TOTAL	57	195	408	221	34

There are new taxa up to the family levels. Some orders have either more (*) or fewer (**) new species than expected by their species richness.

Table 2.—Breakdown of numbers of previously named species (currently recognized as valid) and newly described species by Order of mammals. Expected numbers of new species were calculated by dividing the number of previously named species in an Order by the total number of previously named species in all mammals (5,080) and multiplying by the total number of new species described (341). The allocation of new species across all mammals was not what would be expected due to chance ($\chi^2 = 41.52$, df = 11, p < 0.0005): that is, there are biases in what types of mammals are being newly described.

Here we report on the existence of a new species of even-toed ungulate in the Brazilian Amazon, which we name *Mazama ochroleuca* sp. nov., the fair brocket deer. It is intermediate in size between the two known species of brocket deer, *Mazama americana* and *Mazama (gouazoupira) nemorivaga*, and occurs in sympatry with both. Preliminary mitochondrial partial cytochrome b sequences of fair brocket deer compared with that of the sympatric and morphologically most related grey brocket deer (*Mazama (gouazoupira) nemorivaga*) revealed a sequence difference of 3.7%. Divergence time is therefore estimated at 1.0 million years before present. As in other brocket deer, fair brocket deer are polygynous, territorial, and live in small herds.

Abstract

In 1993, several horns of an unknown mammal were collected in the south of Vietnam. Due to the unusual characteristics of its horns, the 'linh duong', as named by Vietnamese hunters, was quickly described as belonging to a new monospecific genus of bovid, i.e. *Pseudonovibos spiralis* Peter & Feiler, 1994. The taxonomic status of *Pseudonovibos* was a highly controversial subject, and it has been suggested that this enigmatic species may be related to three different groups of Bovidae:

Pseudonovibos spiralis (Artiodactyla: Bovidae): new information on this enigmatic South-east Asian ox

(Accepted 21 January 2000)

Abstract

Two bovid frontlets with horns collected in 1929 and now housed in the collections of the University of Kansas Natural History Museum (KU) from Suoi Kiet, Binh Tuy Province, Vietnam, were previously identified as koupreys (*Bos sauveli*). We believe that they are specimens of the recently discovered bovid, *Pseudonovibos spiralis* Peter & Feiler, 1994. The KU specimens are represented by the posterior half of the frontal bones, the parietals, the horn cores and horns, and the anteriomost supraoccipitals, and are the most complete, best documented, and oldest specimens known of this poorly known species. We believe that both an adult male and an adult female are represented. Although the specimens are fragmentary, they still provide significant information that allows us to describe some aspects of *P. spiralis*, and they are especially critical to our understanding of the relationships of this animal to other bovids. We propose the English name spiral-horned ox, which reflects both its distinctively shaped horns and close relationship to other wild oxen. The Khmer name, *Khting Vor*, is also an appropriate common name. Previously overlooked references from the 1880s and 1950s document that the spiral-horned ox was believed to have magical powers over poisonous snakes.

Key words: Bovidae, Indo-China, *Pseudonovibos spiralis*, South-east Asia, spiral-horned ox

Fig. 3. Radiograph of the right horn sheaths and cores of two adult spiral-horned oxen (*Pseudonovibos spiralis*) (KU 138658 left; KU 138657 right). Note the characteristic bovid trabeculae that may be seen within the horn cores. The tip of the horn core has been sawn off on KU 138658 and the tip of KU 138657 has been broken off. This was done before the specimens were received at the University of Kansas in 1930. Given that these frontlets were in the Suttons' possession only months before they were donated to KU, that the horn cores and sheaths are quite clean and all soft tissues have been removed, and that each horn is tacked to the bony core with a small nail, we suspect that the **frontlets were boiled to remove the horns and the tips of the bony horn cores were sawn or broken off at that time to drain out the marrow as well as to remove the cartilaginous tip**. This was a common practice of hunters in that era (and remains so today) to allow removal of the soft tissues from trophy heads to prevent noxious smells created by decomposition inside the horns and in the skull. However, because the numerous grooves of irregular bone deposition of the bony cores perfectly match the ridges in the horn sheaths, we are confident that the horns and frontlets are correctly matched sets and have not been switched with those of other animals.

Abstract

IN May 1992 a joint survey by the Ministry of Forestry and World Wide Fund for Nature of the Vu Quang Nature Reserve, Ha tinh province, found three sets of long straight horns of a new bovid (Mammalia, Artiodactyla) in hunters' houses¹. None of the specimens had dentition. On four follow-up visits by Vietnamese scientists new specimens were discovered and surveys of forests in neighbouring Nghe an province revealed more localities and some partial specimens. In all, we have examined more than 20 specimens. Three have complete

DAM PROJECT REVEALS SECRET SANCTUARY OF VANISHING DEER

When Ulrike Streicher set out last year to rescue wildlife on the Nakai Plateau of northern Laos, nearly half of which was flooding as the reservoir behind the Nam Theun 2 Hydroelectric Project's dam filled, she expected to encounter the occasional curiosity. But in just 4 months, her team captured an astounding 38 large-antlered muntjacs—a rare deer that was discovered only in 1994 and was photographed for the first time

Jackpot. An amazing 38 large-antlered muntjacs were rescued in Laos.

by a camera trap in the dam area in 2007. "We had our hands on more large-antlered muntjacs than anyone had ever even seen," says Streicher.

The hands-on experience could be a boon for efforts to study and protect Indochina's more exotic denizens. Streicher's mostly Lao team attached radio collars to several large-antlered muntjacs (*Muntiacus vuquangensis*) before releasing them in habitat away from the reservoir.

Although the animals aren't presently being monitored—that was beyond the Nam Theun 2 Power Company's mission—"it was a great dress rehearsal for learning how to track animals like the saola," says Streicher, a wildlife veterinarian based in Da Nang, Vietnam, who headed the NTPC wildlife-rescue program.

From June 2008 to February 2009, Streicher's group rescued 294 animals in Nakai's Thousand Island area, including some pygmy lorises and unexpected critters such as the colugo, only the second field record of this gliding mammal in Laos. In a July review, the World Bank commended the rescue program as "impressive." "Uli and her team did a fantastic job, under often difficult conditions," says Laos-based zoologist William Robichaud.

The fate of the large-antlered muntjac—those Streicher released and the population in general—is not rosy. Unlike the saola (see main text), this heaviest of muntjac species—adult males weigh up to 60 kilograms—is a favorite of hunters. "We tried to be secretive about where we brought captive animals," Streicher says. "But when you run into a bunch of locals and you are carrying a couple cages, it doesn't take much imagination to figure out what you're up to." Streicher hopes outside experts will pick up where NTPC left off and join the quest to save the large-antlered muntjac. Otherwise, she warns, "it could be a big scientific loss."

SUMMARY

Six extant species of non-human great apes are currently recognized: Sumatran and Bornean orangutans, eastern and western gorillas, and chimpan-

utans of a similar developmental stage, we found consistent differences between the Batang Toru individual and other extant Ponginae. Our analyses of 37 orangutan genomes provided a second line of evidence. Model-based approaches revealed that the

Hotspot of new megafauna found in the Central Amazon (Brazil): the lower Rio Aripuanã Basin

Marc G.M. van Roosmalen

¹MVRS Marc van Roosmalen Stichting, Leiden, The Netherlands; e-mail: marc.mvrs@gmail.com

ABSTRACT

Here I announce the discovery of a whole new ecosystem in the central-southern part of the Brazilian Amazon: the Rio Aripuanã Basin. Overall, it seems to have created more ecological niches than any other river basin in the Amazon, in particular so to aquatic and non-volant terrestrial mammals. This is plausibly explained for by the unique geo-morphological history of the region. During the Pliocene and Early Pleistocene the entire area to the southeast of the Rio Madeira contained one huge clear-water system that was drained toward the south into the Atlantic Ocean. In the course of several million years a biome quite different from the rest of Amazonia could evolve in this drainage system. Living relicts from ancient times that happened to survive in isolation here, are: a dwarf manatee here described as *Trichechus pygmaeus* n. sp., a dolphin locally called "boto roxo" that is suspected to be closer related to marine Rio Plata dolphins *Pontoporia blainvilliei* (Gervais et d'Orbigny, 1844) than to Amazonian dolphins of the genus *Inia* (d'Orbigny, 1834), a black dwarf tapir (*Tapirus pygmaeus* Van Roosmalen, 2013, with *T. kabomani* Cozzuol et al., 2013 as junior name), a dwarf marmoset *Callibella humilis* Van Roosmalen et Van Roosmalen, 2003, a new monospecific genus of Callitrichidae that stands at the base of the phylogenetic tree of all extant marmosets (i.e., *Cebuella* Gray, 1866, *Mico* Lesson, 1840, and *Callithrix* Erxleben, 1777), a giant striped paca here described as *Agouti silvagarciae* n. sp., and an arboreal giant anteater spotted in the wild but remains to be collected and described (*Myrmecophaga* n. sp.). A number of other, more advanced mammalian species discovered in the Rio Aripuanã Basin, among which a third species of brocket here described as *Mazama tienhoveni* n. sp., evolved after a dramatic vicariance took place about 1-1.8 MYA (million years ago), the break-through of the continental watershed by the proto-Madeira River during one of the glacial epochs of the Middle Pleistocene. It marked the birth of the modern fast-flowing Rio Madeira, in terms of total discharge the biggest tributary of the Amazon proper and the second strongest river barrier in the entire Amazon Basin. Furthermore, current threats to the environment in this sparsely inhabited and poorly explored river basin will be addressed. We intend to have this 'lost world' preserved as a UNESCO Natural World Heritage Reserve through the divulgation of new, hitherto not yet identified mammals that it appears to harbor.

Skull length 147 mm, skull width 97 mm.

Pecari maximus 2007 –největší pekari

Following a review in 2011, the IUCN moved the giant peccary into synonymy of the collared peccary (*P. tajacu*)

A NEW SPECIES OF LIVING LOWLAND TAPIR (MAMMALIA: TAPIRIDAE) FROM THE BRAZILIAN AMAZON

Marc G.M. van Roosmalen / AAPN Manaus-Amazonas, Brazil

(Left) Adapted rendering of a black dwarf lowland tapir.
(Above) On the left a skull of Brazilian lowland tapir, on the right the skull of black dwarf lowland tapir.

Here we report on the existence of a new species of odd-toed ungulate in the Brazilian Amazon, which we name *Tapirus pygmaeus* sp. nov., the black dwarf lowland tapir. It is much smaller than the since long known Brazilian lowland tapir, *Tapirus terrestris*. As in other tapirs, dwarf tapirs seem to live solitary or in pairs. In view of recent developments in the interfluvies where it lives and due to its limited distribution and apparent rariness, we consider the dwarf tapir highly endangered.

KEY WORDS

New species, Perissodactyla, Tapiridae, *Tapirus pygmaeus* sp. nov., black dwarf lowland tapir, Brazilian Amazon

1. INTRODUCTION

Up to recently only one member of the Pantropical family Tapiridae (tapirs) from lowland Amazonia was known to science belonging to the extant genus *Tapirus* (WILSON & REEDER 1993): the lowland tapir *Tapirus terrestris* (LINNAEUS, 1758).

2. MATERIAL AND METHODS

One complete skull and mandible from an adult female dwarf lowland tapir was obtained shot and eaten by locals from the village of Tucunaré along the lower Rio Aripuanã. In Spix & Martius "Reise in Brasilien in den Jahren 1817-1820" (München, 1828) Carl Friedrich Philip von Martius mentions the occurrence of a dwarf form of the lowland tapir in the Brazilian State of Minas Gerais locally known as anta-xuré claimed to be sympatric there with the anta comum or anta-sapateira (*Tapirus americana* L.). "This animal of low stature, ears of a uniform color, not white at the tips, is probably only a variety of the common tapir, but according to Dr. von Spix should be separated from the much larger common tapir and be considered a full species". It is not known to me if Spix has collected the species during his travels through Brazil together with the botanist Martius. If it turns out that the Zoologischen Staatssammlung, München contains a specimen collected by Spix back in 1818 in Minas Gerais that specimen should be considered the holotype. In that case I will name the dwarf lowland tapir for Johann Baptist von Spix: *Tapirus spixianus*.
