Stano Pekár

Plant-Herbivore

- ▶ consume small amount of many different plant species
 - ▶ consume a lot during life to obtain sufficient amount of N
 - ▶ plant tissue contains about 1% of N
 - ▶ grazers, granivores, frugivores, folivores
 - ▶ plants are not killed only reduced in biomass
-
- ▶ bottom-up control – herbivore abundance is regulated by quantity and quality of plants
 - ▶ top-down control – herbivore abundance is regulated by enemies

Herbivory-regrowth model

▶ Turchin (2003)

▶ assumptions

- continuous herbivory (grazing)
- herbivore is polyphagous
- plant biomass is homogenous
- functional response Type II
- herbivore density is constant
- herbivore density is independent of a certain plant species biomass
- only small quantity of biomass is removed

V .. plant biomass

H .. herbivore density

r .. intrinsic rate of regrowth

K .. carrying capacity

f .. efficiency of removal

T_h .. handling time

$$\frac{dV}{dt} = r \left(1 - \frac{V}{K} \right) - \frac{fHV}{1 + fHT_h}$$

▶ hyperbolic biomass growth

- because only small part of
aboveground tissues is consumed

▶ sucking herbivores (aphids)
are alike parasites

▶ granivores are like true predators

Host-Pathogen

Leishmania

Agents

- ▶ microparasites: viruses, bacteria, protozoans
 - reproduce rapidly in host
 - level of infection depends not on the number of agents but on the host response
- ▶ macroparasites - helminths
 - reproduce in a vector
 - level of infection depends on the number
- ▶ incidence .. number of new infections per unit time
- ▶ prevalence .. proportion of population infected [%]

swine flu virus

E. coli (EHEC)

cercaria

nematode

Epidemiology

- ▶ predicts rates of disease spread
- ▶ predicts occurrence of epidemics
- ▶ predicts expected level of infection

- ▶ Epidemic/epizootic – fast spread of a disease in host population
- ▶ number of human deaths caused by diseases exceeds that of all wars

- ▶ affects also animals
 - rinderpest (viral disease) introduced by cattle to South Africa in 1890
 - 90% buffalo/cattle/wildebeest populations
 - last case diagnosed 2001

- ▶ biological control
 - *Cydia pomonella* granulovirus

▶ epidemics occur in cycles

▶ follows 4 stages:

- establishment - pathogen increases after invasion

- persistence - pathogen persists within host population

- spread - spreads to other non-infected regions, reaches peak

- epidemics terminates

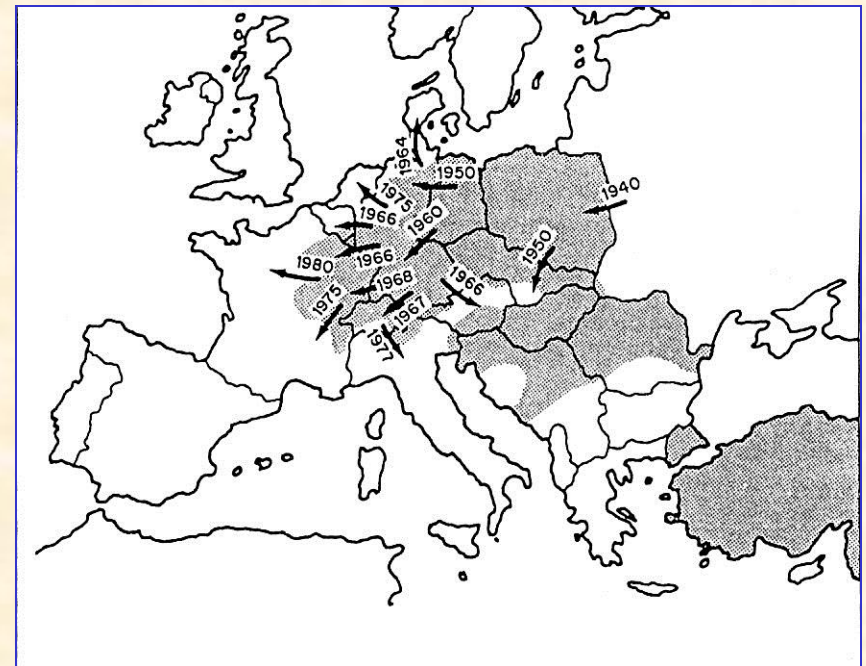

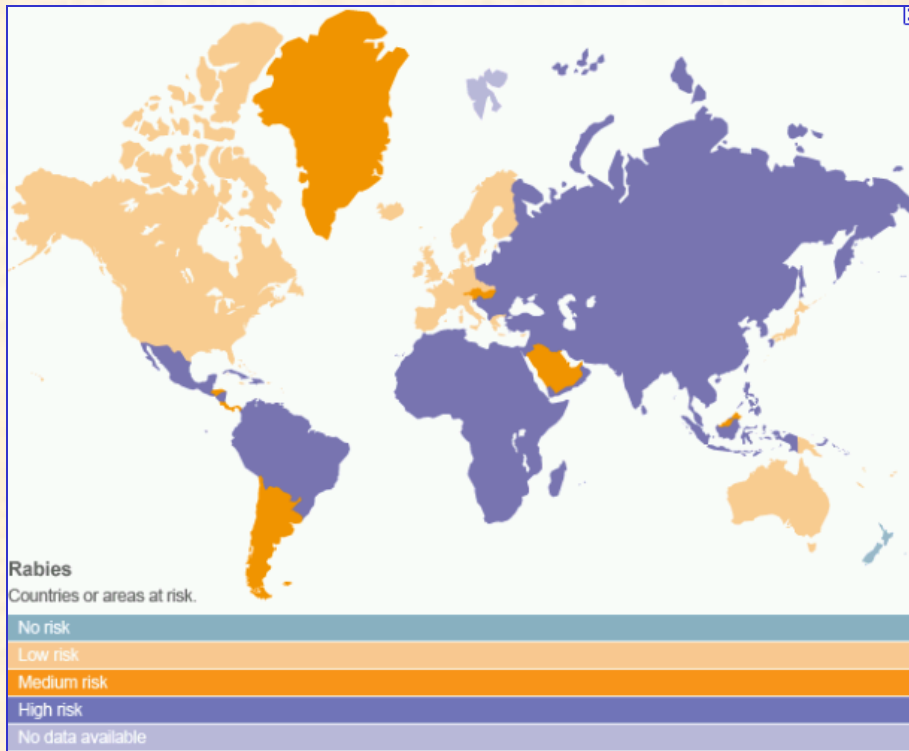

▶ rabies in Europe spread from Poland
1939

- hosts: foxes, badgers, roe-deer

▶ spread rate of 30-60 km/year

virus

Spread of rabies (Bacon 1985)

Host-pathogen/parasite system

- ▶ used to simulate spread of a disease
- ▶ pathogen is much smaller than host
- ▶ models:
 - Kermack & McKendrick (1927)
 - later developed by Anderson & May (1980, 1981)
 - ▶ 3 components:
 - S .. susceptible
 - I .. infected
 - R .. resistant/recovered and immune - can not transmit disease
 - latent stage - infected but not infectious
 - vectors (V) and pathogens (P)
 - malaria is transmitted by mosquitoes, hosts become infected only when they have contact with the vector
 - the number of vectors carrying the pathogens is important
 - such system is further composed of uninfected and infected vectors

Kermack-McKendrick model

▶ β .. transmission rate - number of new infections per unit time
 βSI .. density-dependent transmission function (proportional to the number of contacts)

- mass action

- analogous to search efficiency in predator-prey model

$1/\beta$.. average time for encountering infected individual

▶ γ .. recovery rate of infected hosts
(either die or become immune)

$\gamma = 1/\text{duration of disease}$

Assumptions:

- $S_0 \gg I_0$

- ignores population change (increase of S)

- incubation period is negligible

SI model

$$\frac{dS}{dt} = -\beta SI$$

$$\frac{dI}{dt} = \beta SI - \gamma I$$

Outbreaks

- ▶ outbreak (epidemics) will occur if $S_0 > \frac{\gamma}{\beta}$
- i.e. transmission threshold, when density of S is high
- basic reproductive number, R_0 , expected number of secondary infections per capita
- disease spreads if $R_0 > 1$

$$R_0 = \frac{\beta}{\gamma}$$

▶ herd immunity is achieved by vaccinating susceptible population so that its proportion (p_s) is

$$p_s < \frac{\gamma}{\beta}$$

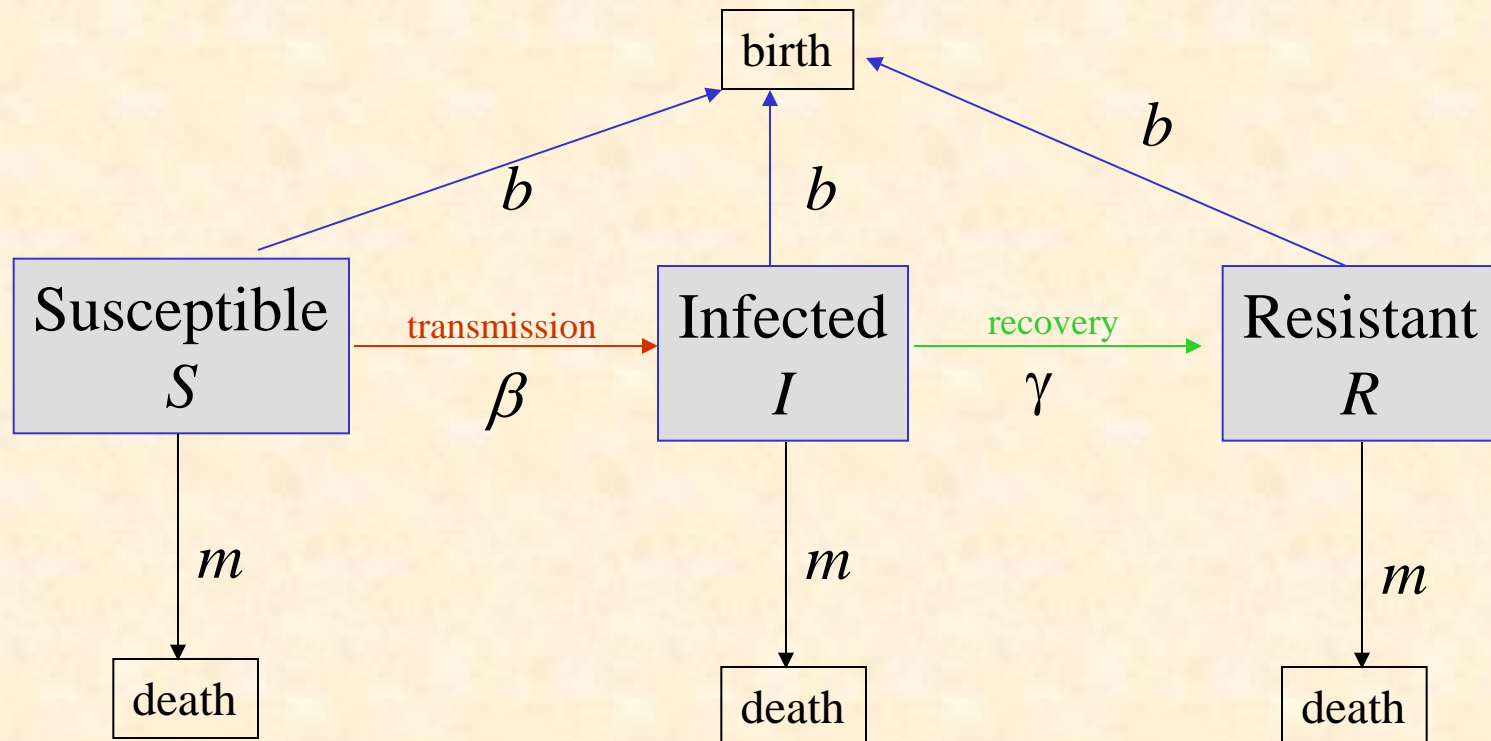

- it will halt the spread

▶ culling or isolation of I will stop disease spread

Anderson-May model

Assumptions:

- host population is dynamic
- newborns are susceptible
- b .. host birth rate
= $1/\text{host life-span}$, given exponential growth and constant population size
- m .. host mortality due to other causes

SIR model

$$\frac{dS}{dt} = b(S + I + R) - \beta SI - mS$$

$$\frac{dI}{dt} = \beta SI - \gamma I - mI$$

$$\frac{dR}{dt} = \gamma I - mR$$

$$N = S + I + R$$

N .. total population of hosts per area:

$$R_0 = \frac{\beta N}{b + \gamma + m}$$

- ▶ R_0 .. basic reproductive rate of the disease
- number of secondary cases that primary infection produces
- if $R_0 > 1$.. disease will persist, if $R_0 < 1$.. disease will disappear
- is dependent on N : R_0 is larger in large populations
- after immunization the equilibrium of infection will decrease
- transmission threshold:

$$S_0 = \frac{b + \gamma + m}{\beta}$$

Biological control

- ▶ fast biocontrol effect is achieved only with viruses with high β
- ▶ regulation is possible if pest $r \ll$ mortality due to disease
- ▶ low host population is achieved with pathogens with lower β

Population dynamic of a moth and the associated granulosis virus
