(x)$  onto it. ○

### B. Fourier series

Having a countable system of orthogonal functions  $T_k$ ,  $k = 0, 1, \dots$ , as in the examples above, we may sequentially project a given function  $f$  to the subspaces  $V_k = \langle T_0, \dots, T_k \rangle$ . If the limit of these projections exists, this determines a series built on linear combinations of  $T_k$ . Under additional conditions, this should allow us to differentiate or integrate the function  $f$  in a similar way, as we did with the power series.

We consider one particular orthogonal system of periodic functions, namely that of J.B.J. Fourier.

The periodic functions are those describing periodic processes, i.e.  $f(t+T) = f(t)$  for some positive constant  $T \in \mathbb{R}$ ,

the basis elements all have length 1, yields the orthonormal basis

the basis elements all have length 1, yields the orthonormal basis

$$h_1 = \sqrt{\frac{1}{2}}, \quad h_2 = \sqrt{\frac{3}{2}}x, \quad h_3 = \frac{1}{2}\sqrt{\frac{5}{2}}(3x^2 - 1).$$

For example,  $h_1 = g_1/\|g_1\|$  and

$$\|g_1\|^2 = \int_{-1}^1 1^2 dx = 2.$$

We could easily continue this procedure in order to find orthonormal generators of  $\mathbb{R}_k[x]$ . The resulting polynomials are called *Legendre polynomials*.

Considering all Legendre polynomials  $h_i, i = 0, \dots$ , we have an infinite orthonormal set of generators such that polynomials of all degrees are uniquely expressed as their finite linear combinations.

**7.1.4. Orthogonal systems of functions.** Generalizing the latter example, suppose we have three polynomials  $h_1, h_2, h_3$  forming an orthonormal set. For any polynomial  $h$ , we can put

$$H = \langle h, h_1 \rangle h_1 + \langle h, h_2 \rangle h_2 + \langle h, h_3 \rangle h_3.$$

We claim that  $H$  is the (unique) polynomial which minimizes the  $L_2$ -distance  $\|h - H\|$ . See 3.4.3.

The coefficients for the best approximation of a given function by a function from a selected subspace are obtained by the integration introduced in the definition of the inner product.

This example of computing the best approximation of  $H$  by a linear combination of the given orthonormal generators suggests the following generalization:

#### ORTHOGONAL SYSTEMS OF FUNCTIONS

Every (at most) countable system of linearly independent functions in  $\mathcal{S}_c^0[a, b]$  such that the inner product of each pair of distinct functions is zero is called an *orthogonal system of functions*. If all the functions  $f_n$  in the sequence are pairwise orthogonal, and if for all  $n$ , the norm  $\|f_n\|_2 = 1$ , we talk about an *orthonormal system of functions*.

Consider an orthogonal system of functions  $f_n \in \mathcal{S}^0[a, b]$  and suppose that for (real or complex) constants  $c_n$ , the series

$$F(x) = \sum_{n=0}^{\infty} c_n f_n(x)$$

converges uniformly on a finite interval  $[a, b]$ . Notice that the limit function  $F(x)$  does not need to belong to  $\mathcal{S}^0[a, b]$ , but this is not our concern now.

By uniform convergence, the inner product  $\langle F, f_n \rangle$  can be expressed in terms of the particular summands (see the corollary 6.3.7), obtaining

$$\langle F, f_n \rangle = \sum_{m=0}^{\infty} c_m \int_a^b f_m(x) \overline{f_n(x)} dx = c_n \|f_n\|_2^2,$$

called the period of  $f$ , and all  $t \in \mathbb{R}$ . One of the fundamental periodic processes which occur in applications is a general simple harmonic oscillation in mechanics. The function  $f(t)$  which describes the position of the point mass on the line in the time  $t$  is of the form

$$(1) \quad f(t) = a \sin(\omega t + b)$$

for certain constants  $a, \omega > 0, b \in \mathbb{R}$ . In the diagram on the left,  $f(t) = \sin(t + 1)$  and on the right,  $f(t) = \sin(4t + 4)$ :

Applying the standard trigonometric formula

$$\sin(\alpha + \beta) = \cos \alpha \sin \beta + \sin \alpha \cos \beta,$$

with  $\alpha, \beta \in \mathbb{R}$ , we write the function  $f(t)$  alternatively as

$$(2) \quad f(t) = c \cos(\omega t) + d \sin(\omega t),$$

where  $c = a \sin b, d = a \cos b$ .

**7.B.1.** Show that the system of functions  $1, \sin(x), \cos(x), \dots, \sin(nx), \cos(nx), \dots$  is orthogonal with respect to the  $L_2$  inner product on the interval  $I = [-\pi, \pi]$ . ○

Building an orthogonal system of periodic functions  $\sin(nx)$  and  $\sin(nx + \pi/2) = \cos(nx)$  leads to the classical *Fourier series*.<sup>1</sup>

In application problems, we often meet the superposition of different harmonic oscillations. The superposition of finitely many harmonic oscillations is expressed by sums of functions of the form

$$f_n(x) = a_n \cos(n\omega x) + b_n \sin(n\omega x)$$

for  $n \in \{0, 1, \dots, m\}$ . These particular functions have prime period  $2\pi/(n\omega)$ . Therefore, their sum

$$(3) \quad \frac{a_0}{2} + \sum_{n=1}^m (a_n \cos(n\omega x) + b_n \sin(n\omega x))$$

is a periodic function with period  $T = 2\pi/\omega$ .

<sup>1</sup>The Fourier series are named in honour of the French mathematician and physicist Jean B. J. Fourier, who was the first to apply the Fourier series in practice in his work from 1822 devoted to the issue of heat conduction (he began to deal with this issue in 1804-1811). He introduced mathematical methods which even nowadays lie at the core of theoretical physics. He did not pay much attention to physics himself.

since each term in the sum is 0 except when  $m = n$ . Exactly as in the example above, each finite sum  $\sum_{n=0}^k c_n f_n(x)$  is the best approximation of the function  $F(x)$  among the linear combinations of the first  $k + 1$  functions  $f_n$  in the orthogonal system.

Actually, we can generalize the definition further to any vector space of functions with an inner product. See the exercise 7.A.3 for such an example. For the sake of simplicity we confine ourselves to the  $L_2$  distance, but the reader can check that the proofs work in general.

We extend our results from finite-dimensional spaces to infinite dimensional ones. Instead of finite linear combinations of base vectors, we have infinite series of pairwise orthogonal functions. The following theorem gives us a transparent and very general answer to the question as to how well the partial sums of such a series can approximate a given function:

**7.1.5. Theorem.** Let  $f_n, n = 1, 2, \dots$ , be an orthogonal sequence of (real or complex) functions in  $\mathcal{S}^0[a, b]$  and let  $g \in \mathcal{S}^0[a, b]$  be an arbitrary function. Put

$$c_n = \|f_n\|^{-2} \int_a^b g(x) \overline{f_n(x)} dx.$$

Then

(1) For any fixed  $n \in \mathbb{N}$ , the expression which has the least  $L_2$ -distance from  $g$  among all linear combinations of functions  $f_1, \dots, f_n$  is

$$h_n = \sum_{i=1}^n c_i f_i(x).$$

(2) The series  $\sum_{n=1}^{\infty} |c_n|^2 \|f_n\|^2$  always converges, and moreover

$$\sum_{n=1}^{\infty} |c_n|^2 \|f_n\|^2 \leq \|g\|^2.$$

(3) The equality  $\sum_{n=1}^{\infty} c_n^2 \|f_n\|^2 = \|g\|^2$  holds if and only if  $\lim_{n \rightarrow \infty} \|g - h_n\|_2 = 0$ .

Before presenting the proof, we consider the meaning of the individual statements of this theorem. Since we are working with an arbitrarily chosen orthogonal system of functions, we cannot expect that all functions can be approximated by linear combinations of the functions  $f_i$ .

For instance, if we consider the case of Legendre orthogonal polynomials on the interval  $[-1, 1]$  and restrict ourselves to even degrees only, surely we can approximate only even functions in a reasonable way. Nevertheless, the first statement of the theorem says that the best approximation possible (in the  $L_2$ -distance), is by the partial sums as described.

The second and third statements can be perceived as an analogy to the orthogonal projections onto subspaces in terms of Cartesian coordinates. Indeed, if for a given function  $g$ , the series  $F(x) = \sum_{n=1}^{\infty} c_n f_n(x)$  converges pointwise, then the function  $F(x)$  is, in a certain sense, the orthogonal projection of  $g$  into the vector subspace of all such series.

**7.B.2.** Show that the system of functions  $1, \sin(n\omega x), \cos(n\omega x)$ , for all positive integers  $n$  is orthogonal with respect to the  $L_2$  inner product on the interval  $[-\pi/\omega, \pi/\omega]$ .

○

When projecting a given function orthogonally to the subspace of functions (3), the key concept is the set of *Fourier coefficients*  $a_n$  and  $b_n, n \in \mathbb{N}$ .

**7.B.3.** Find the Fourier series for the periodic extension of the function

(a)  $g(x) = 0, x \in [-\pi, 0), \quad g(x) = \sin x, x \in [0, \pi);$

(b)  $g(x) = |x|, x \in [-\pi, \pi);$

(c)  $g(x) = 0, x \in [-1, 0), \quad g(x) = x + 1, x \in [0, 1).$

**Solution.** Before starting the computations, consider the illustrations of the resulting approximation of the given functions. The first two display the finite approximation in the cases a) and b) up to  $n = 5$ , while the third illustration for the case c) goes up to  $n = 20$ . Clearly the approximation of the discontinuous function is much slower and it also demonstrates the Gibbs phenomenon. This is the overshooting in the jumps, which is proportional to the magnitudes of the jumps.

The case (a). Direct calculation gives (using formulae from 7.1.6)

$$\begin{aligned} a_0 &= \frac{1}{\pi} \int_{-\pi}^{\pi} g(x) \, dx = \frac{1}{\pi} \int_{-\pi}^0 0 \, dx + \frac{1}{\pi} \int_0^{\pi} \sin x \, dx \\ &= \frac{1}{\pi} [-\cos x]_0^{\pi} = \frac{2}{\pi}, \end{aligned}$$

The second statement is called *Bessel's inequality* and it is an analogy of the finite-dimensional proposition that the size of the orthogonal projection of a vector cannot be larger than the original vector. The equality from the third statement is called *Parseval's theorem* and it says that if a given vector does not decrease in length by the orthogonal projection onto a given subspace, then it belongs to this subspace.

On the other hand, the theorem does not claim that the partial sums of the considered series need to converge pointwise to some function. There is no analogy to this phenomenon in the finite-dimensional world. In general, the series  $F(x)$  need not be convergent for any given  $x$ , even under the assumption of the equality in (3). However, if the series  $\sum_{n=1}^{\infty} |c_n|$  converges to a finite value, and if all the functions  $f_n$  are bounded uniformly on  $I$ , then, the series  $F(x) = \sum_{n=1}^{\infty} c_n f_n(x)$  converges at every point  $x$ . Yet it need not converge to the function  $g$  everywhere. We return to this problem later.

The proof of all of the three statements of the theorem is similar to the case of finite-dimensional Euclidean spaces. That is to be expected since the bounds for the distances of  $g$  from the partial sum  $f$  are constructed in the finite-dimensional linear hull of the functions concerned:

**PROOF OF THEOREM 7.1.5.** Choose any linear combination  $f = \sum_{n=1}^k a_n f_n$  and calculate its distance from  $g$ . We obtain

$$\begin{aligned} \|g - \sum_{n=1}^k a_n f_n\|^2 &= \int_a^b \left| g(x) - \sum_{n=1}^k a_n f_n(x) \right|^2 dx \\ &= \int_a^b |g(x)|^2 dx - \int_a^b \sum_{n=1}^k g(x) \overline{a_n f_n(x)} dx - \\ &\quad - \int_a^b \sum_{n=1}^k a_n f_n(x) \overline{g(x)} dx + \int_a^b \left| \sum_{n=1}^k a_n f_n(x) \right|^2 dx \\ &= \|g\|^2 - \sum_{n=1}^k \overline{a_n} c_n \|f_n\|^2 - \sum_{n=1}^k a_n \overline{c_n} \|f_n\|^2 + \sum_{n=1}^k a_n^2 \|f_n\|^2 \\ &= \|g\|^2 + \sum_{n=1}^k \|f_n\|^2 ((c_n - a_n) \overline{(c_n - a_n)} - |c_n|^2) \\ &= \|g\|^2 + \sum_{n=1}^k \|f_n\|^2 (|c_n - a_n|^2 - |c_n|^2). \end{aligned}$$

Since we are free to choose  $a_n$  as we please, we minimize the last expression by choosing  $a_n = c_n$ , for each  $n$ . This completes the proof of the first statement. With this choice of  $a_n$ , we obtain *Bessel's identity*

$$\|g - \sum_{n=1}^k c_n f_n\|^2 = \|g\|^2 - \sum_{n=1}^k |c_n|^2 \|f_n\|^2.$$

Since the left-hand side is non-negative, it follows that:

$$\sum_{n=1}^k c_n^2 \|f_n\|^2 \leq \|g\|^2.$$

$$\begin{aligned}
 a_n &= \frac{1}{\pi} \int_{-\pi}^{\pi} g(x) \cos(nx) \, dx \\
 &= \frac{1}{\pi} \int_{-\pi}^0 0 \, dx + \frac{1}{\pi} \int_0^{\pi} \sin x \cos(nx) \, dx \\
 &= \frac{1}{2\pi} \int_0^{\pi} \sin((1+n)x) + \sin((1-n)x) \, dx \\
 &= \frac{1}{2\pi} \left[ -\frac{\cos((1+n)x)}{1+n} - \frac{\cos((1-n)x)}{1-n} \right]_0^{\pi} \\
 &= \frac{1}{2\pi} \left( -\frac{\cos((1+n)\pi)}{1+n} - \frac{\cos((1-n)\pi)}{1-n} + \frac{1}{1+n} + \frac{1}{1-n} \right) \\
 &= \frac{1}{2\pi} \left( -\frac{(-1)^{1+n}}{1+n} - \frac{(-1)^{1-n}}{1-n} + \frac{1}{1+n} + \frac{1}{1-n} \right) \\
 &= \frac{1}{2\pi} \left( \frac{(-1)^n + 1}{1+n} + \frac{(-1)^n + 1}{1-n} \right) \\
 &= \frac{1}{\pi} \left( \frac{(-1)^n + 1}{1-n^2} \right), \quad n \in \mathbb{N}, n \neq 1, \\
 a_1 &= \frac{1}{2\pi} \int_0^{\pi} \sin(2x) \, dx = 0 \\
 b_1 &= \frac{1}{\pi} \int_{-\pi}^{\pi} g(x) \sin x \, dx = \frac{1}{\pi} \int_{-\pi}^0 0 \, dx + \frac{1}{\pi} \int_0^{\pi} \sin^2 x \, dx \\
 &= \frac{1}{2\pi} \int_0^{\pi} 1 - \cos(2x) \, dx = \frac{1}{2\pi} \left[ x - \frac{\sin(2x)}{2} \right]_0^{\pi} = \frac{1}{2}, \\
 b_n &= \frac{1}{\pi} \int_{-\pi}^{\pi} g(x) \sin(nx) \, dx \\
 &= \frac{1}{\pi} \int_0^{\pi} 0 \, dx + \frac{1}{\pi} \int_0^{\pi} \sin x \sin(nx) \, dx \\
 &= \frac{1}{2\pi} \int_0^{\pi} \cos((1-n)x) - \cos((1+n)x) \, dx \\
 &= \frac{1}{2\pi} \left[ \frac{\sin((1-n)x)}{1-n} - \frac{\sin((1+n)x)}{1+n} \right]_0^{\pi} = 0, \\
 &\text{for } n \in \mathbb{N} \setminus \{1\}.
 \end{aligned}$$

Thus, we arrive at the Fourier series

$$\frac{1}{\pi} + \frac{\sin x}{2} + \frac{1}{\pi} \sum_{n=2}^{\infty} \left( \frac{(-1)^n + 1}{1-n^2} \cos(nx) \right).$$

Since  $(-1)^n + 1 = 0$  when  $n$  is odd, and  $= 2$  when  $n$  is even, we can put  $n = 2m$  to obtain the series

$$\frac{1}{\pi} + \frac{\sin x}{2} - \frac{2}{\pi} \sum_{m=1}^{\infty} \frac{\cos(2mx)}{4m^2 - 1}.$$

The case (b). The given function is of a sawtooth-shaped oscillation. Its expression as a Fourier series is very important in practice. Since the function  $g$  is even on  $(-\pi, \pi)$ , it is immediate that  $b_n = 0$  for all  $n \in \mathbb{N}$ . Therefore, it suffices to determine  $a_n$  for  $n \in \mathbb{N}$ :

$$a_0 = \frac{1}{\pi} \int_{-\pi}^{\pi} g(x) \, dx = \frac{2}{\pi} \int_0^{\pi} x \, dx = \frac{2}{\pi} \left[ \frac{x^2}{2} \right]_0^{\pi} = \pi.$$

For other  $n \in \mathbb{N}$ , use integration by parts, to get

$$\begin{aligned}
 a_n &= \frac{1}{\pi} \int_{-\pi}^{\pi} g(x) \cos(nx) \, dx = \frac{2}{\pi} \int_0^{\pi} x \cos(nx) \, dx \\
 &= \frac{2}{\pi} \left[ \frac{x}{n} \sin(nx) \right]_0^{\pi} - \frac{2}{n\pi} \int_0^{\pi} \sin(nx) \, dx \\
 &= \frac{2}{n^2\pi} [\cos(nx)]_0^{\pi} = \frac{2}{n^2\pi} ((-1)^n - 1).
 \end{aligned}$$

So  $a_n = -\frac{4}{n^2\pi}$  for  $n$  odd,  $a_n = 0$  for  $n$  even.

Let  $k \rightarrow \infty$ . Since every non-decreasing sequence of real numbers which is bounded from above has a limit, it follows that

$$\sum_{n=1}^{\infty} c_n^2 \|f_n\|^2 \leq \|g\|^2,$$

which is Bessel's inequality.

If equality occurs in Bessel's inequality, then statement (3) follows straight from the definitions and the Bessel's identity proved above.  $\square$

An orthogonal system of functions is called a *complete orthogonal system* on an interval  $I = [a, b]$  for some space of functions on  $I$  if and only if Parseval's equality holds for every function  $g$  in this space.

**7.1.6. Fourier series.** The coefficients  $c_n$  from the previous theorem are called the *Fourier coefficients* of a given function in the (abstract) *Fourier series*.

The previous theorem indicates that we are able to work with countable orthogonal systems of functions  $f_n$  in much the same way as with finite orthogonal bases of vector spaces.

There are, however, essential differences:

- It is not easy to decide what the set of convergent or uniformly convergent series

$$F(x) = \sum_{n=1}^{\infty} c_n f_n$$

looks like.

- For a given integrable function, we can find only the “best approximation possible” by such a series  $F(x)$  in the sense of  $L_2$ -distance.

In the case when we have an orthonormal system of functions  $f_n$ , the formulae mentioned in the theorem are simpler, but still there is no further improvement in the approximations.

The choice of an orthogonal system of functions for use in practice should address the purpose for which the approximations are needed. The name “Fourier series” itself refers to the following choice of a system of real-valued functions:

FOURIER'S ORTHOGONAL SYSTEM

$$1, \sin x, \cos x, \sin 2x, \cos 2x, \dots, \sin nx, \cos nx, \dots$$

An elementary exercise on integration by parts shows that this is an orthogonal system of functions on the interval  $[-\pi, \pi]$ .

These functions are periodic with common period  $2\pi$  (see the definition below). “Fourier analysis”, which builds upon this orthogonal system, allows us to work with all piecewise continuous periodic functions with extraordinary efficiency. Since many physical, chemical, and biological data are perceived, received, or measured, in fact, by frequencies of the signals (the measured quantities), it is really an essential mathematical tool. Biologists and engineers often use the word “signal” in the sense of “function”.

This determines the Fourier series of a function of sawtooth-shaped oscillation as

$$\begin{aligned} & \frac{\pi}{2} + \frac{2}{\pi} \sum_{n=1}^{\infty} \left( \frac{(-1)^n - 1}{n^2} \cos(nx) \right) \\ &= \frac{\pi}{2} - \frac{4}{\pi} \sum_{n=1}^{\infty} \frac{\cos((2n-1)x)}{(2n-1)^2} \\ &= \frac{\pi}{2} - \frac{4}{\pi} \left( \cos x + \frac{\cos(3x)}{3^2} + \frac{\cos(5x)}{5^2} + \dots \right). \end{aligned}$$

This series could have been found by an easier means, namely by integrating the Fourier series of Heaviside's function (see "square wave function" in 7.1.9).

The case (c). The period for this function is  $T = 2$ , and so  $\omega = 2\pi/T = \pi$ . Use the more general formulae from 7.1.6, namely

$$\begin{aligned} a_0 &= \frac{2}{T} \int_{x_0}^{x_0+T} g(x) \, dx = \int_{-1}^1 g(x) \, dx \\ &= \int_{-1}^0 0 \, dx + \int_0^1 (x+1) \, dx = \frac{3}{2}, \\ a_n &= \frac{2}{T} \int_{x_0}^{x_0+T} g(x) \cos(n\omega x) \, dx = \int_{-1}^1 g(x) \cos(n\pi x) \, dx \\ &= \int_{-1}^0 0 \, dx + \int_0^1 (x+1) \cos(n\pi x) \, dx = \frac{(-1)^n - 1}{n^2 \pi^2}, \\ b_n &= \frac{2}{T} \int_{x_0}^{x_0+T} g(x) \sin(n\omega x) \, dx = \int_{-1}^1 g(x) \sin(n\pi x) \, dx \\ &= \int_{-1}^0 0 \, dx + \int_0^1 (x+1) \sin(n\pi x) \, dx = \frac{1-2(-1)^n}{n\pi}. \end{aligned}$$

The calculation of  $a_0$  was simple and needs no further comment. As for determining the integrals at  $a_n$  and  $b_n$ , it sufficed to use integration by parts once. Thus, the desired Fourier series is

$$\frac{3}{4} + \sum_{n=1}^{\infty} \left( \frac{(-1)^n - 1}{n^2 \pi^2} \cos(n\pi x) + \frac{1-2(-1)^n}{n\pi} \sin(n\pi x) \right).$$

Some refinements of the expression are available. For instance, for  $n \in \mathbb{N}$ ,

$$a_n = -\frac{2}{n^2 \pi^2} \text{ for } n \text{ odd, } \quad a_n = 0 \text{ for } n \text{ even,}$$

and, similarly,

$$b_n = \frac{3}{n\pi} \text{ for } n \text{ odd, } \quad b_n = -\frac{1}{n\pi} \text{ for } n \text{ even.}$$

□

In the next exercise we show that the calculation of the Fourier series does not always require an integration. Especially in the case when the function  $g$  is a sum of products (powers) of functions  $y = \sin(mx)$ ,  $y = \cos(nx)$  for  $m, n \in \mathbb{N}$ , one can rewrite  $g$  as a finite linear combination of basic functions.

PERIODIC FUNCTIONS

A real or complex valued function  $f$  defined on  $\mathbb{R}$  is called a *periodic function* with period  $T > 0$  if  $f(x+T) = f(x)$  for every  $x \in \mathbb{R}$ .

It is evident that sums and products of periodic functions with the same period are again periodic functions with the same period.

We note that the integral  $\int_{x_0}^{x_0+T} f(x) \, dx$  of a periodic function  $f$  on an interval whose length equals the period  $T$  is independent of the choice of  $x_0 \in \mathbb{R}$ . To prove it, it is enough to suppose  $0 \leq x_0 < T$ , using a translation by a suitable multiple of  $T$ . Then,

$$\begin{aligned} \int_{x_0}^{x_0+T} f(x) \, dx &= \int_{x_0}^T f(x) \, dx + \int_T^{x_0+T} f(x) \, dx \\ &= \int_{x_0}^T f(x) \, dx + \int_0^{x_0} f(x) \, dx = \int_0^T f(x) \, dx \end{aligned}$$

FOURIER SERIES

The series of functions

$$F(x) = \frac{a_0}{2} + \sum_{n=1}^{\infty} (a_n \cos(nx) + b_n \sin(nx))$$

from the theorem 7.1.5, with coefficients

$$\begin{aligned} a_n &= \frac{1}{\pi} \int_{x_0}^{x_0+2\pi} g(x) \cos(nx) \, dx, \\ b_n &= \frac{1}{\pi} \int_{x_0}^{x_0+2\pi} g(x) \sin(nx) \, dx, \end{aligned}$$

is called the *Fourier series* of a function  $g$  on the interval  $[x_0, x_0 + 2\pi]$ .

The coefficients  $a_n$  and  $b_n$  are called *Fourier coefficients of the function*  $g$ .

If  $T$  is the time taken for one revolution of an object moving round the unit circle at constant speed, then that constant speed is  $\omega = 2\pi/T$ . In practice, we often want to work with Fourier series with an arbitrary primary period  $T$  of the functions, not just  $2\pi$ . Then we should employ the functions  $\cos(\omega nx)$ ,  $\sin(\omega nx)$ , where  $\omega = \frac{2\pi}{T}$ . By substitution  $t = \omega x$ , we can verify the orthogonality of the new system of functions and recalculate the coefficients in the Fourier series  $F(x)$  of a function  $g$  on the interval  $[x_0, x_0 + T]$ :

$$F(x) = \frac{a_0}{2} + \sum_{n=1}^{\infty} (a_n \cos(n\omega x) + b_n \sin(n\omega x)),$$

which have values

$$\begin{aligned} a_n &= \frac{2}{T} \int_{x_0}^{x_0+T} g(x) \cos(n\omega x) \, dx, \\ b_n &= \frac{2}{T} \int_{x_0}^{x_0+T} g(x) \sin(n\omega x) \, dx. \end{aligned}$$

**7.B.4.** Determine the Fourier coefficients of the function

(a)  $g(x) = \sin(2x) \cos(3x)$ ,  $x \in [-\pi, \pi]$ ;

(b)  $g(x) = \cos^4 x$ ,  $x \in [-\pi, \pi]$ .

**Solution.** Case (a). Using suitable trigonometric identities,

$$\begin{aligned} \sin(2x) \cos(3x) &= \frac{1}{2}(\sin(2x + 3x) + \sin(2x - 3x)) \\ &= \frac{1}{2} \sin(5x) - \frac{1}{2} \sin x. \end{aligned}$$

It follows that the Fourier coefficients are all zero except for  $b_1 = -1/2$ ,  $b_5 = 1/2$ .

Case (b). Similarly, from

$$\begin{aligned} \cos^4 x &= (\cos^2 x)^2 = \left(\frac{1+\cos(2x)}{2}\right)^2 \\ &= \frac{1}{4}(1 + 2 \cos(2x) + \cos^2(2x)) \\ &= \frac{1}{4}\left(1 + 2 \cos(2x) + \frac{1+\cos(4x)}{2}\right) \\ &= \frac{3}{8} + \frac{1}{2} \cos(2x) + \frac{1}{8} \cos(4x), \quad x \in \mathbb{R}. \end{aligned}$$

Hence  $a_0 = 3/4$ ,  $a_2 = 1/2$ ,  $a_4 = 1/8$ , and the other coefficients are all zero.  $\square$

**7.B.5.** Given the Fourier series of a function  $f$  on the interval  $[-\pi, \pi]$  with coefficients  $a_m, b_n$ ,  $m \in \mathbb{N}$ ,  $n \in \mathbb{Z}^+$ , prove the following statements:

(a) If  $f(x) = f(x + \pi)$ ,  $x \in [-\pi, 0]$ , then  $a_{2k-1} = b_{2k-1} = 0$  for every  $k \in \mathbb{N}$ .

(b) If  $f(x) = -f(x + \pi)$ ,  $x \in [-\pi, 0]$ , then  $a_0 = a_{2k} = b_{2k} = 0$  for every  $k \in \mathbb{N}$ .

**Solution.** The case (a). For any  $k \in \mathbb{N}$ , the statement can be proved directly by calculations, but we provide here a conceptual explanation.

The definition of the function  $f$  ensures it is periodic with period  $\pi$ . Thus we may write its Fourier series on the shorter interval  $[-\frac{\pi}{2}, \frac{\pi}{2}]$  as follows

$$f(t) = \frac{\tilde{a}_0}{2} + \sum_{n=1}^{\infty} (\tilde{a}_n \cos(2nt) + \tilde{b}_n \sin(2nt)).$$

Clearly this must be also the Fourier series of the same function  $f$  over the interval  $[-\pi, \pi]$  and so the claim is proved.

Alternatively, if

$$f(x) = a_0/2 + \sum_{n=1}^{\infty} (a_n \cos(nx) + b_n \sin(nx))$$

then

$$\begin{aligned} f(x+\pi) &= a_0/2 + \sum_{n=1}^{\infty} (a_n \cos(nx+n\pi) + b_n \sin(nx+n\pi)) \\ &= a_0/2 + (-1)^n \sum_{n=1}^{\infty} (a_n \cos(nx) + b_n \sin(nx)) \end{aligned}$$

The two series are the same only when the odd coefficients are zero.

**7.1.7. The complex Fourier coefficients.** Parametrize the unit circle in the form:

$$e^{i\omega t} = \cos \omega t + i \sin \omega t.$$

For all integers  $m, n$  with  $m \neq n$ ,

$$\begin{aligned} \int_{-\pi}^{\pi} e^{imx} e^{-inx} dx &= \int_{-\pi}^{\pi} e^{i(m-n)x} dx \\ &= \frac{1}{i(m-n)} [e^{i(m-n)x}]_{-\pi}^{\pi} = 0. \end{aligned}$$

Thus for  $m \neq n$ , the integral  $\langle e^{imx}, e^{inx} \rangle = 0$ .

FOURIER'S COMPLEX ORTHOGONAL SYSTEM

$$e^{-n\omega t}, \dots, e^{-\omega t}, 1, e^{\omega t}, e^{2\omega t}, \dots, e^{n\omega t}, \dots$$

Note that if  $m = n$ , then

$$\int_{-\pi}^{\pi} e^{imx} e^{-imx} dx = \int_{-\pi}^{\pi} dx = 2\pi.$$

The orthogonality of this system can be easily used to recover the orthogonality of the real Fourier's system: Rewrite the above result as

$$\int_{-\pi}^{\pi} (\cos mx + i \sin mx)(\cos nx - i \sin nx) dx = 0$$

By expanding and separating into real and imaginary parts we get both

$$\int_{-\pi}^{\pi} (\cos mx \cos nx + \sin mx \sin nx) dx = 0$$

$$\int_{-\pi}^{\pi} (\sin mx \cos nx - \cos mx \sin nx) dx = 0$$

By replacing  $n$  with  $-n$ , we have also

$$\int_{-\pi}^{\pi} (\cos mx \cos nx - \sin mx \sin nx) dx = 0$$

$$\int_{-\pi}^{\pi} (\sin mx \cos nx + \cos mx \sin nx) dx = 0$$

and hence, with  $m \neq n$ ,

$$\int_{-\pi}^{\pi} \cos mx \cos nx dx = 0$$

$$\int_{-\pi}^{\pi} \sin mx \sin nx dx = 0$$

$$\int_{-\pi}^{\pi} \sin mx \cos nx dx = 0$$

which proves again the orthogonality of the real valued Fourier system.

Note the case  $m = n > 0$ , when

$$\int_{-\pi}^{\pi} \cos^2 nx dx = \|\cos(nx)\|_2^2 = \pi,$$

$$\int_{-\pi}^{\pi} \sin^2 nx dx = \|\sin(nx)\|_2^2 = \pi,$$

If  $n = 0$ , then  $\|1\|_2^2 = 2\pi$ .

The case (b). Similarly if

$$f(x) = a_0/2 + \sum_{n=1}^{\infty} (a_n \cos(nx) + b_n \sin(nx))$$

then  $-f(x + \pi)$

$$\begin{aligned} &= -a_0/2 - \sum_{n=1}^{\infty} (a_n \cos(nx + n\pi) + b_n \sin(nx + n\pi)) \\ &= -a_0/2 + (-1)^{n+1} \sum_{n=1}^{\infty} (a_n \cos(nx) + b_n \sin(nx)). \end{aligned}$$

The two series are the same only when the even coefficients are zero.  $\square$

**Complex Fourier series.** It is sometimes convenient (and often easier) to express the Fourier series using the complex coefficients  $c_n$  instead of the real coefficients  $a_n$  and  $b_n$ . This is a straightforward consequence of the facts

$$e^{in\omega x} = \cos(n\omega x) + i \sin(n\omega x) \quad \text{or, vice versa}$$

$$\cos(n\omega x) = \frac{1}{2}(e^{in\omega x} + e^{-in\omega x})$$

$$\sin(n\omega x) = \frac{1}{2i}(e^{in\omega x} - e^{-in\omega x}).$$

The resulting series for a real or complex valued function  $g$  on the interval  $[-\pi, \pi]$  is  $F(x) = \sum_{n=-\infty}^{\infty} c_n e^{inx}$  with

$$c_n = \frac{1}{2\pi} \int_{-\pi}^{\pi} e^{-inx} g(x) dx.$$

See the explanation in 7.1.7. We need just one formula for  $c_n$ , rather than one for  $a_n$  and another one for  $b_n$ .

**7.B.6.** Compute the complex version of the Fourier series  $F(x)$  of the  $2\pi$ -periodic function  $g(x)$  defined by  $g(x) = 0$ , if  $-\pi < x < 0$ , while  $g(x) = 1$  if  $0 < x < \pi$ .

**Solution.** We have for  $n \neq 0$ ,

$$c_n = \frac{1}{2\pi} \int_0^{\pi} e^{-inx} dx = \frac{1}{2\pi} \left[ \frac{e^{-inx}}{-in} \right]_0^{\pi} = \frac{1}{2\pi} \frac{(1 - (-1)^n)}{in}.$$

while  $c_0 = \frac{1}{2\pi} \int_0^{\pi} dx = 1/2$ . So

$$\begin{aligned} F(x) &= \frac{1}{2} + \sum_{n=1}^{\infty} c_n e^{inx} + \sum_{n=-\infty}^{-1} c_n e^{inx} \\ &= \frac{1}{2} + \sum_{n=1}^{\infty} \frac{1}{2\pi} \frac{(1 - (-1)^n)}{in} e^{inx} + \sum_{n=-\infty}^{-1} \frac{1}{2\pi} \frac{(1 - (-1)^n)}{in} e^{inx} \end{aligned}$$

For a (real or complex) function  $f(t)$  with  $-T/2 \leq t \leq T/2$ , and all integers  $n$ , we can define, in this context, its *complex Fourier coefficients* by the complex numbers

$$c_n = \frac{1}{T} \int_{-T/2}^{T/2} f(t) e^{-i\omega nt} dt.$$

The relation between the coefficients  $a_n$  and  $b_n$  of the Fourier series (after recalculating the formulae for these coefficients for functions with a general period of length  $T$ ) and these complex coefficients  $c_n$  follow from the definitions.  $c_0 = a_0/2$ , and for natural numbers  $n$ , we have

$$c_n = \frac{1}{2}(a_n - ib_n), \quad c_{-n} = \frac{1}{2}(a_n + ib_n).$$

If the function  $f$  is real valued,  $c_n$  and  $c_{-n}$  are complex conjugates of each other.

We note here that for real valued functions with period  $2\pi$ , the Bessel inequality in this notation becomes

$$(1/2)|a_0|^2 + \sum_{n=1}^{\infty} (|a_n|^2 + |b_n|^2) \leq \|f\|_2^2 = \frac{1}{\pi} \int_{-\pi}^{\pi} |f(t)|^2 dt.$$

We have expressed the Fourier series  $F(t)$  for a function  $f(t)$  in the form

$$F(t) = \sum_{n=-\infty}^{\infty} c_n e^{i\omega nt}.$$

In both cases of real or complex valued functions, the corresponding Fourier series can be written in this form. In general, the coefficients are complex. We return to this expression later, in particular when dealing with Fourier transforms.

For fixed  $T$ , the expression  $\omega = 2\pi/T$  describes how the frequency changes if  $n$  is increased by one.

We wish to show that the Fourier orthogonal system is complete on  $S^0[-\pi, \pi]$ . This needs a thorough technical preparation. So now, we only formulate the main result, and add some practical notes. The proof of the theorem will be discussed later, see 7.1.15.

**7.1.8. Theorem.** Consider a bounded interval  $[a, b]$  of length  $T = b - a$ . Let  $f$  be a real or complex valued function in  $S^1[a, b]$  (i.e. a piecewise continuous function with a piecewise continuous first derivative), extended periodically on  $\mathbb{R}$ . Then:

(1) The partial sums  $s_N$  of its Fourier series converge pointwise to the function

$$g(x) = \frac{1}{2} \left( \lim_{y \rightarrow x^+} f(y) + \lim_{y \rightarrow x^-} f(y) \right).$$

(2) Moreover, if  $f$  is a continuous periodic function with a piecewise continuous derivative, then the pointwise convergence of its Fourier series is uniform.

The  $L_2$ -distance  $\|s_N - f\|_2$  converges to zero for  $N \rightarrow \infty$ .

In the second of the sums, replace  $n$  with  $-n$ . The second sum is then  $\sum_{n=1}^{\infty} \frac{1}{2\pi} \frac{(1-(-1)^n)}{-in} e^{-inx}$  so that

$$\begin{aligned} F(x) &= \frac{1}{2} + \frac{1}{2\pi} \sum_{n=1}^{\infty} \frac{(1-(-1)^n)}{in} (e^{inx} - e^{-inx}) \\ &= \frac{1}{2} + \frac{1}{2\pi} \sum_{n=1}^{\infty} \frac{(1-(-1)^n)}{in} 2i \sin(nx) \\ &= \frac{1}{2} + \frac{1}{\pi} \sum_{n=1}^{\infty} \frac{(1-(-1)^n)}{n} \sin(nx). \end{aligned}$$

The terms when  $n$  is even are all 0. For  $n$  odd, put  $n = 2m-1$  to obtain

$$\begin{aligned} F(x) &= \frac{1}{2} + \frac{2}{\pi} \sum_{m=1}^{\infty} \left( \frac{1}{2m-1} \right) \sin(2m-1)x \\ &= \frac{1}{2} + \frac{2}{\pi} \left( \sin x + \frac{\sin 3x}{3} + \frac{\sin 5x}{5} + \dots \right). \end{aligned}$$

Clearly, this is similar to the one problem of 7.1.9 which also could have been used directly to obtain the result just by an easy transformation.  $\square$

**7.B.7.** Expand the following functions  $g(x)$  on the interval  $[-\pi, \pi]$  into the Fourier series, in the form  $F(x) = \sum_{n=-\infty}^{\infty} c_n e^{inx}$ .

- (i)  $g(x) = x$ , if  $-\pi < x < \pi$ .
- (ii)  $g(x) = |x|$ , if  $-\pi < x < \pi$ .
- (iii)  $g(x) = x^2$ , if  $-\pi < x < \pi$ .
- (iv)  $g(x) = 1$  if  $-1/2 \leq x \leq 1/2$  and  $g(x) = 0$  otherwise.
- (v)  $g(x) = 0$  if  $-\pi < x < 0$ , and  $g(x) = x$  if  $0 \leq x \leq \pi$ .

$\circ$

**7.B.8.** Repeat the task from the previous problem with the functions  $g$  defined again by the formulas (i) through (v), but taken on the interval  $0 < x < 2\pi$ .  $\circ$

**7.B.9.** Determine the convergence and uniform convergence of the Fourier series for the function

$g(x) = e^{-x}$ ,  $x \in [-1, 1)$ .

**Solution.** It is not necessary to calculate the corresponding Fourier series if we wish only to check convergence (for the similar calculation in the case of function  $e^x$  see 7.B.13). Define the function  $s(x)$  on  $\mathbb{R}$  with period  $T = 2$  as follows:

$$\begin{aligned} s(x) &= g(x) = e^{-x}, \quad x \in (-1, 1), \\ s(1) &= \frac{g(-1) + \lim_{x \rightarrow 1^-} g(x)}{2} = \frac{e + e^{-1}}{2}. \end{aligned}$$

**7.1.9. Periodic extension of functions.** The Fourier series converges, of course, outside the original interval  $[-T/2, T/2]$ , since it is a periodic function on  $\mathbb{R}$ . The Heaviside function  $g$  is defined by

$$g(x) = \begin{cases} -1 & \text{if } -\pi < x < 0, \\ 1 & \text{if } 0 < x < \pi \end{cases}$$

(We do not need to define the values at zero and at the end points of the interval, because these do not effect the coefficients of the Fourier series.) The periodic extension of the Heaviside function onto all of  $\mathbb{R}$  is usually called the *square wave function*.

Since  $g$  is an odd function, the coefficients of the functions  $\cos(nx)$  are all zero. The coefficients of  $\sin(nx)$ , are given by

$$\begin{aligned} b_n &= \frac{1}{\pi} \int_{-\pi}^{\pi} g(x) \sin(nx) dx = \frac{2}{\pi} \int_0^{\pi} \sin(nx) dx \\ &= \frac{2}{n\pi} (1 - (-1)^n). \end{aligned}$$

Thus the Fourier series of  $g$  is

$$g(x) = \frac{4}{\pi} \left( \sin(x) + \frac{1}{3} \sin(3x) + \frac{1}{5} \sin(5x) + \dots \right).$$

The partial sums of its first five and fifty terms, respectively, are shown in the following diagrams.

If the interval  $[-T/2, T/2]$  is chosen for the prime period  $T$  of such a square wave function, the resulting Fourier series is

$$g(x) = \frac{4}{\pi} \left( \sin(\omega x) + \frac{1}{3} \sin(3\omega x) + \frac{1}{5} \sin(5\omega x) + \dots \right).$$

The number  $\omega = \frac{2\pi}{T}$  is also called the *phase frequency* of the wave.

As the number of terms of the series increases, the approximation gets much better except in a (still shrinking) neighbourhood of the discontinuity point. There, the maximum of the deviation remains roughly the same. This is a general property of Fourier series and it is called the *Gibbs phenomenon*.

In accordance with 7.1.8(1), the Fourier series of the Heaviside function converges to the mean of the two one-sided limits at the points of discontinuity.

This function is the sum of the Fourier series in question, cf. Theorem 7.1.8. In other words, the Fourier series converges to the periodic function  $s(x)$ . Moreover, this convergence is uniform on every closed interval which contains none of the points  $2k + 1$ ,  $k \in \mathbb{Z}$ . This follows from the continuity of the functions  $g$  and  $g'$  on  $(-1, 1)$ . On the other hand, the convergence cannot be uniform on any interval  $(c, d)$  such that  $[c, d]$  contains an odd integer. This is because the uniform limit of continuous functions is always a continuous function, and the periodic extension of  $s$  is not continuous at the odd integers. Thus, the series converges to the function  $g$  on  $(-1, 1)$ , yet this convergence is uniform only on the subintervals  $[c, d]$  which satisfy the restriction  $-1 < c < d < 1$ .  $\square$

**7.B.10.** Determine the cosine Fourier series (see the definitions at the end of the paragraph 7.1.10) for a periodic extension of the function

$$g(x) = 1, x \in [0, 1), \quad g(x) = 0, x \in [1, 4).$$

Determine also the sine Fourier series for

$$f(x) = x - 1, x \in (0, 2), \quad f(x) = 3 - x, x \in [2, 4).$$

**Solution.** We have already encountered the construction of a cosine Fourier series in 7.B.4(b) and also 7.B.3(b). It is the case of the Fourier series of an even function. Therefore, the first thing we do is extend the definition of the function  $g$  to the interval  $(-4, 0)$  so that it is even. This means

$$g(x) := 1 \text{ for } x \in (-1, 0), \quad g(x) := 0 \text{ for } x \in (-4, -1].$$

Now we can consider its periodic extension onto the whole  $\mathbb{R}$  with period  $x_0 = -4, T = 8$  and  $\omega = \pi/4$ .

Necessarily  $b_n = 0$  for all  $n \in \mathbb{N}$  in a cosine Fourier series. We determine the Fourier coefficients  $a_n, n \in \mathbb{N}$

$$a_0 = \frac{2}{T} \int_{x_0}^{x_0+T} g(x) dx = \frac{2}{8} \int_{-1}^1 1 dx = \frac{1}{2} \int_0^1 1 dx = \frac{1}{2},$$

$$a_n = \frac{2}{T} \int_{x_0}^{x_0+T} g(x) \cos(n\omega x) dx = \frac{1}{2} \int_0^1 \cos \frac{n\pi x}{4} dx = \frac{2}{n\pi} \sin \frac{n\pi}{4}.$$

We use

$$(1) \quad \int_{-a}^a f(x) dx = 2 \int_0^a f(x) dx,$$

which is valid for every even function  $f$  integrable on the interval  $[0, a]$ .

The expression  $\sin(n\pi/4)$  is conveniently left as is, rather than the alternative of sorting out when it attains which

Of course, we cannot expect that the convergence of Fourier series for functions  $g$  with discontinuity points be uniform (then, the function  $g$  would have to be continuous itself, being a uniform limit of continuous functions). However, the convergence is uniform on any subinterval where the original function is continuous.

**7.1.10. Utilizing symmetry of functions.** We consider the problem of finding the Fourier series of the function  $f(x) = x^2$  on the interval  $[0, 1]$ . If we just periodically extend this function from the given interval  $[0, 1]$ , the resulting function would not be continuous, and so the convergence at integers would be as slow as in the case of a square wave function. However, we can easily extend the domain of  $f$  to the interval  $[-1, 1]$ , so that  $f(x) = x^2$  is an even function for  $-1 \leq x \leq 1$ . If we then extend periodically, the result is continuous. The resulting Fourier series then converges uniformly, and since then  $f$  is even, only the coefficients  $a_n$  are non-zero.

For  $n > 0$ , iterated application of integration by parts yields:

$$a_n = \frac{2}{2} \int_{-1}^1 x^2 \cos\left(\frac{2\pi nx}{2}\right) dx = 2 \int_0^1 x^2 \cos(\pi nx) dx = \frac{4}{\pi^2 n^2} (-1)^n.$$

The remaining coefficient is

$$a_0 = \frac{2}{2} \int_{-1}^1 x^2 dx = 2 \int_0^1 x^2 dx = \frac{2}{3}.$$

The entire series giving the periodic extension of  $x^2$  from the interval  $[-1, 1]$  thus equals

$$g(x) = \frac{1}{3} + \frac{4}{\pi^2} \sum_{n=1}^{\infty} \frac{(-1)^n}{n^2} \cos(\pi nx).$$

By the Weierstrass criterion, this series converges uniformly. Therefore,  $g(x)$  is continuous. By theorem 7.1.8,  $g(x) = f(x) = x^2$  on the interval  $[-1, 1]$ . Thus our series approximates the function  $x^2$  on the interval  $[0, 1]$  better (i.e. faster) than we could achieve with the periodic extension of the function from  $[0, 1]$  interval only. If we put  $x = 1$  and rearrange, we obtain the remarkable result

$$\frac{\pi^2}{4} \left(g(1) - \frac{1}{3}\right) = \frac{\pi^2}{6} = \sum_{n=1}^{\infty} \frac{(-1)^{2n}}{n^2} = \sum_{n=1}^{\infty} \frac{1}{n^2}.$$

We proceed with a further illustration. Because of the uniform convergence, we can differentiate term by term and calculate the Fourier series on the interval  $-1 < x < 1$ , for the function  $x$

$$x = \frac{2}{\pi} \sum_{n=1}^{\infty} \frac{(-1)^{n+1}}{n} \sin(\pi nx).$$

This series cannot converge uniformly since the periodic extension of the function  $x$  from the interval  $[-1, 1]$  is not a continuous function. However, it does converge pointwise

of its five different values. Thus we write the cosine Fourier series in the form:

$$\frac{1}{4} + \sum_{n=1}^{\infty} \left( \frac{2}{n\pi} \sin \frac{n\pi}{4} \cos \frac{n\pi x}{4} \right).$$

The sine Fourier transform of the function can be determined analogously from the odd extension of the given segment. Again,  $T = 8$  and  $\omega = \pi/4$  for the function  $f$ . This time it is the coefficients  $a_n, n \in \mathbb{N} \cup \{0\}$ , which are zero. To find the remaining coefficients, use integration by parts and (1) (the product of two odd functions is an even function). For all  $n \in \mathbb{N}$

$$\begin{aligned} b_n &= \frac{2}{T} \int_{x_0}^{x_0+T} f(x) \sin(n\omega x) dx \\ &= \frac{1}{2} \left( \int_0^2 (x-1) \sin \frac{n\pi x}{4} dx - \int_2^4 (x-3) \sin \frac{n\pi x}{4} dx \right) \\ &= \left[ (1-x) \frac{2}{n\pi} \cos \frac{n\pi x}{4} \right]_0^2 + \left[ \frac{8}{n^2\pi^2} \sin \frac{n\pi x}{4} \right]_0^2 \\ &\quad - \left[ (3-x) \frac{2}{n\pi} \cos \frac{n\pi x}{4} \right]_2^4 - \left[ \frac{8}{n^2\pi^2} \sin \frac{n\pi x}{4} \right]_2^4 \\ &= \frac{2}{n\pi} \left( (-1)^n - 1 \right) + \frac{16}{n^2\pi^2} \sin \frac{n\pi}{2}. \end{aligned}$$

Immediately,  $b_n = 0$  when  $n$  is even. So the sine Fourier series can be written

$$\begin{aligned} &\sum_{n=1}^{\infty} \left( \left( \frac{2}{n\pi} \left( (-1)^n - 1 \right) + \frac{16}{n^2\pi^2} \sin \frac{n\pi}{2} \right) \sin \frac{n\pi x}{4} \right) \\ &= \sum_{n=1}^{\infty} \left( \left( \frac{-4}{(2n-1)\pi} + \frac{(-1)^{n-1} 16}{(2n-1)^2\pi^2} \right) \sin \frac{(2n-1)\pi x}{4} \right). \quad \square \end{aligned}$$

**7.B.11.** Express the function  $g(x) = \cos x, x \in (0, \pi)$ , as the cosine Fourier series and the sine Fourier series.

**Solution.** Start with the sine series. This is the odd extension of the cosine function.

Necessarily,  $a_n = 0, n \in \mathbb{N} \cup \{0\}$  for the sine series.

$$\begin{aligned} b_1 &= \frac{2}{\pi} \int_0^{\pi} \cos x \sin x dx = \frac{1}{\pi} \int_0^{\pi} \sin(2x) dx = 0. \text{ For all } n \\ b_n &= \frac{2}{\pi} \int_0^{\pi} \cos x \sin(nx) dx \\ &= \frac{1}{\pi} \int_0^{\pi} \sin((n+1)x) + \sin((n-1)x) dx \\ &= -\frac{1}{\pi} \left[ \frac{\cos((n+1)x)}{n+1} + \frac{\cos((n-1)x)}{n-1} \right]_0^{\pi} = \frac{2n \left( (-1)^n + 1 \right)}{(n^2-1)\pi}. \end{aligned}$$

So  $b_n = 0$  for odd  $n \in \mathbb{N}$ , and  $b_n = \frac{4n}{(n^2-1)\pi}$  for even  $n$ .

We conclude that

$$\cos x = \sum_{n=1}^{\infty} \left( \frac{8n}{(4n^2-1)\pi} \sin(2nx) \right), \quad x \in (0, \pi).$$

Of course, for the even extension of the function  $g$  in question,

$$g(x) = \cos x, \quad x \in (-\pi, \pi).$$

Thus the right hand side is the uniquely given cosine Fourier series.  $\square$

$-1 < x < 1$ , (see our reasonings about alternating series in 5.4.6), thus we have verified the above equality.

Similarly, we can integrate the Fourier series of  $x^2$  term by term obtaining

$$\frac{1}{3}x^3 = \frac{2}{3}x + \frac{4}{\pi^3} \sum_{n=1}^{\infty} \frac{(-1)^n}{n^3} \sin(\pi nx).$$

This is valid for  $-1 < x < 1$ . It is not valid for other values of  $x$ , since the series is periodic, but the other two terms are not. Of course, we may substitute the above Fourier series of the function  $x$  and thus obtain the Fourier series for  $x^3$  on the interval  $[-1, 1]$  this way.

In this context, we use the following terminology:

THE SINE AND COSINE FOURIER SERIES

For a given (real or complex) valued function  $f$  on an interval  $[0, T]$  of length  $T > 0$ , the Fourier series of it's even periodic extension (with period  $2T$ ) is called the *cosine Fourier series* of  $f$ , while the Fourier series of the the odd periodic extension of  $f$  is called the *sine Fourier series* of the function  $f$ .

**7.1.11. General Fourier series and wavelets.** In the case of a general orthogonal system of functions

$f_n$  and the series generated from it, we often talk about the *general Fourier series* with respect to the orthogonal system of functions  $f_n$ .

Fourier series and further tools built upon them are used for processing various signals, illustrations, and other data. In fact, these mathematical tools also underpin many fundamental models in science, including, for example, modeling of the function of the brain, as well as much of theoretical physics.

The periodic nature of the sine and cosine functions used in classical Fourier series, and their simple scaling by increasing the frequency by unit steps, limit their usability. In many applications, the nature of the data may suggest more convenient and possibly more efficient orthogonal systems of functions.

Requirements for fast numerical processing usually include quick scalability and the possibility of easy translations by constant values. In other words, we want to be able to zoom quickly in and out with respect to the frequencies and, at the same time, to localize in time.

Fast scalability can be achieved by having just one *wavelet mother function*<sup>1</sup>  $\psi$ , if possible with compact support, from which we create countably many functions  $\psi_{j,k}$ ,

<sup>1</sup>The roots of wavelets go back to various attempts, how to localize the basic signals in both time and frequency, with diverse motivations from engineering and other applications. The name wavelet seems to be related to the idea of having a wave similar signal which begins and ends with zero amplitude. Since late 1970's, these attempts were related to many names (e.g. Morlet, Meyer) and the wavelet theory became the main tool in signal analysis. . Of course, first examples of wavelets are much older, the Haar's construction goes back to 1909. Actually, many of the wavelet types do not represent orthogonal systems of functions, they rather share the idea of a

**7.B.12.** Write the Fourier series of the  $\pi$ -periodic function which equals cosine on the interval  $(-\pi/2, \pi/2)$ . Then write the cosine Fourier series of the  $2\pi$ -periodic function  $y = |\cos x|$ .

**Solution.** We are looking for one Fourier series only, since the second part of the problem is just a reformulation of the first part. Therefore, we construct the Fourier series for the function  $g(x) = \cos x$ ,  $x \in [-\pi/2, \pi/2]$ . Since  $g$  is even,  $b_n = 0$ ,  $n \in \mathbb{N}$ . We compute

$$\begin{aligned} a_n &= \frac{2}{\pi} \int_{-\pi/2}^{\pi/2} \cos x \cos(2nx) \, dx \\ &= \frac{2}{\pi} \int_{-\pi/2}^{\pi/2} \frac{1}{2} (\cos((2n+1)x) + \cos((2n-1)x)) \, dx \\ &= \frac{1}{\pi} \left[ \frac{\sin((2n+1)x)}{2n+1} + \frac{\sin((2n-1)x)}{2n-1} \right]_{-\pi/2}^{\pi/2} \\ &= \frac{2}{\pi} \left( \frac{(-1)^n}{2n+1} + \frac{(-1)^{n+1}}{2n-1} \right) \\ &= \frac{4}{\pi} \frac{(-1)^{n+1}}{4n^2-1} \end{aligned}$$

for every  $n \in \mathbb{N}$ . The calculation is also valid for  $n = 0$ , thus  $a_0 = 4/\pi$ . The desired Fourier series is

$$\frac{2}{\pi} + \frac{4}{\pi} \sum_{n=1}^{\infty} \left( \frac{(-1)^{n+1}}{4n^2-1} \cos(2nx) \right).$$

□

**7.B.13.** Expand the function  $g(x) = e^x$  into

- (a) a Fourier series on the interval  $[0, 1]$ ;
- (b) a cosine Fourier series on the interval  $[0, 1]$ ;
- (c) a sine Fourier series on the interval  $(0, 1]$ .

**Solution.** Note the differences between the three cases as shown in the diagrams. The approximation differs in relation to the continuity. The first diagram uses  $n = 5$ , the second uses  $n = 3$ , while the last diagram uses  $n = 10$ .

$j, k \in \mathbb{Z}$ , by integer translations and dyadic dilations:

$$\psi_{j,k}(x) = 2^{j/2} \psi(2^j x - k).$$

It is wise to rescale and choose  $\psi$  with  $L_2$ -norm equal to one (as a function on  $\mathbb{R}$ ). Then the coefficients  $2^{j/2}$  ensure that the same is true for all  $\psi_{j,k}$ .

Of course, the shape of the mother wavelet  $\psi$  should match and cover all typical local behaviour of the data to be processed. We say that  $\psi$  is an *orthogonal mother wavelet* if the resulting countable system of functions  $\psi_{j,k}$  is orthogonal and, at the same time, it is “reasonably dense” in the space of functions with integrable squares. We come to this concept in more detail later on.

The effectivity of the wavelet analysis is another issue which needs further ideas and concepts to be built in. We do not have space here to go into details, but the readers may find many excellent specialized books in this fascinating area of applied Mathematics. Here we consider one simple example.

**7.1.12. The Haar wavelets.** Perhaps the first question to start with is, how to effectively approximate any given function with piecewise constant ones.

For various reasons, it is good if our mother wavelet  $\psi$  has zero mean, too. Thus we want to consider an analogue of the Heaviside function

$$\psi(x) = \begin{cases} 1 & x \in [0, 1/2) \\ -1 & x \in [1/2, 1) \end{cases}$$

As a straightforward exercise we may check that, indeed, the resulting system of functions  $\psi_{j,k}$  is orthonormal. Another exercise shows, using finite linear combinations of these functions, that we may approximate any constant function with given precision over a bounded interval. In an exercise we shall see ?? that this already verifies the density properties required for the orthogonal mother wavelet functions.

Now we consider the question of effective treatment. Notice that we can also use the characteristic function  $\varphi$  of the interval  $[0, 1]$  and write

$$\psi(x) = \varphi(2x) - \varphi(2x-1) = \frac{1}{\sqrt{2}} \sqrt{2} \varphi_{1,0}(x) - \frac{1}{\sqrt{2}} \sqrt{2} \varphi_{1,1}(x).$$

The function  $\varphi$  plays the role of the *father wavelet function* and it itself satisfies

$$\varphi(x) = \varphi(2x) + \varphi(2x-1) = \frac{1}{\sqrt{2}} \sqrt{2} \varphi_{1,0}(x) + \frac{1}{\sqrt{2}} \sqrt{2} \varphi_{1,1}(x).$$

This can be interpreted as differencing and averaging the two consecutive values at the half scale.

With these properties, there is no need for an explicit analytic form of  $\psi$  and  $\varphi$ , since we can find their values recurrently in all dyadic points  $x$ . Indeed,

$$\varphi(2^{j-1}n) = \varphi(2^j n) + \varphi(2^j n - 1).$$

combination of the high pass filters and low pass filters. The reader is advised to consult extremely rich literature, if interested in more details

We use the formulae ( $\alpha, \beta \in \mathbb{R}$ )

$$(1) \int e^x \cos(\alpha x) \, dx = \frac{e^x (\alpha \sin(\alpha x) + \cos(\alpha x))}{1 + \alpha^2} + C,$$

$$(2) \int e^x \sin(\beta x) \, dx = \frac{e^x (\sin(\beta x) - \beta \cos(\beta x))}{1 + \beta^2} + C,$$

both of which can be obtained by two integrations by parts. Actually, the second one was computed in detail in 6.B.5(d).

We obtain

$$(a) \begin{aligned} a_n &= 2 \int_0^1 e^x \cos(2n\pi x) \, dx \\ &= 2 \left[ \frac{e^x (2n\pi \sin(2n\pi x) + \cos(2n\pi x))}{1 + 4n^2 \pi^2} \right]_0^1 \\ &= \frac{2(e-1)}{1 + 4n^2 \pi^2}, \quad n \in \mathbb{N} \cup \{0\}, \end{aligned}$$

$$\begin{aligned} b_n &= 2 \int_0^1 e^x \sin(2n\pi x) \, dx \\ &= 2 \left[ \frac{e^x (\sin(2n\pi x) - 2n\pi \cos(2n\pi x))}{1 + 4n^2 \pi^2} \right]_0^1 \\ &= \frac{4n\pi(1-e)}{1 + 4n^2 \pi^2}, \quad n \in \mathbb{N}; \end{aligned}$$

$$(b) \begin{aligned} a_n &= 2 \int_0^1 e^x \cos(n\pi x) \, dx \\ &= 2 \left[ \frac{e^x (n\pi \sin(n\pi x) + \cos(n\pi x))}{1 + n^2 \pi^2} \right]_0^1 \\ &= \frac{2((-1)^n e - 1)}{1 + n^2 \pi^2}, \quad n \in \mathbb{N} \cup \{0\}; \end{aligned}$$

$$(c) \begin{aligned} b_n &= 2 \int_0^1 e^x \sin(n\pi x) \, dx \\ &= 2 \left[ \frac{e^x (\sin(n\pi x) - n\pi \cos(n\pi x))}{1 + n^2 \pi^2} \right]_0^1 \\ &= \frac{2n\pi(1 + (-1)^{n+1} e)}{1 + n^2 \pi^2}, \quad n \in \mathbb{N}. \end{aligned}$$

Substitution then yields the corresponding Fourier series for  $g(x)$ :

$$(a) \begin{aligned} e - 1 + 2(e - 1) \sum_{n=1}^{\infty} \frac{\cos(2n\pi x)}{1 + 4n^2 \pi^2} \\ + 4\pi(1 - e) \sum_{n=1}^{\infty} \frac{n \sin(2n\pi x)}{1 + 4n^2 \pi^2}; \end{aligned}$$

$$(b) e - 1 + 2 \sum_{n=1}^{\infty} \frac{((-1)^n e - 1) \cos(n\pi x)}{1 + n^2 \pi^2};$$

$$(c) 2\pi \sum_{n=1}^{\infty} \frac{n(1 + (-1)^{n+1} e) \sin(n\pi x)}{1 + n^2 \pi^2}.$$

The function  $\varphi$  has another useful feature. Namely we can obtain the unit constant function by adding all its integer translations

$$\sum_{k=-\infty}^{\infty} \varphi_{0,k}(x) = 1$$

for all  $x \in \mathbb{R}$ .

Finally, nearly all the coefficients in the general Fourier series with the base  $\psi_{j,k}$  vanish for piecewise constant functions. On the contrary, the function  $\varphi$  "sees" the constants. In engineering terminology, this is an instance of the *high pass filter* and *low pass filter*.

**7.1.13. Example.** To illustrate the above considerations, we approximate the following function  $f(x)$  in  $\mathbb{R}$  by the Haar wavelets,

$$f(x) = \begin{cases} 0.3(x + 3), & -2 \leq x \leq -1 \\ 0.7(x + 1), & 0 \leq x \leq 1 \\ 0 & \text{otherwise} \end{cases}.$$

The function in question is not periodic and could not be approximated well by classical Fourier series. The individual functions  $\psi_{j,k}$  from 7.1.11 have compact support, but in order to approximate constant or linear behaviour, we still need a large number of them. The following illustrations have been acquired in Maple working with indices  $|j| \leq n$  and  $|k| \leq n$ , the first one with  $n = 5$ , the second one with  $n = 10$ .

The approximation on the sides of the interval is not as good as in the middle, because we do not include enough shifts, i.e. values of  $k$ . One of the motivations for the scaling and shifting in the construction of wavelets is the hope for a small amount of non-zero coefficients. But this does not mean that most of the coefficients would be zero. In our case the percentage of non-zero coefficients for  $n = \{1, 2, \dots, 10\}$  is 55.6, 44., 38.8, 34.6, 32.2, 30.8, 29.8, 28.7, 28.0, 27.4.

**7.1.14. Concluding remarks.** A series of famous wavelets  $D_N$  has been called after Ingrid Debauchies. They are constructed by very similar recurrent averaging and differencing relations based on certain natural requirements. Just as

□

**7.B.14.** Express the function  $g(x) = \pi^2 - x^2$  on the interval  $[-\pi, \pi]$  in the form of a Fourier series. Using this expression, sum the two series

$$(1) \quad \sum_{n=1}^{\infty} \frac{(-1)^{n+1}}{n^2}, \quad \sum_{n=1}^{\infty} \frac{1}{n^2}.$$

**Solution.** We could take advantage of the function  $g$  being even, and calculate the non-zero coefficients  $a_n$  by integration by parts. However, in 7.1.10 the Fourier series for the function  $f(x) = x^2$  on the interval  $[-1, 1]$  is derived. This proves the identity

$$f(x) = \frac{1}{3} + \frac{4}{\pi^2} \sum_{n=1}^{\infty} \frac{(-1)^n \cos(n\pi x)}{n^2}, \quad x \in (-1, 1),$$

valid also for  $x = \pm 1$ . By adding  $\pi^2$  and rescaling, it follows

$$g(x) = \pi^2 - \left( \frac{1}{3} + \frac{4}{\pi^2} \sum_{n=1}^{\infty} \frac{(-1)^n \cos \frac{n\pi x}{\pi}}{n^2} \right) \pi^2$$

that

$$= \frac{2}{3}\pi^2 + 4 \sum_{n=1}^{\infty} \frac{(-1)^{n+1} \cos(nx)}{n^2}, \quad x \in [-\pi, \pi].$$

Of course, one can also calculate the Fourier series of the function  $g$  directly.

Substituting  $x = 0$  and  $x = \pi$  then gives

$$\pi^2 = \frac{2}{3}\pi^2 + 4 \sum_{n=1}^{\infty} \frac{(-1)^{n+1}}{n^2}, \quad \text{i.e.} \quad \sum_{n=1}^{\infty} \frac{(-1)^{n+1}}{n^2} = \frac{\pi^2}{12},$$

and

$$0 = \frac{2}{3}\pi^2 + 4 \sum_{n=1}^{\infty} \frac{(-1)^{n+1}(-1)^n}{n^2}, \quad \text{i.e.} \quad \sum_{n=1}^{\infty} \frac{1}{n^2} = \frac{\pi^2}{6}.$$

In other words,

$$\pi^2 = 12 \left( 1 - \frac{1}{2^2} + \frac{1}{3^2} - \frac{1}{4^2} + \dots \right)$$

$$= 6 \left( 1 + \frac{1}{2^2} + \frac{1}{3^2} + \frac{1}{4^2} + \dots \right).$$

**7.B.15.** Sum the series

$$\sum_{n=1}^{\infty} \frac{1}{(2n-1)^2}.$$

**Solution.** To determine the value of this series, one can successfully apply several known Fourier series. For instance, the Fourier series

$$\frac{\pi}{2} - \frac{4}{\pi} \sum_{n=1}^{\infty} \frac{\cos((2n-1)x)}{(2n-1)^2},$$

was calculated for the function  $g(x) = |x|$ ,  $x \in [-\pi, \pi]$ , see 7.B.3(b). Since this function is continuous on  $[-\pi, \pi]$  and  $|\pi| = |-\pi|$ ,

$$|x| = \frac{\pi}{2} - \frac{4}{\pi} \sum_{n=1}^{\infty} \frac{\cos((2n-1)x)}{(2n-1)^2}, \quad x \in [-\pi, \pi].$$

Substituting  $x = 0$  gives

$$0 = \frac{\pi}{2} - \frac{4}{\pi} \sum_{n=1}^{\infty} \frac{1}{(2n-1)^2}, \quad \text{hence} \quad \sum_{n=1}^{\infty} \frac{1}{(2n-1)^2} = \frac{\pi^2}{8}.$$

□

an indication, consider the slightly more general recurrent relations

$$\varphi(x) = \sqrt{2} \sum_{k=0}^N h_k \varphi(2x - k)$$

$$\psi(x) = \sqrt{2} \sum_{k=0}^N g_k \varphi(2x - k)$$

with yet unknown constants  $g_k$  and  $h_k$ . If we want the mother wavelet  $\psi(x-k)$  to have zero coefficients in the resulting series for all polynomials up to the order  $N-1$ , then we must ensure that

$$\int_{-\infty}^{\infty} x^k \psi(x) dx = 0$$

for all  $k = 0, 1, \dots, N-1$ . Similar conditions determine the Daubechies wavelets.

The standards of JPEG2000 are based on similar wavelets and such techniques provide tools for professional compression of visual data in film industry, or the format DjVu for compressed publications.

In the diagram below, there are the Daubechies D4 mother and father wavelets.

In real applications, the orthogonality of the mother wavelet can be relaxed. As long as the functions  $\psi_{k,l}$  are linearly independent and generate the whole space of interest, we always get the dual basis with respect to the  $L_2$  inner product.

**7.1.15. Proof of theorem 7.1.8 about Fourier series.** We

return to the detailed proof of the basic properties of the classical Fourier series. The reader could enjoy reading first the general context of metrics and convergence which we will introduce later in this chapter.

Thus, skipping the paragraphs up to 7.3.1, reading first there, and returning later might be a good idea. On the other hand, we do not need much from the general theory of metric spaces and so our considerations of various concepts of convergence in the proof could also be of assistance for the abstract developments later.

We do not worry here about necessary conditions for convergence, and many other formulations can be found in literature. On the other hand, the statement of theorem 7.1.8 is quite simple and deals with many useful situations, as we have seen already.

**7.B.16.** Using the Fourier series of the function  $g(x) = e^x$ ,  $x \in [0, 2\pi)$ , calculate  $\sum_{n=1}^{\infty} \frac{1}{1+n^2}$ .

**Solution.** (See (1), (2))

$$\begin{aligned} a_0 &= \frac{1}{\pi} \int_0^{2\pi} e^x \, dx = \frac{1}{\pi} (e^{2\pi} - 1), \\ a_n &= \frac{1}{\pi} \int_0^{2\pi} e^x \cos(nx) \, dx = \frac{1}{\pi} \left[ \frac{e^x [\cos(nx) + n \sin(nx)]}{1+n^2} \right]_0^{2\pi} \\ &= \frac{e^{2\pi} - 1}{(1+n^2)\pi}, \\ b_n &= \frac{1}{\pi} \int_0^{2\pi} e^x \sin(nx) \, dx \\ &= \frac{1}{\pi} \left[ \frac{e^x [\sin(nx) - n \cos(nx)]}{1+n^2} \right]_0^{2\pi} = -\frac{n(e^{2\pi} - 1)}{(1+n^2)\pi}. \end{aligned}$$

Therefore,

$$e^x = \frac{e^{2\pi} - 1}{\pi} \left( \frac{1}{2} + \sum_{n=1}^{\infty} \frac{\cos(nx) - n \sin(nx)}{1+n^2} \right), \quad x \in (0, 2\pi).$$

However, no choice of  $x \in (0, 2\pi)$  yields the series  $\sum_{n=1}^{\infty} \frac{1}{1+n^2}$  on the right-hand side. It would be obtained for  $x = 0$ . The periodic extension of  $g$  to  $\mathbb{R}$  is not continuous at this point, so

$$\begin{aligned} \frac{e^0 + e^{2\pi}}{2} &= \frac{g(0) + \lim_{x \rightarrow 2\pi^-} g(x)}{2} \\ &= \frac{e^{2\pi} - 1}{\pi} \left( \frac{1}{2} + \sum_{n=1}^{\infty} \frac{\cos 0 - n \sin 0}{1+n^2} \right), \end{aligned}$$

hence it follows that

$$\frac{e^{2\pi} + 1}{2} \cdot \frac{\pi}{e^{2\pi} - 1} = \frac{1}{2} + \sum_{n=1}^{\infty} \frac{1}{1+n^2}$$

which can be refined to

$$\sum_{n=1}^{\infty} \frac{1}{1+n^2} = \frac{(\pi-1)e^{2\pi} + \pi + 1}{2(e^{2\pi} - 1)}.$$

□

A few more cases of interesting series of numbers are shown in the exercises in the end of this Chapter, starting at the page 502. We add one more such exercise which reveals a different strategy.

**7.B.17.** Using Parseval's identity for Fourier's orthogonal system (part (3) of the theorem 7.1.5), verify that

$$\sum_{n=1}^{\infty} \frac{1}{(2n-1)^4} = \frac{\pi^4}{96}.$$

**Solution.** It is imperative to choose an appropriate Fourier series. For instance, consider the Fourier series

$$\frac{\pi}{2} - \frac{4}{\pi} \sum_{n=1}^{\infty} \frac{\cos((2n-1)x)}{(2n-1)^2},$$

which we obtained for the function  $g(x) = |x|$ ,

$x \in [-\pi, \pi]$  in 7.B.3(b). Parseval's identity

$$\frac{a_0^2}{2} + \sum_{n=1}^{\infty} a_n^2 + \sum_{n=1}^{\infty} b_n^2 = \frac{2}{T} \int_{x_0}^{x_0+T} (g(x))^2 \, dx$$

says, substituting for the  $a$ 's and  $b$ 's from our particular series, that

Although we need only the  $L_1$  and  $L_2$  norms now, we should observe that for general  $1 \leq p < \infty$ , the formula

$$\|f\|_p = \left( \int_a^b |f|^p \right)^{1/p}$$

defines also a norm. See the definition in 7.3.1 and the paragraph on the  $L_p$ -norms and Hölder inequality in 7.3.4 below. Moreover, there is the  $L_\infty$  norm given by the suprema of values of  $f$  over the interval in question.

For the sake of simplicity, we always work in the space  $S_c^0$  or  $S_c^1$  with respect to the corresponding norm (which always makes sense there).

Hölder's inequality (applied to the functions  $f$  and constant 1) yields the the following bound on  $\mathcal{S}^0[a, b]$ . Namely, for  $p > 1$  and  $1/p + 1/q = 1$ ,

$$\begin{aligned} \int_a^b |f(x)| \, dx &\leq |b-a|^{1/q} \left( \int_a^b |f(x)|^p \, dx \right)^{1/p} \\ &\leq |b-a|^{1/q} \|f\|_p. \end{aligned}$$

Replace  $f$  with  $f_n - f$ . It is then clear from the above bound that  $L_p$ -convergence  $f_n \rightarrow f$  implies, for any  $p > 1$ ,  $L_1$ -convergence. (The terminology  $L_p$ -convergence is stronger than  $L_1$ -convergence is sometimes used). With a modified bound, we can derive an even stronger proposition, namely that on a bounded interval,  $L_q$ -convergence is stronger than  $L_p$ -convergence whenever  $q > p$ ; try this by yourselves.

If uniform boundedness of the sequence of functions  $f_n$  is given, then there is a constant  $C$  independent of  $n$ , so that  $\|f_n\| \leq C$ .

Then we can assert that  $|f_n(x) - f(x)| \leq 2C$ , and it then follows that  $L_1$ -convergence implies  $L_p$ -convergence, since then

$$\begin{aligned} \int_a^b |f(x) - f_n(x)|^p \, dx &= \\ &= \int_a^b |f(x) - f_n(x)|^{p-1} |f(x) - f_n(x)| \, dx \\ &\leq (2C)^{p-1} \int_a^b |f(x) - f_n(x)| \, dx \end{aligned}$$

which can be written

$$\|f - f_n\|_p \leq (2C)^{1/q} \|f - f_n\|_1^{1/p}.$$

It follows that the  $L_p$ -norms on the space  $S^0[a, b]$  are equivalent with respect to the convergence of uniformly bounded sequences of functions.

The most difficult (and most interesting) problem is to prove the first statement of the theorem 7.1.8, which in the literature is often referred to as the *Dirichlet condition*, which seems to have been derived as early as in 1824.

We begin by proving how this property of piecewise convergence implies the statements (2) and (3) of the theorem. Without loss of generality, we assume that we are working on the interval  $[-\pi, \pi]$ , i. e. with period  $T = 2\pi$ .

$$\frac{\pi^2}{2} + \frac{16}{\pi^2} \sum_{n=1}^{\infty} \frac{1}{(2n-1)^4} = \frac{1}{\pi} \int_{-\pi}^{\pi} |x|^2 dx = \frac{2}{\pi} \int_0^{\pi} x^2 dx = \frac{2\pi^2}{3},$$

so,

$$\sum_{n=1}^{\infty} \frac{1}{(2n-1)^4} = \left( \frac{2\pi^2}{3} - \frac{\pi^2}{2} \right) \frac{\pi^2}{16} = \frac{\pi^4}{96}.$$

□

There are other ways of obtaining this result, see for example (3) at the page 502. We recommend comparing the solutions of this exercise to the previous one.

We started our discussion of Fourier series with the simplest of periodic functions

$$f(t) = a \sin(\omega t + b)$$

for certain constants  $a, \omega > 0, b \in \mathbb{R}$ . They appear as the general solution to the homogeneous linear differential equation

$$(1) \quad y'' + \omega^2 y = 0$$

which arises in mechanics by Newton's law of force for a moving particle. Recall the brief introduction to the simplest differential equations in 6.2.14 on page 407. Much more follows in Chapter 8.

We mention that the function  $f$  has period  $T = 2\pi/\omega$ . In mechanics, one often talks about frequency  $1/T$ . The positive value  $a$  expresses the maximum displacement of the oscillating point from the equilibrium position and it is called the amplitude. The value  $b$  determines the position of the point at the initial time  $t = 0$  and it is called the initial phase, while  $\omega$  is the angular frequency of the oscillation.

Similarly, the function  $z \equiv g(t)$  describes the dependence of voltage upon time  $t$  in an electrical circuit with inductance  $L$  and capacity  $C$  and which is the solution of the differential equation

$$(2) \quad z'' + \omega^2 z = 0.$$

The only difference between the equations (1) and (2) (besides the dissimilar physical interpretation) is the constant  $\omega$ . In the equation (1), there is  $\omega^2 = k/m$  where  $k$  is the proportionality constant and  $m$  is the mass of the point, while in the equation (2), there is  $\omega^2 = (LC)^{-1}$ .

We illustrate how Fourier series can be applied in the theory of differential equations. Consider only the non-homogeneous (compare to (1)) differential equation

$$(3) \quad y'' + a^2 y = f(x)$$

with  $y$  an unknown in variable  $x \in \mathbb{R}$ , with a periodic, continuously differentiable function  $f : \mathbb{R} \rightarrow \mathbb{R}$  on the right-hand

As the first step, we prepare simple bounds for the coefficients of the Fourier series. One bound is of course

$$|a_n| \leq \frac{1}{\pi} \int_{-\pi}^{\pi} |f(x)| dx,$$

and similarly for all the coefficients  $b_n$ . This is because both  $\cos(x)$  and  $\sin(x)$  are bounded by 1 in absolute value. However, if  $f$  is a continuous function in  $\mathcal{S}^1[a, b]$ , we can integrate by parts, thus obtaining

$$\begin{aligned} a_n(f) &= \frac{1}{\pi} \int_{-\pi}^{\pi} f(x) \cos(nx) dx \\ &= \frac{1}{n\pi} [f(x) \sin(nx)]_{-\pi}^{\pi} - \frac{1}{n\pi} \int_{-\pi}^{\pi} f'(x) \sin(nx) dx \\ &= \frac{1}{n} b_n(f'). \end{aligned}$$

We write  $a_n(f)$  for the corresponding coefficient of the function  $f$ , and so on.

Iterating this procedure, we really obtain a bound for functions  $f$  in  $\mathcal{S}^{k+1}[-\pi, \pi]$  with continuous derivatives up to order  $k$  inclusive

$$|a_n(f)| \leq \frac{1}{n^{k+1}\pi} \int_{-\pi}^{\pi} |f^{(k+1)}(x)| dx,$$

and similarly for  $b_n(f)$ .

Thus we can see that the “smoother” a function is, the more rapidly the Fourier coefficients approach zero. For sufficiently smooth functions  $f$ , the  $n^k$ -multiples of their Fourier coefficients  $a_n$  and  $b_n$  are bounded by the  $L_1$ -norm of their  $k$ -th derivative  $f^{(k)}$ .

Let  $f$  be a continuous function in the space  $\mathcal{S}^1[a, b]$  such that the partial sums of its Fourier series converge pointwise to  $f$ . Then we can assert that

$$\begin{aligned} |s_N(x) - f(x)| &= \left| \sum_{k=N+1}^{\infty} (a_k \cos(kx) + b_k \sin(kx)) \right| \\ &\leq \sum_{k=N+1}^{\infty} (|a_k| + |b_k|). \end{aligned}$$

The right-hand side can further be estimated by the coefficients  $a'_n$  and  $b'_n$  of the derivative  $f'$ . By applying in succession the inequality above, then Hölder's inequality for infinite series (with  $p = q = 2$ ), and then with the arithmetic-geometric inequality, we obtain

$$\begin{aligned} |s_N(x) - f(x)| &\leq \sum_{k=N+1}^{\infty} \frac{1}{k} (|a'_k| + |b'_k|) \\ &\leq \left( \sum_{k=N+1}^{\infty} \frac{1}{k^2} \right)^{\frac{1}{2}} \left( \sum_{k=N+1}^{\infty} (|a'_k|^2 + 2|a'_k||b'_k| + |b'_k|^2) \right)^{\frac{1}{2}} \\ &\leq \left( \sum_{k=N+1}^{\infty} \frac{1}{k^2} \right)^{\frac{1}{2}} \left( \sum_{k=N+1}^{\infty} (2|a'_k|^2 + 2|b'_k|^2) \right)^{\frac{1}{2}} \\ &\leq \sqrt{2} \left( \int_N^{\infty} \frac{1}{x^2} dx \right)^{\frac{1}{2}} \frac{1}{\sqrt{\pi}} \|f'\|_2 \end{aligned}$$

side and a constant  $a > 0$ . Let  $T > 0$  be the prime period of the function  $f$  and let its Fourier series on  $[-T/2, T/2]$  be known, i.e. we assume

$$(4) \quad f(x) = \frac{A_0}{2} + \sum_{n=1}^{\infty} \left( A_n \cos \frac{2\pi nx}{T} + B_n \sin \frac{2\pi nx}{T} \right).$$

**7.B.18.** Prove that if the equation (3) has a periodic solution on  $\mathbb{R}$ , then the period of this solution is also a period of the function  $f$ . Further, prove that the equation (3) has a unique periodic solution with period  $T$  if and only if

$$(1) \quad a \neq \frac{2\pi n}{T} \quad \text{for every } n \in \mathbb{N}.$$

**Solution.** Let a function  $y = g(x)$ ,  $x \in \mathbb{R}$ , be a solution of the equation (3) with  $f(x) \not\equiv 0$  and with period  $p > 0$ . In order to substitute the function  $g$  into a second-order differential equation, its second derivative  $g''$  must exist. Since the functions  $g, g', g'', \dots$  share the same period, the function

$$g''(x) + a^2 g(x) = f(x)$$

is also periodic with period  $p$ . In other words, the function  $f$  is periodic as a linear combination of functions with period  $p$ . Thus, we have proved the first statement claiming that  $p = lT$  for a certain  $l \in \mathbb{N}$ .

Suppose that the function  $y = g(x)$ ,  $x \in \mathbb{R}$ , is a periodic solution of the equation (3) with period  $T$  and that it is expressed by a Fourier series as follows:

$$(2) \quad g(x) = \frac{a_0}{2} + \sum_{n=1}^{\infty} (a_n \cos(\omega n x) + b_n \sin(\omega n x)), \quad x \in \mathbb{R},$$

where  $\omega = 2\pi/T$ . If  $g$  satisfies the equation (3), it has a continuous second derivative on  $\mathbb{R}$ . Therefore, for  $x \in \mathbb{R}$ ,

$$(3) \quad g'(x) = \sum_{n=1}^{\infty} (\omega n b_n \cos(\omega n x) - \omega n a_n \sin(\omega n x)),$$

$$g''(x) = \sum_{n=1}^{\infty} (-\omega^2 n^2 a_n \cos(\omega n x) - \omega^2 n^2 b_n \sin(\omega n x)),$$

Substituting (4), (2) and (3) into (3) yields

$$\begin{aligned} & a^2 \frac{1}{2} a_0 + \sum_{n=1}^{\infty} ((-\omega^2 n^2 a_n + a^2 a_n) \cos(n\omega x) + \\ & \quad (-\omega^2 n^2 b_n + a^2 b_n) \sin(n\omega x)) \\ & = \frac{A_0}{2} + \sum_{n=1}^{\infty} (A_n \cos(n\omega x) + B_n \sin(n\omega x)). \end{aligned}$$

It follows that

$$(4) \quad a^2 \frac{a_0}{2} = \frac{A_0}{2}, \quad \text{that is} \quad a^2 a_0 = A_0,$$

$$= \left( \frac{\sqrt{2}}{\sqrt{\pi}} \|f'\|_2 \right) \cdot \frac{1}{\sqrt{N}}.$$

Thus we have obtained not only a proof of the uniform convergence of our series to the anticipated value, but also a bound for the speed of the convergence:

$$\sup_{x \in \mathbb{R}} |s_N(x) - f(x)| \leq \left( \frac{\sqrt{2}}{\sqrt{\pi}} \|f'\|_2 \right) \cdot \frac{1}{\sqrt{N}}.$$

This proves the statement 7.1.8.(2), supposing the Dirichlet condition 7.1.8.(1) holds.

**7.1.16.  $L_2$ -convergence.** In the next step of our proof, we derive  $L_2$ -convergence of Fourier series under the condition of uniform convergence. The proof utilizes the common technique of approximation objects which are not continuous by ones which are. We describe it without further details. Interested readers should be able to fill in the gaps by themselves without any difficulties. First, we formulate the statement we need.

**Lemma.** The subset of continuous functions  $f$  in  $S^0[a, b]$  on a finite interval  $[a, b]$  is a dense subset in this space with respect to the  $L_2$ -norm.

Here "dense" means that for any  $g$  in  $S^0[a, b]$  and any  $\varepsilon > 0$ , there is some continuous  $f$  satisfying  $\|f - g\|_2 < \varepsilon$ . We deal with abstract topological concepts like this in the last part of this chapter.

The idea of the proof can be seen easily via the example of approximation of Heaviside's function  $h$  on the interval  $[-\pi, \pi]$ . We recall that  $h(x) = -1$  for  $x < 0$ , and  $h(x) = 1$  for  $x > 0$ . For every  $\delta$  satisfying  $\pi > \delta > 0$ , we define the function  $f_\delta$  as  $x/\delta$  for  $|x| \leq \delta$  and  $f_\delta(x) = h(x)$  otherwise. All the functions  $f_\delta$  are continuous, in fact, piecewise linear. It can be calculated easily that  $\|h - f_\delta\|_2 \rightarrow 0$  so that  $h$  can be approximated in  $L_2$  norm by a sequence of continuous functions.

All discontinuity points of a general function  $f$  can be catered for in exactly the same way. There are only finitely many of them, and so all of the considered functions are limit points of sequences of continuous functions.

Now, our proof is already simple because for the given function  $f$ , the distance between the partial sums of its Fourier series can be bounded by using a sequence of continuous functions  $f_\varepsilon$  in this way. (All norms in this paragraph are the  $L_2$  norms):

$$\|f - s_N(f)\| \leq \|f - f_\varepsilon\| + \|f_\varepsilon - s_N(f_\varepsilon)\| + \|s_N(f_\varepsilon) - s_N(f)\|$$

and the particular summands on the right-hand side can be controlled.

The first one of them is at most  $\varepsilon$ , and according to the assumption of uniform convergence for continuous functions, the second summand can be bounded also by  $\varepsilon$ . Notice that the third term has the value of the partial sum of the Fourier series for  $f - f_\varepsilon$ . Thus,

$$\|f - f_\varepsilon - s_N(f - f_\varepsilon)\| \leq \|f - f_\varepsilon\|.$$

and for  $n \in \mathbb{N}$ ,

$$(5) \quad (-\omega^2 n^2 + a^2) a_n = A_n, \quad (-\omega^2 n^2 + a^2) b_n = B_n.$$

There is exactly one pair of sequences  $\{a_n\}_{n \in \mathbb{N} \cup \{0\}}$ ,  $\{b_n\}_{n \in \mathbb{N}}$  satisfying these conditions if and only if

$$-\omega^2 n^2 + a^2 = -\left(\frac{2\pi n}{T}\right)^2 + a^2 \neq 0 \quad \text{for every } n \in \mathbb{N},$$

i.e., if (1) holds. In this case, the only solution of (3) with period  $T$  is determined by the only solution

$$(6) \quad a_n = \frac{A_n}{-\omega^2 n^2 + a^2}, \quad b_n = \frac{B_n}{-\omega^2 n^2 + a^2}, \quad n \in \mathbb{N}$$

of the system (5). We emphasize that we utilized the uniform convergence of the series in (3).  $\square$

**7.B.19.** Using the solution of the previous problem, find all  $2\pi$ -periodic solutions of the differential equation

$$y'' + 2y = \sum_{n=1}^{\infty} \frac{\sin(nx)}{n^2}, \quad x \in \mathbb{R}.$$

**Solution.** The equation is in the form of (3) for  $a = \sqrt{2}$  and the continuously differentiable function

$$f(x) = \sum_{n=1}^{\infty} \frac{\sin(nx)}{n^2}, \quad x \in \mathbb{R}$$

with prime period  $T = 2\pi$ . According to problem 7.B.18, the condition  $\sqrt{2} \notin \mathbb{N}$  implies that there is exactly one  $2\pi$ -periodic solution. If we look for it as the value of the series

$$\frac{a_0}{2} + \sum_{n=1}^{\infty} (a_n \cos(nx) + b_n \sin(nx)), \quad x \in \mathbb{R},$$

we know also that (see (4) and (6))

$$a_0 = a_n = 0, \quad b_n = \frac{1}{n^2(2-n^2)}, \quad n \in \mathbb{N}.$$

Thus, the given equation has the unique  $2\pi$ -periodic solution

$$y = \sum_{n=1}^{\infty} \frac{\sin(nx)}{n^2(2-n^2)}, \quad x \in \mathbb{R}. \quad \square$$

### C. Convolution and Fourier Transform

Convolution is a typical integral operation used for smoothing data. See 7.2.2 for the definition and basic comments. It is defined by the formula

$$(f * g)(y) = \int_{-\infty}^{\infty} f(x)g(y-x) dx.$$

The next problems introduces these features.

**7.C.1.** Find the convolutions  $f * g$  and  $f * h$  of the following functions and in each case check the "smoothing" of  $f$ .

Therefore by the triangle inequality,

$$\|s_N(f-f_\varepsilon)\| \leq \|s_N(f-f_\varepsilon)-f+f_\varepsilon\| + \|f-f_\varepsilon\| \leq 2\|f-f_\varepsilon\|.$$

Altogether,  $\|f - s_N(f)\| \leq 4\varepsilon$ .

This verifies the  $L_2$  convergence of the continuous functions  $s_N(f)$  to  $f$  which is we wanted to prove.

**7.1.17. Dirichlet kernel.** Finally, we arrive at the proof of the first statement of theorem 7.1.8. It follows from the definition of the Fourier series  $F(t)$  for a function  $f(t)$ , using its expression with the complex exponential in 7.1.7, that the partial sums  $s_N(t)$  can be written as

$$s_N(t) = \frac{1}{T} \sum_{k=-N}^N \int_{-T/2}^{T/2} f(x) e^{-i\omega kx} e^{i\omega kt} dx,$$

where  $T$  is the period we are working with and  $\omega = 2\pi/T$ . This expression can be rewritten as

$$(1) \quad s_N(t) = \int_{-T/2}^{T/2} K_N(t-x)f(x) dx,$$

where the function

$$K_N(y) = \frac{1}{T} \sum_{k=-N}^N e^{i\omega ky}$$

is called the *Dirichlet kernel*. The sum is a (finite) geometric series with common ratio  $e^{i\omega y}$ . By multiplying by  $e^{i\omega y}$  and then subtracting, we obtain

$$e^{i\omega y} K_N(y) = \frac{1}{T} \sum_{k=-N}^N e^{i\omega(k+1)y}$$

$$(1 - e^{i\omega y})K_N(y) = \frac{1}{T} \left( e^{-iN\omega y} - e^{i(N+1)\omega y} \right).$$

Provided  $\omega y$  is not a multiple of  $2\pi$ , we continue to obtain

$$\begin{aligned} K_N(y) &= \frac{1}{T} \frac{e^{-iN\omega y} - e^{i(N+1)\omega y}}{1 - e^{i\omega y}} \\ &= \frac{1}{T} \frac{1 - e^{-i(N+1/2)\omega y} + e^{i(N+1/2)\omega y}}{e^{i\omega y/2} - e^{-i\omega y/2}} \\ &= \frac{1}{T} \frac{\sin((N+1/2)\omega y)}{\sin(\omega y/2)} \end{aligned}$$

in which the key step was to multiply both the numerator and the denominator by  $-e^{-i\omega y/2}$ . When  $y = 0$ ,  $K_N(0) = \frac{1}{T}(2N+1)$ .

The last expression shows that  $K_N(y)$  is an even function. By l'Hospital's rule, applied at  $y = 0$ , it is continuous everywhere. Since all the partial sums of the series for the constant function  $f(x) = 1$  also equal 1, we obtain from the definition of the Dirichlet kernel, cf. (1), that

$$\int_{-T/2}^{T/2} K_N(x) dx = 1.$$

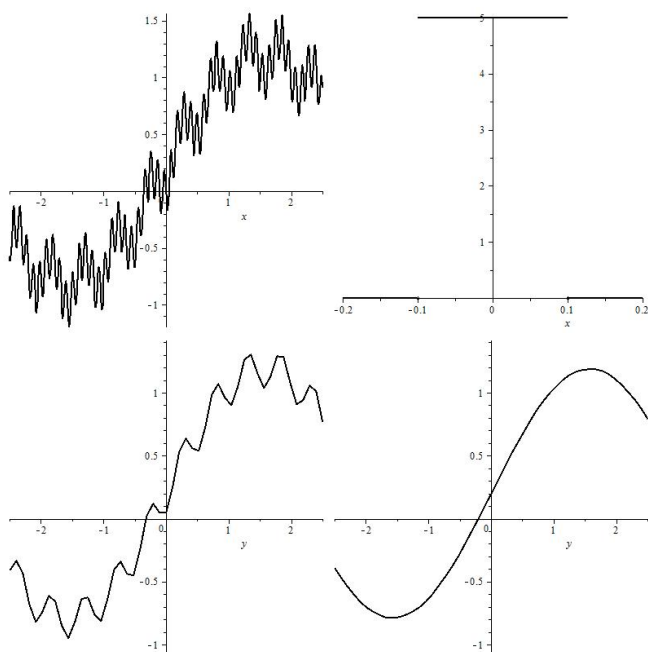

In the case of periodic functions, the integrals over intervals whose length equals the period are independent of the choice

$$f(x) = \sin(x) + \frac{2}{5} [\sin(6x)]^2 - \frac{1}{5} \sin(60x)$$

$$g(x) = \begin{cases} \frac{1}{2\varepsilon} & -\varepsilon < x < \varepsilon \\ 0 & \text{otherwise} \end{cases}, \quad \varepsilon > 0$$

$$h(x) = \frac{1}{\sqrt{2\pi}\sigma} e^{-\frac{(x-\mu)^2}{2\sigma^2}}, \quad \mu, \sigma \in \mathbb{R}, \sigma > 0.$$

**Solution.** The function  $g$  is chosen to provide the mean of  $f$  over (small) intervals of length  $2\varepsilon$  and it is normalized so that the integral of  $g$  over all of  $\mathbb{R}$  is one. We should expect some smoothing of the oscillations of the function  $f(x)$ . Drawing the resulting functions by Maple shows:

The graph depicted in the upper left is the original  $f$ , while the graph in the upper right is of  $g$  with  $\varepsilon = 1/10$ . The two lower graphs show their convolution with (respectively) parameters for  $g$  selected as  $\varepsilon = 1/10$  and  $\varepsilon = 13/50$ . It is straightforward to compute the convolution explicitly, too:

$$\begin{aligned} f * g(y) &= \frac{1}{2\varepsilon} \int_{y-\varepsilon}^{y+\varepsilon} \sin(x) + \frac{2}{5} \sin(6x)^2 - \frac{1}{5} \sin(60x) \, dx \\ &= \frac{1}{2\varepsilon} \left[ -\cos(x) - \frac{1}{30} \sin(6x) \cos(6x) + \frac{1}{5}x + \frac{1}{300} \cos(60x) \right]_{y-\varepsilon}^{y+\varepsilon} \end{aligned}$$

Similarly, the other function  $h$  is a typical smoothing function which gives much more weight to the values of  $f$  near the point  $y$ , and much less weight to the values of  $f$  further from  $y$ . This is the famous *Gaussian* function. We meet it frequently. Using Maple again, we see that the integral of  $h$

of the end points. Hence, changing the coordinates, we can also use the expression

$$s_N(x) = \int_{-T/2}^{T/2} K_N(y) f(x+y) \, dy$$

for the partial sums.

Finally, we are fully prepared. First, we consider the case when the function  $f$  is continuous and differentiable at the point  $x$ . We want to prove that in this case, the Fourier series  $F(x)$  for the function  $f$  converges to the value  $f(x)$  at the point  $x$ . We have

$$s_N(x) - f(x) = \int_{-T/2}^{T/2} (f(x+y) - f(x)) K_N(y) \, dy.$$

The integrand can be rewritten

$$\begin{aligned} & \frac{f(x+y) - f(x)}{\sin(\omega y/2)} \sin((N+1/2)\omega y) = \\ &= \varphi_x(y) (\cos(\omega y/2) \sin(N\omega y) + \sin(\omega y/2) \cos(N\omega y)), \end{aligned}$$

where

$$\varphi_x(y) = \frac{f(x+y) - f(x)}{\sin(\omega y/2)}$$

for  $y \neq 0$ , while  $\varphi_x(0) = 2f'(x)/\omega$ . Since  $f$  is differentiable and continuous at the point  $x$ , the function  $\varphi_x(y)$  is clearly continuous on the entire interval  $[-T/2, T/2]$  (use L'Hospital's rule to see it).

Now, we can rewrite the integral expression for  $s_N - f$  as

$$\frac{2}{T} \int_{-T/2}^{T/2} (\psi_1(y) \sin(N\omega y) + \psi_2(y) \cos(N\omega y)) \, dy$$

with the continuous and bounded functions

$$\psi_1(y) = \frac{T}{2} \varphi_x(y) \cos(\omega y/2), \quad \psi_2(y) = \frac{T}{2} \varphi_x(y) \sin(\omega y/2).$$

Thus, we deal with the Fourier coefficients of the functions  $\psi_1$  and  $\psi_2$ , which converge to zero. Hence

$$\lim_{N \rightarrow \infty} \int_{-T/2}^{T/2} \psi_1(y) \sin(N\omega y) \, dy = 0,$$

and

$$\lim_{N \rightarrow \infty} \int_{-T/2}^{T/2} \psi_2(y) \cos(N\omega y) \, dy = 0.$$

But this means  $\lim s_N(x) - f(x) = 0$ , as desired. See 7.1.5.(2).

Now suppose the function  $f$  or its derivative has a discontinuity at  $x = 0$ . Since the function belongs to  $\mathcal{S}^1$ , it is already continuous and differentiable on a neighbourhood of the point  $x = 0$  (outside the point itself). Split  $f$  into its even part  $f_1$  and its odd part  $f_2$ . That is, write  $f(x) = f_1(x) + f_2(x)$ ,

labels in drawings -  
proc ne, ale  
pripsat rukou,  
popis je ale v  
textu stejne ?

over  $\mathbb{R}$  is one (we prove this in 13.2.8). It is not easy to find the convolution analytically, but Maple can do it approximately. The resulting diagrams are as follows.

As before, the graph depicted in the upper left is the original  $f$ , while the graph in the upper right is of  $h$  with  $\mu = 0$ , and  $\sigma = 1/10$ . Below that, their convolutions are shown with parameters  $\mu = 0$ ,  $\sigma^2 = 1/60$  and (lower right)  $\mu = 0$ ,  $\sigma^2 = 5/60$ .

**7.C.2.** Determine the convolution  $f_1 * f_2$  where

$$f_1(x) = \begin{cases} \frac{1}{x} & \text{for } x \neq 0 \\ 0 & \text{for } x = 0 \end{cases}$$

$$f_2(x) = \begin{cases} x & \text{for } x \in [-1, 1] \\ 0 & \text{otherwise} \end{cases}$$

**Solution.**

$$(f_1 * f_2)(t) = \int_{-\infty}^{\infty} f_1(x) f_2(t-x) dx = \int_{-\infty}^{\infty} \frac{1}{x} f_2(t-x) dx.$$

Since  $f_2(x) = 0$  outside the interval  $[-1, 1]$ , necessarily  $-1 \leq t - x \leq 1$  that is,  $t - 1 \leq x \leq t + 1$ . So

$$(f_1 * f_2)(t) = \int_{t-1}^{t+1} \frac{1}{x} (t-x) dx = t \int_{t-1}^{t+1} \frac{1}{x} dx - 2.$$

where

$$f_1(x) = \frac{1}{2}(f(x) + f(-x)) \quad \text{for } x \neq 0$$

$$f_1(0) = \frac{1}{2}\left(\lim_{x \rightarrow 0^+} f(x) + \lim_{x \rightarrow 0^-} f(x)\right)$$

$$f_2(x) = \frac{1}{2}(f(x) - f(-x)).$$

Then the even part  $f_1(x)$  is continuous and differentiable at the point  $x = 0$  because of the existence of the one-sided limits, and so on a neighbourhood of the point  $x = 0$ . Also  $f_2(0) = 0$ , and the Fourier series for  $f_2$  contains only the terms with  $\sin(n\omega x)$ .

Thus we can refer to the previous continuous case and obtain, for the Fourier series  $F(x)$  of the function  $f$ , the equation

$$F(0) = \frac{1}{2}\left(\lim_{x \rightarrow 0^+} f(x) + \lim_{x \rightarrow 0^-} f(x)\right) + 0,$$

which is what we wanted to prove.

In the case of discontinuity at a point other than  $x = 0$ , we can proceed similarly. This completes the proof. This also completes the proof of the statements (2) and (3) of theorem 7.1.8 where we required that the Dirichlet condition be true.

## 2. Integral operators

**7.2.1. Functionals.** In the case of finite-dimensional vector spaces, we can regard the vectors as mappings from a finite set of fixed generators into the space of coordinates. The sums of vectors and the scalar multiples of vectors were then given by the corresponding operations with such functions. We also worked with the vector spaces of functions of a real variable in the same way when their values were scalars (or vectors as well). 

The simplest linear mapping  $\alpha$  between vector spaces maps vectors to scalars. It is called a linear functional. It is defined as the sum of products of coordinates  $x_i$  of vectors with fixed values  $\alpha_i = \alpha(e_i)$  at the generators  $e_i$ , i.e. by one-row matrices:

$$(x_1, \dots, x_n)^T \mapsto (\alpha_1, \dots, \alpha_n) \cdot (x_1, \dots, x_n)^T.$$

More complicated mappings, with values lying in the same space, are given similarly by square matrices. We approach linear operations on spaces of functions in an analogous way.

For simplicity, we work with the real vector space  $\mathcal{S}$  of all piecewise continuous real-valued functions having compact support and defined on the whole  $\mathbb{R}$  or on an interval  $I = [a, b]$ . Linear mappings  $\mathcal{S} \rightarrow \mathbb{R}$  are called (real) *linear functionals*. Examples of such functionals can be given in two different ways — by evaluating the function's values (or its derivatives) at some fixed points or in terms of integration.

We can, for instance consider the functional  $L$  given by evaluating the function at a sole fixed point  $x_0 \in I$ , i. e.,

$$L(f) = f(x_0).$$

This last integral is improper if  $t - 1 \leq 0 \leq t + 1$ . For  $t$  outside that interval, the integration gives

$$(f_1 * f_2)(t) = t \ln \left| \frac{t+1}{t-1} \right| - 2.$$

If instead,  $-1 < t < 1$ , we can for small  $\varepsilon > 0$ , replace  $\int_{t-1}^{t+1} \frac{1}{x} dx$  with

$$\int_{\varepsilon}^{t+1} \frac{1}{x} dx + \int_{t-1}^{-\varepsilon} \frac{1}{x} dx$$

which computes to  $\ln |t+1| - \ln |\varepsilon| + \ln |-\varepsilon| - \ln |t-1|$ . The terms in  $\varepsilon$  cancel, so when we take the limit  $\varepsilon \rightarrow 0$ , we obtain the same answer for the integral as before.

Thus

$$(f_1 * f_2)(t) = t \ln \left| \frac{t+1}{t-1} \right| - 2$$

for all values of  $t$  except for  $t = 1$ , or for  $t = -1$ . □

We calculate the convolution of two functions both of which have a bounded support.

**7.C.3.** Determine the convolution  $f_1 * f_2$  where

$$f_1(x) = \begin{cases} 1 - x^2 & \text{for } x \in [-1, 1], \\ 0 & \text{otherwise,} \end{cases}$$

$$f_2(x) = \begin{cases} x & \text{for } x \in [0, 1], \\ 0 & \text{otherwise.} \end{cases}$$

**Solution.** Since the integrand is zero when  $f_1(x) = 0$ ,

$$f_1 * f_2(t) = \int_{-\infty}^{\infty} f_1(x)f_2(t-x) dx$$

$$= \int_{-1}^1 (1-x^2)f_2(t-x) dx$$

But the integrand is also zero when  $f_2(t-x) = 0$ , so we need  $0 \leq t-x \leq 1$  ie.  $t-1 < x < t$  for the integrand to be non zero. So for a non zero value of  $f_1 * f_2(t)$ , we integrate over the intersection of the intervals  $[t-1, t]$  and

Or, we can have the functional given by integration of the product with a fixed function  $g(x)$ , i.e.,

$$L(f) = \int_a^b f(x)g(x) dx.$$

The function  $g(x)$  in the previous example is a function which weighs the particular values representing the function  $f(x)$  in the definition of the Riemann integral. The simplest case of such a functional is, of course, the Riemann integral itself, i.e. the case of  $g(x) = 1$  for all points  $x$ .

A good example is given by

$$g(x) = \begin{cases} 0 & \text{if } |x| \geq \varepsilon \\ \frac{1}{2\varepsilon} & \text{if } |x| < \varepsilon. \end{cases}$$

for any  $\varepsilon > 0$ . The integral of the function  $g$  over  $\mathbb{R}$  equals one, and our linear functional can be perceived as a (uniform) averaging of the values of the function  $f$  over the  $\varepsilon$ -neighbourhood of the origin. Similarly, we can work with the function

$$g(x) = \begin{cases} 0 & \text{if } |x| \geq \varepsilon \\ e^{\frac{1}{x^2-\varepsilon^2} + \frac{1}{\varepsilon^2}} & \text{if } |x| < \varepsilon \end{cases}$$

which we used in the paragraph 6.1.5. This function is smooth on  $\mathbb{R}$  with compact support on the interval  $(-\varepsilon, \varepsilon)$ .

Our functional has the meaning of a weighted combination of the values, but this time, the weights of the input values decrease rapidly as their distance from the origin increases. The integral of  $g$  over  $\mathbb{R}$  is finite, but it is not equal to one. Dividing  $g$  by this integral would lead to a functional which would have the meaning of a non-uniform averaging of a given function  $f$ .

Another example is the Gaussian function

$$g(x) = \frac{1}{\sqrt{\pi}} e^{-x^2},$$

which also has its integral over  $\mathbb{R}$  equal to one (we verify this later). This time, all the input values  $x$  in the corresponding “average” have a non-zero weight, yet this weight becomes insignificantly small as the distance from the origin increases.

**7.2.2. Function convolution.** Integral functionals from the previous paragraph can easily be modified to obtain a “streamed averaging” of the values of a given function  $f$  near a given point  $y \in \mathbb{R}$ :

$$L_y(f) = \int_{-\infty}^{\infty} f(x)g(y-x) dx$$

$[-1, 1]$ . Consequently,
