## Contents – practice

Chapter 1. Initial warmup	4
A. Numbers and functions	4
B. Difference equations	12
C. Combinatorics	16
D. Probability	20
E. Plane geometry	28
F. Relations and mappings	43
G. Additional exercises for the whole chapter	47
Chapter 2. Elementary linear algebra	83
A. Vectors and matrices	83
B. Determinants	100
C. Vector spaces and linear mappings	107
D. Properties of linear mappings	133
E. Additional exercises for the whole chapter	142
Chapter 3. Linear models and matrix calculus	193
A. Linear optimization	193
B. Recurrence relations	204
C. Models of growth and iterated processes	210
D. More matrix calculus	224
E. Matrix decompositions	248
F. Additional exercises for the whole chapter	262
Chapter 4. Analytic geometry	319
A. Affine geometry	319
B. Euclidean geometry	327
C. Geometry of quadratic forms	341
D. Further exercise on this chapter	361
Chapter 5. Establishing the ZOO	368
A. Polynomial interpolation	368
B. Real numbers and limit processes	380
C. Derivatives	407
D. Infinite sums and power series	428
E. Additional exercises for the whole chapter	444
Chapter 6. Differential and integral calculus	508
A. Derivatives of higher orders	508
B. Integration	534
C. Sequences, series and limit processes	566
D. Additional exercises for the whole chapter	577
Chapter 7. Continuous tools for modelling	631
A. Fourier series	631
B. Integral operators and Fourier Transform	654
C. Metric spaces	667
D. Additional exercises to the whole chapter	686

## Preface

This textbook is a followup of the Czech course material “Matematika drsně a svižně”, reflecting many years of lecturing Mathematics at the Faculty of Informatics at the Masaryk University in Brno. Their programme required introduction to genuine mathematical thinking and precision, but within a quite limited time-frame for lectures. This endeavor was undertaken by Jan Slovák and Martin Panák since 2004, with further collaborators joining later. Our goal was to cover seriously, but quickly, about as much of mathematical methods as usually seen in bigger courses in the classical Science and Technology programmes. At the same time, we did not want to give up the completeness and correctness of the mathematical exposition. We wanted to introduce and explain more demanding parts of Mathematics together with elementary explicit examples how to use the concepts and results in practice. But we did not want to decide how much of theory or practice the reader should enjoy and in which order.

Now, we have tried to accommodate all the above features in one book providing a more or less complete account on basics of Mathematics, as taught in typical Mathematics Bachelor programmes, but in a way relevant to the coming era of computational powers and artificial intelligence resources, including the GPT and other chatbots available widely. Thus, we chose the two column format of the textbook, where the theoretical explanation on one side and the practical procedures and exercises on the other side are split. Moreover, we suppose the practice learning will be heavily supported by Computer Aided Mathematic tool, we chose mainly Sage in our illustrations. This way, we want to encourage and help the readers to find their own way. Either to go through the examples and algorithms first (perhaps with the help of Sage or GPT-like chatbots), and then to come to more serious thinking on why the things work, or the other way round.

We also hope to overcome the usual stress of the readers horrified by the amount of the stuff. With our text, they are not supposed to read through the book in a linear order. On the opposite, the readers should enjoy browsing through the text and finding their own thrilling paths through the new mathematical landscapes.

In both columns, we intend to present rather standard exposition of basic Mathematics, but focusing on the essence of the concepts and their relations. The exercises are addressing simple mathematical problems but we also try to show the exploitation of mathematical models in practice as much as possible.

We are aware that the text is written in a very compact and non-homogeneous way. A lot of details are left to readers, in particular in the more difficult paragraphs, while we try to provide a lot of simple intuitive explanation when introducing new concepts or formulating important theorems. Similarly, the examples display the variety from very simple ones to those requesting independent thinking.

We would very much like to help the reader:

- to formulate precise definitions of basic concepts and to prove simple mathematical results;
- to perceive the meaning of roughly formulated properties, relations and outlooks for exploring mathematical tools;
- to understand the instructions and algorithms underlying mathematical models and to appreciate their usage.

These goals are ambitious and there are no simple paths reaching them without failures on the way. This is one of the reasons why we come back to basic ideas and concepts several times with growing complexity and width of the discussions. Of course, this might also look chaotic but we very much hope that this approach gives a better chance to those who will persist in their efforts. We also hope, this textbook should be a perfect beginning and help for everybody who is ready to think and who is ready to return back to earlier parts again and again.

To make the task simpler and more enjoyable, we have added what we call "emotive icons". We hope they will spirit the dry mathematical text and indicate which parts should be read more carefully, or better left out in the first round. They should work as a sort of switches, so when loosing the ground, the reader is advised to find the next appealing icon and go on.

The usage of the icons follows the feelings of the authors and we tried to use them in a systematic way. We hope the readers will assign the meaning to icons individually. Roughly speaking, there are icons indicating complexity, difficulty etc.:

Further icons indicate unpleasant technicality and need of patience, or possible entertainment and pleasure:

Some icons are related to feelings when solving problems and appear mainly in the practical column:

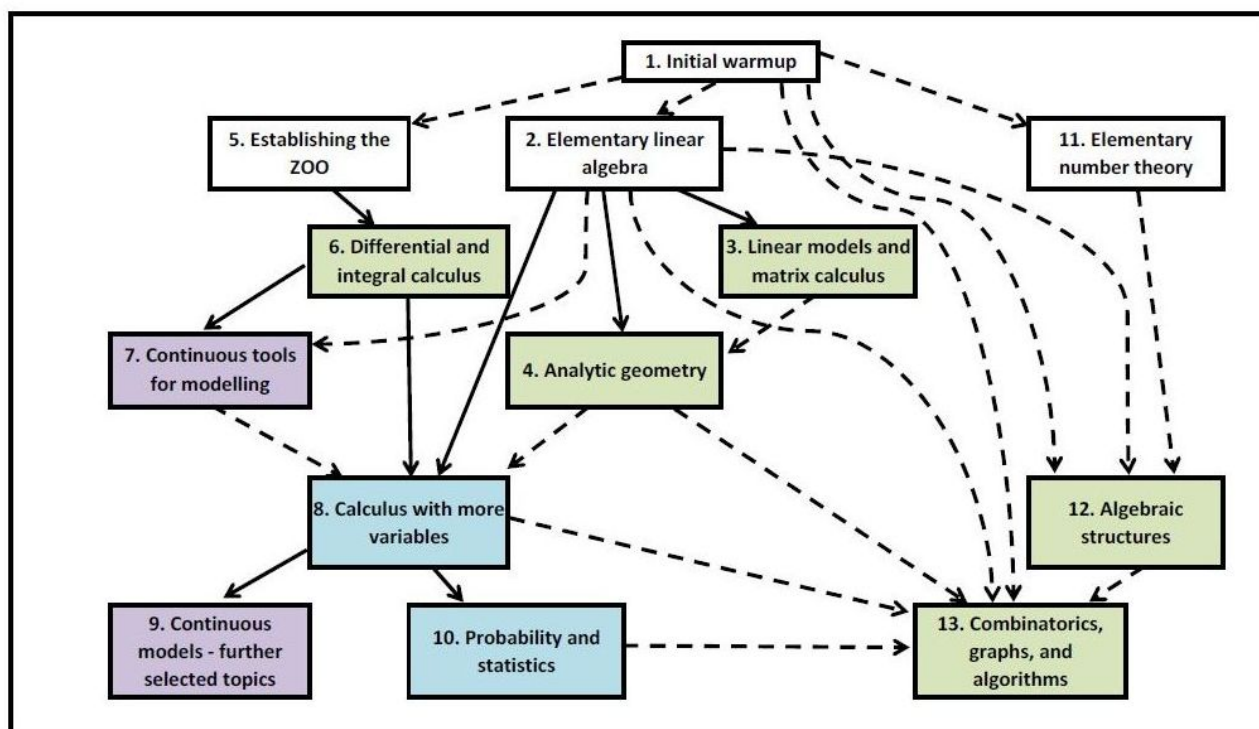

The practical column with the solved problems and exercises should be readable nearly independently of the theory. Without the ambition to know the deeper reasons why the algorithms work, it should be possible to read mainly just this column. In order to help such readers, some definitions and descriptions in the theoretical text are marked in order to catch the eyes easily when reading the exercises. The exercises and theory are partly coordinated to allow jumping there and back, but the links are not tight. The numbering in the two columns is distinguished by using the different numberings of sections, i.e., those like 1.2.1 belong to the theoretical column, while 1.A.14 points to the practical column. The equations are numbered within subsections and their quotes include the subsection numbers if necessary.

In general, our approach stresses the fact that the methods of the so called discrete Mathematics seem to be more important for mathematical models nowadays. They seem also simpler to get perceived, supported by the computational tools, and grasped.

However, the continuous methods are strictly necessary too. First of all, the classical continuous mathematical analysis is essential for understanding of convergence and robustness of computations. It is hard to imagine how to deal with error estimates and computational complexity of numerical processes without it. Moreover, the continuous models are often the efficient and effectively computable approximations to discrete problems coming from practice.

As usual with textbooks, there are numerous figures completing the exposition. We very much advise the readers to draw their own pictures whenever necessary, in particular in the later chapters, where we provide only a few.

The rough structure of the book and the dependencies between its chapters are depicted in the diagram below. The darker the color is, the more demanding is the particular chapter (or at least its essential parts). In particular, the chapters 7 and 9 include a lot of material which would perhaps not be covered in the regular course activities or required at exams in great detail. The solid arrows mean strong dependencies, while the dashed links indicate only partial dependencies. In particular, the textbook could support courses starting with any of the white boxes, i.e. aiming at standard linear algebra and geometry (chapters 2 through 4), discrete chapters of mathematics (11 through 13), and the rudiments of Calculus (5, 6, 8).

All topics covered in the book are now included (with more or less details) in teaching within our Mathematics Minor programme, complemented by numerical seminars. In this block of four courses, the first semester covers chapters 1 and 2 and selected topics from chapters 3 and 4. The second semester essentially includes chapters 5, 6, and 7. The third semester is now split into two parts. The first one is covered by chapter 8 (with only a few glimpses towards the more advanced topics from chapter 9), while the rest of the semester is devoted to the rudiments of the graph theory in chapter 13. The last semester provides large parts of the chapters 11 through 13.

This textbook project got a new impuls when developing the main background material for a new professional programme Data Analytics, a cross-disciplinary endeavor aiming at formal education of top-tier young programmers in the era of GPT and further AI resources. There, the two elementary maths courses in the first semester are covered by Chapters 1-7, while in the second semester, another two courses are based on Chapters 8-9, and 13. Finally one course in the third semester is covered by Chapters 11-12. Two more courses are devoted to Probability and Statistics and they already go much beyond the Chapter 10 here.

## Initial warmup

“value, difference, position”  
– what it is and how to comprehend it?

### A. Numbers and functions

People mostly think that “Mathematics” equals “counting”. Indeed, we start the introduction with number systems including integers, rationals, reals, and complex numbers, denoted by  $\mathbb{Z}$ ,  $\mathbb{Q}$ ,  $\mathbb{R}$  and  $\mathbb{C}$ , respectively. Counting is based on functions, and numbers are their arguments and values. We approach these elementary and well known concepts now in order to invoke the more realistic view at Mathematics as a way of thinking. The reader is always advised to keep an eye at the right-hand column if the concepts and methods get unclear. In the next pages, we also use basic properties of numbers which we carefully discuss only in Chapter 12 (e.g., the unique decomposition of integers into products of primes, etc.).

As soon as mathematical tasks approach counting, it can be easily done in computer aided mathematics software in a few lines of code. Therefore, our exposition will often include Sage cells, but we avoid presenting preliminaries on programming with Sage. Our experience indicates that the Sage (Python based) interface is user-friendly and even unfamiliar readers should feel comfortable with basic coding in Sage really fast.

**1.A.1.** Integers are *discrete*, in the sense that for any  $m \in \mathbb{Z}$ , there is no integer between  $m$  and  $m + 1$ . Show with an example that this fails for each couple of rational numbers.

The goal of this first chapter is to introduce the reader to the fascinating world of mathematical thinking.

The name of this chapter can be also understood as an encouragement for patience. Even the simplest tasks and ideas are easy only for those who have already seen similar ones.

We start with the simplest thing: numbers.

They will also serve as the first example of how mathematical objects and theories are built. The entire first chapter will become a quick tour through various mathematical landscapes (including germs of analysis, combinatorics, probability, geometry, and the language of Mathematics itself).

Perhaps sometimes our definitions and ideas will look too complicated and not practical enough. The simpler the objects and tasks are, the more difficult the mastering of depth and all nuances of the relevant tools and procedures might be. We shall come back to all of the notions again and again in the further chapters and hopefully this will be the crucial step in the ultimate understanding.

Thus the advice: do not worry if you find some particular part of the exposition too formal or otherwise difficult – come back later for another look.

### 1. Numbers and functions

Since the dawn of time, people want to know “how much” about something they have, or “how much” is something worth, “how long” will a particular task take, etc. The answer for such ideas is usually some kind of “number”. We consider something to be a number, if it behaves according to the usual rules – either according to all the rules we accept, or maybe only to some of them. For instance, the result of multiplication does not depend on the order of multiplicands. We have the number zero whose addition to another number does not change the result. We have the number one whose product with another number does not change the result. And so on.

The simplest example of numbers are the positive integers which we denote  $\mathbb{Z}^+ = \{1, 2, 3, \dots\}$ . The natural numbers consist of either just the positive integers, or the positive integers together with the number zero. The number zero is either considered to be a natural number, as is usual in computer science, or not a natural number as is usual in some other contexts.

**Solution.** Let  $p = a/b$  and  $q = c/d$  be two rationals, where  $a, b, c, d \in \mathbb{Z}$ , and suppose for instance that  $p < q$ . Consider the average  $\alpha$  of  $p, q$ , i.e.,  $\alpha = \frac{1}{2}(p + q)$ . Then  $\alpha = \frac{ad+cb}{2bd}$ , and this is a rational number as the quotient of the integers  $ad+cb$  and  $2bd$ . Now, adding  $p$  to both sides of the inequality  $p < q$  we get  $2p < p + q$ , whereas adding  $q$  to both sides gives  $p + q < 2q$ . Hence we have  $2p < p + q < 2q$  and so  $p < \alpha < q$ .  $\square$

**1.A.2.**

**1.A.3.** Show that the integer 2 does not have a rational square root (hint: think about the number of copies of 2 appearing in the decompositions of integers).  $\circ$

**1.A.4.** An irrational number is a real number which cannot be written as the ratio of two integers. Using 1.A.3, prove that between any two different rational numbers there is an irrational number.  $\circ$

*Perhaps, people reading this book are familiar with naturals, integers, rationals, and reals. However, there are larger sets of numbers as the complex numbers, or the quaternions, the latter introduced by William H. Hamilton already in 1843. Next we provide examples on complex numbers, see their introduction in 1.1.3. The algebra of quaternions is a topic requiring some knowledge from linear algebra. Hence it will be discussed later in paragraph 2.E.66, in terms of the so-called Pauli matrices.<sup>1</sup>*

**1.A.5.** Consider the function  $f(x) = x^2 - 4x + 8$ . Use its graph to ensure yourself that we need to extend the real numbers to solve each quadratic equation with real coefficients. Recall the formula for such a universal solution.

**Solution.** Given a function  $f$  with domain  $X$  and codomain  $Y$ , its graph is the set  $G_f = \{(x, f(x)) : x \in X\}$ . Thus  $G_f$  is a subset of the Cartesian product  $X \times Y$  of  $X, Y$ , i.e.,

$$G_f \subseteq X \times Y = \{(x, y) : x \in X, y \in Y\},$$

where here  $(x, y)$  are ordered pairs, see also 1.6.1.

To illustrate the graph of the given  $f$ , we first note that  $G_f \subseteq \mathbb{R} \times \mathbb{R}$ . This means that  $G_f$  is a subset of the real plane  $\mathbb{R}^2$ , also called *Euclidean plane* (see the discussion in 1.5.1 and 1.5.2 for more details on  $\mathbb{R}^2$ ). To visualize  $G_f$  or parts of it, there are many alternatives. Next we will demonstrate how to use SageMath, which

<sup>1</sup>Complex numbers appear already in *Ars Magna* by Gerolamo Cardano (1501-1576, Italian), around 1545 in relation to solving cubic equations (see 1.A.21 below). Another known number system consists of the *octonions*, also referred to as “Cayley numbers”. Roughly speaking, octonions provide a generalization of quaternions. In a similar fashion, quaternions can be thought of as a generalization of complex numbers, and complex numbers of reals.

William Rowan Hamilton (1805-1865) was an Irish mathematician, astronomer, and physicist. Arthur Cayley (1821-1895) was a British mathematician working mainly in algebra. Actually, the octonions were introduced slightly earlier independently by John T. Graves in 1843, the same year as his friend discovered the quaternions.

Thus the set of natural numbers is either  $\mathbb{Z}^+$ , or the set  $\mathbb{N} = \{0, 1, 2, 3, \dots\}$ . To count “one, two, three, ...” is learned already by children in their pre-school age. Later on, we meet all the integers  $\mathbb{Z} = \{\dots, -2, -1, 0, 1, 2, \dots\}$  and finally we get used to floating-point numbers. We know what a 1.19-multiple of the price means if we have a 19% tax.

**1.1.1. Properties of numbers.** In order to be able to work properly with numbers, we need to be careful with their definition and properties. In mathematics, the basic statements about properties of objects, whose validity is assumed without the need to prove them, are called *axioms*.

We list the basic properties of the operations of addition and multiplication for our calculations with numbers, which we denote by letters  $a, b, c, \dots$ . Both operations work by taking two numbers  $a, b$ . By applying addition or multiplication we obtain the resulting values  $a + b$  and  $a \cdot b$ .

PROPERTIES OF NUMBERS

**Properties of addition:**

- (CG1)  $(a + b) + c = a + (b + c)$ , for all  $a, b, c$
- (CG2)  $a + b = b + a$ , for all  $a, b$
- (CG3) there exists 0 such that for all  $a$ ,  $a + 0 = a$
- (CG4) for all  $a$  there exists  $b$  such that  $a + b = 0$ .

The properties (CG1)-(CG4) are called the properties of a *commutative group*. They are called respectively *associativity*, *commutativity*, *the existence of a neutral element* (when speaking of addition we usually say zero element), and *the existence of an inverse element* (when speaking of addition we also say the negative of  $a$  and denote it by  $-a$ ).

**Properties of multiplication:**

- (R1)  $(a \cdot b) \cdot c = a \cdot (b \cdot c)$ , for all  $a, b, c$
- (R2)  $a \cdot b = b \cdot a$ , for all  $a, b$
- (R3) there exists 1 such that for all  $a$ ,  $1 \cdot a = a$
- (R4)  $a \cdot (b + c) = a \cdot b + a \cdot c$ , for all  $a, b, c$ .

The properties (R1)-(R4) are called respectively *associativity*, *commutativity*, *the existence of a unit element* and *distributivity of addition with respect to multiplication*. The sets with operation  $+$ ,  $\cdot$  that satisfy the properties (CG1)-(CG2) and (R1)-(R4) are called *commutative rings*. Two further properties of multiplication are:

- (F) for every  $a \neq 0$  there exists  $b$  such that  $a \cdot b = 1$ .
- (ID) if  $a \cdot b = 0$ , then either  $a = 0$  or  $b = 0$  or both.

The property (F) is called *the existence of an inverse element* with respect to multiplication (this element is then denoted by  $a^{-1}$ ). For normal arithmetic, this is called the reciprocal of  $a$ , the same as  $1/a$  or  $\frac{1}{a}$ .

The property (ID) then says that there exists no “divisors of zero”. A *divisor of zero* is a number  $a, a \neq 0$ , such that there is a number  $b, b \neq 0$ , with  $a \cdot b = 0$ .

is a free mathematical software system that can be accessed at <https://sagecell.sagemath.org>

The graph of the given function  $f$  is displayed in the image on the right. The Sage cell that generates this graph uses the `plot` command, which requires three parameters: “what to plot”, “what the variable is” and “the range of plotting”. Thus, in general, the syntax we use is as follows:

```
plot(f(x), (x, x_min, x_max))
```

In our case this takes the very simple form

```
f(x) = x**2 - 4*x + 8; plot(f(x), x, -10, 10)
```

In this block observe that we used “;” to type different commands in the same line, while the values  $-10, 10$  specify where  $x$  is evaluated. In the graph we see that  $f$  does not intersect the  $x$ -axis. Thus the equation  $f(x) = x^2 - 4x + 8 = 0$  cannot admit a solution over the reals.

In general, this reflects the negative value of the discriminant  $\Delta = b^2 - 4ac$  of an equation  $ax^2 + bx + c = 0$ . Indeed  $\Delta = -16$  in our case. Recall the well known formula for the solutions  $x_{1,2} = \frac{-b \pm \sqrt{\Delta}}{2a}$ , giving us the (possibly) complex solutions  $x_{1,2}$  once we introduce  $\sqrt{-1} = i$ . Indeed, in our case  $\sqrt{\Delta} = \sqrt{-1}\sqrt{-\Delta} = \sqrt{-1}\sqrt{16} = i\sqrt{16} = 4i$  and the solutions are  $x_{1,2} = 2 \pm i2$ .  $\square$

**1.A.6. A comment on power functions.** Suppose that  $n \in \mathbb{N}$  is a positive natural number.<sup>2</sup> The  $n$ th root  $\sqrt[n]{x} = x^{\frac{1}{n}}$  of some positive real  $x > 0$  is the inverse of the power function  $f(x) = x^n$ , so  $(\sqrt[n]{x})^n = \sqrt[n]{x^n} = x$ . A *polynomial function* is the sum of a finite number of (constant) multiples of power functions with natural exponents, as for example the function  $f(x) = 2(x - 4)^3 - 16$ . Note that it holds  $x^0 = 1$  for each real or complex number  $x$ . Consider the equation  $f(x) = 0$ , i.e.,  $2(x - 4)^3 = 16$ . We have  $(x - 4) = \sqrt[3]{2^3} = 2$ , which gives  $x = 6$  as a quick solution. This is visible also in the graph of  $f$ , given below (this was obtained in Sage via the command `plot(f, -2, 10)`, as before). However, since our equation is of degree 3, over  $\mathbb{C}$  one expects three solutions (based on the fundamental theorem of algebra, see in Chapter 12, and also in the end of this section). In order to determine all the

<sup>2</sup>In this book we mainly adopt the notation  $\mathbb{N} = \{0, 1, 2, 3, \dots\}$  for the (ordered) set of naturals, so we view 0 as a natural number (except Chapter 11 on number theory, where 0 is not considered as a natural number).

**1.1.2. Remarks.** The integers  $\mathbb{Z}$  are a good example of a commutative group. The natural numbers are not such an example since they do not satisfy (CG4) (and possibly do not even contain the neutral element if one does not consider zero to be a natural number). If a commutative ring also satisfies the property (F), we speak of a *field* (often also about a *commutative field*).

The last stated property (ID) is automatically satisfied if (F) holds. However, the converse statement is false. Thus we say that the property (ID) is weaker than (F). For example, the ring of integers  $\mathbb{Z}$  does not satisfy (F) but does satisfy (ID). In such a case we use the term *integral domain*.

Notice that the set of all non-zero elements in the field along with the operation of multiplication satisfies (R1), (R2), (R3), (F) and thus is also a commutative group. However in this case, instead of addition we speak of multiplication. As an example, the set of all non-zero real numbers forms a commutative group under multiplication.

The elements of some set with operations  $+$  and  $\cdot$  satisfying (not necessarily all) stated properties (for example, a commutative field, an integral domain) may be called *scalars*. To denote them we usually use lowercase Latin letters, either from the beginning or from the end of the alphabet.

We will use only these properties of scalars and thus our results will hold for any objects with such properties. This is the true power of mathematical theories – they do not hold just for a specific solved example. Quite the opposite, when we build ideas in a rational way they are always universal. We will try to emphasise this aspect, although our ambitions are modest due to the limited size of this book.

Before coming to any use of scalars, we should make a short formal detour and pay attention to their existence. We shall come back to this in the very end of this chapter, when we shall deal with the formal language of Mathematics in general, cf. the constructions starting in 1.6.5. There we indicate how to get natural numbers  $\mathbb{N}$ , integers  $\mathbb{Z}$ , and rational numbers  $\mathbb{Q}$ , while the real numbers  $\mathbb{R}$  will be treated much later in chapter 5.

At this point, let us just remark that it is not enough to pose the axioms of objects. We have to be sure that the given conditions are not in conflict and such objects might exist.

We suppose the readers are sure about the existence of the domains  $\mathbb{N}$ ,  $\mathbb{Z}$ ,  $\mathbb{Q}$  and can handle them easily. The real numbers are usually understood as a dense and better version of  $\mathbb{Q}$ , but what about the domain of complex numbers?

As is usual in mathematics, we will use variables (letters of alphabet or other symbols) to denote numbers, and it does not matter whether we know their value beforehand or not.

**1.1.3. Complex numbers.** We are forced to extend the domain of real numbers as soon as we want to see solutions of equations like  $x^2 = b$  for all real numbers  $b$ .

We know that this equation always has a solution  $x$  in the domain of real numbers, whenever  $b$  is non-negative. If

solutions, we may use the command `solve` in Sage. This is an appropriate tool for solving equations and system of equations.

In the sequel we will encounter the `solve` command in various contexts and analyze its possible implementations in more detail. For the function  $f$  of our example, we can proceed as follows:

```
x=var("x"); f = 2*(x-4)**3-16
sol = solve([f==0], x); sol
```

and as an output we obtain a list of the three solutions, with two of them being complex conjugate, i.e.,

```
[x == -I*sqrt(3) + 3,
 x == I*sqrt(3) + 3, x == 6]
```

A traditional way to find the roots of polynomials relies on the so called *Horner's scheme*. This provides a quick way to evaluate a given polynomial  $f(x)$ , and occurs by rewriting the polynomial as follows:

$$f(x) = a_0 + a_1x + a_2x^2 + a_3x^3 + \dots + a_nx^n = a_0 + x(a_1 + x(a_2 + x(a_3 + \dots + x(a_{n-1} + xa_n) \dots)))$$

Observe that such a procedure requires  $n$  multiplications and  $n$  additions (and this turns out to be optimal). In fact we can treat the division of polynomials by divisors of the form  $x - \rho$  ( $\rho \in \mathbb{R}$ ), using the *Horner's table*:

$\rho$	$a_n$	$a_{n-1}$	$\dots$	$a_0$
	-	$\rho a_n$	$\dots$	
	$a_n$	$\rho a_n + a_{n-1}$	$\dots$	$f(\rho)$

In this table, each entry in the second row is the product of  $\rho$  with the bottom-row entry immediately to the left. The bottom line is the sum of the previous two lines. For example, if  $f(x) = x^3 + x^2 - x + 2$  and  $\rho = -2$ , we obtain

$\rho = -2$	1	1	-1	2
		-2	2	-2
	1	-1	1	0

The zero in the last entry (the remainder), verifies that  $\rho = -2$  is a root of our polynomial, i.e.,  $f(\rho) = 0$ .<sup>3</sup>

**I.A.7.** Use the Horner's scheme to find the division of  $p(x) = 5x^4 + x^2 - 2x + 2$  by  $x - 4$ . Then verify your answer by the classical algorithm of (long) division. ○

Polynomials can be defined also over the complex numbers, and the Horner's scheme is applicable in this case as well. Recall that to each complex number  $z = x + iy \in \mathbb{C}$  we can associate the ordered pair  $(x, y)$  in the Euclidean plane. Thus, complex numbers can be viewed as ordered pairs of real numbers  $(x, y) \in \mathbb{R}^2$ , and such pairs correspond to vectors on  $\mathbb{R}^2$  with initial point the origin of  $\mathbb{R}^2$ . As usual we will use the  $x$ -axis for the reals  $\text{Re } z$ , and the  $y$ -axis to denote the purely

<sup>3</sup>The motivation back of the notation  $\rho$  in the Horner's scheme, is due to the greek word " $\rho\iota\chi\alpha$ ", which means "root".

$b < 0$ , then such a real  $x$  cannot exist. Thus we need to find a larger domain, where this equation has a solution.

The crucial idea is to add the new number  $i$  to the real numbers, the *imaginary unit*, for which we require  $i^2 = -1$ . Next we try to extend the definitions of addition and multiplication in order to preserve the usual behaviour of numbers (as summarised in 1.1.1).

Clearly we need to be able to multiply the new number  $i$  by real numbers and sum it with real numbers. Therefore we need to work in our newly defined domain of *complex numbers*  $\mathbb{C}$  with formal expressions of the form  $z = a + ib$ , being called *algebraic form* of  $z$ . The real number  $a$  is called the *real part* of the complex number  $z$ , the real number  $b$  is called the *imaginary part* of the complex number  $z$ , and we write  $\text{Re}(z) = a$ ,  $\text{Im}(z) = b$ . It should be noted that if  $z = a + ib$  and  $w = c + id$  then  $z = w$  implies both  $a = c$  and  $b = d$ . In other words, we can equate both real and imaginary parts. For positive  $x$  we then get  $(i \cdot x)^2 = -1 \cdot x^2$  and thus we can solve the equations as requested.

In order to satisfy all the properties of associativity and distributivity, we define the addition so that we add independently the real parts and the imaginary parts. Similarly, we want the multiplication to behave as if we multiply the pairs of real numbers, with the additional rule that  $i^2 = -1$ , thus

$$(a + ib) + (c + id) = (a + c) + i(b + d),$$

$$(a + ib) \cdot (c + id) = (ac - bd) + i(bc + ad).$$

Next, we have to verify all the properties (CG1-4), (R1-4) and (F) of scalars from 1.1.1. But this is an easy exercise: zero is the number  $0 + i0$ , one is the number  $1 + i0$ , both these numbers are for simplicity denoted as before, that is, 0 and 1. For non-zero  $z = a + ib$  we easily check that  $z^{-1} = (a^2 + b^2)^{-1}(a - ib)$ . All other properties are obtained by direct calculations.

**1.1.4. The complex plane and polar form.**

A complex number is given by a pair of real numbers, therefore it corresponds to a point in the real plane  $\mathbb{R}^2$ . Our algebraic form of the complex numbers  $z = x + iy$  corresponds in this picture to understanding the  $x$ -coordinate axis as the real part while the  $y$ -coordinate axis is the imaginary part of the number. The *absolute value* of the complex number  $z$  is defined as its distance from the origin, thus  $|z| = \sqrt{x^2 + y^2}$ .

The reflection with respect to the real axis then corresponds to changing the sign of the imaginary part. We call this operation  $z \mapsto \bar{z} = x - iy$  the *complex conjugation*.

Let us now consider complex numbers of the form  $z = \cos \varphi + i \sin \varphi$ , where  $\varphi$  is a real parameter giving the angle between the real axis and the line from the origin to  $z$  (measured in the positive, i.e. counter-clockwise sense). These numbers describe all points on the unit circle in the complex plane. Every non-zero complex number  $z$  can be then written as

$$z = |z|(\cos \varphi + i \sin \varphi).$$

imaginary numbers  $i \operatorname{Im} z$ . We proceed with basic exercises on the arithmetic of complex numbers. Recall that both the addition and the multiplication of complex numbers attain a geometric interpretation: Addition corresponds to vector sum, while multiplication by  $i = \sqrt{-1}$ , for example, is equivalent to a counterclockwise rotation by the right angle.

**1.A.8. Arithmetic in  $\mathbb{C}$ .** Compute  $\operatorname{Re}(z_1)$ ,  $\operatorname{Im}(z_1)$ ,  $\bar{z}_1$ ,  $|z_2|$ ,  $z_1 + z_2$ , and  $z_1 z_2$ , for the cases:

- (a)  $z_1 = 1 - 2i$ ,  $z_2 = 4i - 3$ ;
- (b)  $z_1 = 3 + 4i$ ,  $z_2 = 3 - 4i$ .

**Solution.** (a) We have  $\operatorname{Re}(z_1) = 1$ ,  $\operatorname{Im}(z_1) = -2$ ,  $\bar{z}_1 = 1 + 2i$ ,  $|z_2| = \sqrt{4^2 + (-3)^2} = 5$ ,  $z_1 + z_2 = -2 + 2i$ ,  $z_1 z_2 = 5 + 10i$ .

(b) Here we use Sage, where the field of complex numbers is denoted by `CC`, while as we saw above the square root of  $-1$  is denoted by `I` (or `i`). To introduce a complex number there are many alternatives, e.g., we simply type `z1 = 3 + 4 * I`, where `*` is the general multiplication operator in Sage<sup>4</sup>, or type `z1 = CC(3, 4)`. As for the additional code that gives the computations, type and run successively the following

```
z1 = CC(3, 4); z2 = CC(3, -4)
z1.real (); z1.imag ()
z1.conjugate (); abs(z2); z1+z2; z1*z2
```

Note that in case (b) we have  $z_2 = \bar{z}_1$ . In Sage a verification of this takes the form `z1 == conjugate(z2)`, after introducing  $z_1, z_2$  as above. As it is usual also in Python (the mother of Sage), this means that one uses “=” to determine a quantity, instead of “==” which is used to determine an equation between two quantities (in the latter case Sage returns `True` or `False`). It follows that  $|z_1| = |z_2| = \sqrt{25} = 5$  (see also 1.A.10 below), and the multiplication  $z_1 z_2$  occurs also by the usual formula  $z\bar{z} = |z|^2$ , with  $z \in \mathbb{C}$  (verify this).  $\square$

**1.A.9.** Show that the Euclidean distance between two arbitrary complex numbers  $z = x + iy$  and  $w = u + iv$  is given by the formula  $d = |z - w| = \sqrt{(x - u)^2 + (y - v)^2}$ , with  $x, y, u, v \in \mathbb{R}$ .  $\circ$

**1.A.10.** Given the complex number  $1 + i\sqrt{3}$ , make use only of the figure given below to calculate its distance from its complex conjugate. Next, consider the complex number  $z = \frac{2+2i\sqrt{3}+3i-3\sqrt{3}}{1-i\sqrt{3}}$ . Relate a verification of the equality  $|z| = \sqrt{13}$  with the given figure and find another  $z' \in \mathbb{C}$  with the same property, i.e.,  $|z'| = \sqrt{13}$ .

**Solution.** Complex conjugates are symmetric with respect to the  $x$ -axis. Moreover, the distance of a complex number from the  $x$ -axis equals its imaginary part. Thus, as we deduce also from the given figure, the distance between  $1 + i\sqrt{3}$  and its conjugate  $1 - i\sqrt{3}$  equals to  $2\sqrt{3}$ . Now, from the Pythagorean

<sup>4</sup>As we will see later, in Sage the multiplication of matrices and vectors is also denoted by `*`.

For given  $z \neq 0$ ,  $\varphi$  is unique if  $0 \leq \varphi < 2\pi$ . The number  $\varphi$  is called the argument of the complex number  $z$  and this form of  $z$  is called the *polar form* of the complex number. This way of writing the complex numbers is very convenient for understanding the multiplication.

Consider the numbers  $z = |z|(\cos \varphi + i \sin \varphi)$  and  $w = |w|(\cos \psi + i \sin \psi)$  and calculate their product

$$\begin{aligned} z \cdot w &= |z|(\cos \varphi + i \sin \varphi)|w|(\cos \psi + i \sin \psi) \\ &= |z||w|(\cos \varphi \cos \psi - \sin \varphi \sin \psi \\ &\quad + i(\cos \varphi \sin \psi + \sin \varphi \cos \psi)) \\ &= |z||w|(\cos(\varphi + \psi) + i \sin(\varphi + \psi)). \end{aligned}$$

The last equality is a result of the addition formulas for trigonometric functions (we shall deal with them in more detail later in our discussion of rotations in the plane, see the page 37).

Division is equally easy. If  $z = |z|(\cos \varphi + i \sin \varphi) \neq 0$ , then  $w = |z|^{-1}(\cos \varphi - i \sin \varphi)$  satisfies  $zw = wz = 1$ , hence we can write  $w = z^{-1} = 1/z$ .

We can summarize (and iterate the application of the previous formula on the product of the number  $z$  with itself):

POLAR FORM AND DE MOIVRE THEOREM

Consider two complex numbers  $z = |z|(\cos \varphi + i \sin \varphi)$  and  $w = |w|(\cos \psi + i \sin \psi)$  in polar forms. Then if  $n$  is an integer, positive or negative,

$$\begin{aligned} z w &= |z||w|(\cos(\varphi + \psi) + i \sin(\varphi + \psi)) \\ z^n &= |z|^n(\cos(n\varphi) + i \sin(n\varphi)). \end{aligned}$$

**1.1.5. Functions.** In most tasks we do not deal just with numbers, i.e. with individual values of scalars. More often the values are associated to each of the elements in a set of objects.

Formally we talk about a *mapping*  $f : A \rightarrow B$  assigning to each element  $x$  in the *domain* set  $A$  the value  $f(x)$  in the *codomain* set  $B$ . The set of all images  $f(x) \in B$  is called the *range* of  $f$ .

The set  $A$  or  $B$  can be a set of numbers, but there is nothing to stop them being sets of other objects. The mapping  $f$ , however it is described, must unambiguously determine a unique member of  $B$  for each member of  $A$ .

In another terminology, the member  $x \in A$ , is often called the *independent variable*. Then  $y = f(x) \in B$ , is called the *dependent variable*. We also say that the value  $y = f(x)$  is a *function* of the independent variable  $x$  in the domain of  $f$ .

For now, we shall restrict ourselves to the case where the codomain  $B$  is a subset of scalars and we shall talk about *scalar functions*.

The simplest way to define a function appears if  $A$  is a finite set. Then we can describe the function  $f$  by a table or a listing showing the image of each member of  $A$ . We have certainly seen many examples of such functions:

Theorem it follows that a complex number  $x + iy$  and its complex conjugate  $x - iy$  have the same length (absolute value), given by  $r := \sqrt{x^2 + y^2}$ .

For our task this applies to  $1 + i\sqrt{3}$ . On the other hand, recall that the absolute value of the product of any two complex numbers is the product of their absolute values. Thus, if  $z_1, z_2$  are two complex numbers, provided that  $z_2 \neq 0$ , we see that

$$\left| \frac{z_1 z_2}{z_2} \right| = \frac{|z_1 z_2|}{|z_2|} = \frac{|z_1| |z_2|}{|z_2|} = |z_1|.$$

Observe now the numerator of the given  $z$  is expressed as

$$\begin{aligned} 2 + 2i\sqrt{3} + 3i - 3\sqrt{3} &= 2(1 + i\sqrt{3}) + 3i(1 + i\sqrt{3}) \\ &= (2 + 3i)(1 + i\sqrt{3}). \end{aligned}$$

This means that our  $z$  has the form  $\frac{z_1 z_2}{z_2}$  with  $z_1 = 2 + i3$  and  $z_2 = 1 + i\sqrt{3}$ , respectively, and hence the result:  $|z| = |z_1| = |2 + i3| = \sqrt{2^2 + 3^2} = \sqrt{13}$ . Because  $z_2$  does not play any essential role in this computation, one can find infinitely many complex numbers with the same property as the given  $z$ .  $\square$

**1.A.11.** Determine the distance  $d$  of the numbers  $z, \bar{z}$  in the complex plane for  $z = \sqrt{\sqrt{13}} - i(\sqrt{13}/2)$ .  $\circ$

**1.A.12.** Use the Horner's scheme to solve the equation

$$z^3 + (1 + i)z^2 + az + 2 = 0, \quad z \in \mathbb{C},$$

when it is already known that  $z_0 = i$  is a root of the given equation.  $\circ$

**1.A.13.** Solve the equation  $x^2 + 2(1 + i)x = 14i$  (observe that this is a quadratic equation with complex coefficients).

**Solution.** Add to both sides of the equation the term  $(1 + i)^2$ . This gives  $x^2 + 2(1 + i)x + (1 + i)^2 = 14i + (1 + i)^2$ , or equivalently,

$$(x + (1 + i))^2 = 16i.$$

Therefore,  $x + (1 + i) = \pm 4\sqrt{i}$ , that is,  $x = -(1 + i) \pm 4\sqrt{i}$  and it remains to compute  $\sqrt{i}$ . Suppose that  $a + ib = \sqrt{i}$  for some reals  $a, b \in \mathbb{R}$ . Then  $(a + ib)^2 = i$  or in other words  $a^2 + 2iab - b^2 = i = 0 + 1i$ . By comparing the real and imaginary parts, we obtain the equations  $a^2 - b^2 = 0$  and  $2ab = 1$ . The first relation gives  $a = \pm b$ . If  $a = b$  then the

Let  $f$  denote the pay of a worker in some company in certain year. The values of independent variable, that is, the domain of the function, are individual workers  $x$  from the set of all considered workers. The value  $f(x)$  is their pay for the given year. Similarly we can talk about the age of students or their teachers in years, the litres of beer and wine consumed by individuals from a given group, etc.

Another example is a food dispensing machine. The domain of a function  $f$  would be the button pushed together with the money inserted to determine the selection of the food item.

Let  $A = \{1, 2, 3\} = B$ . The set of equalities  $f(1) = 1, f(2) = 3, f(3) = 3$ , defines a function  $f : A \rightarrow B$ . Generally, as there are 3 possible values for  $f(1)$ , and the same for  $f(2)$ , and  $f(3)$ , there are 27 possible functions from  $A$  into  $B$  in total.

But there are other ways to define a function than as a table. For example, the function  $f$  can denote the area of a planar region. Here, the domain consists of subsets of the plane (e.g. all triangles, circles or other planar regions with a defined area). The range of  $f$  consists of the respective areas of the regions. Rather than providing a list of areas for a finite number regions, we hope for a formula allowing us to compute the functional value  $f(P)$  for any given planar region  $P$  from a suitable class.

Of course, there are many simple functions given by formulae, e.g.  $f(x) = 3x + 7$  with  $A = B = \mathbb{R}$  or  $A = B = \mathbb{N}$ .

Not all functions can be given by a formula or list. For example, let  $f(t)$  denote the speed of the car at time  $t$ . For any given car and time  $t$ , we know there will be the functional values  $f(t)$  denoting its speed. Which can of course be measured approximately, but usually not by a formula.

Another example: Let  $f(n)$  be the  $n^{\text{th}}$  digit in the decimal expansion of  $\pi \doteq 3.1415\dots$ . So for example  $f(4) = 5$ . The value of  $f(n)$  is defined but unknown if  $n$  is large enough.

The mathematical approach in modelling real problems often starts from the indication of certain dependencies between some quantities and aims at explicit formulas for functions which describe them. Often a full formula is not available but we may obtain the values  $f(x)$  at least for some instances of the independent variable  $x$ , or we may be able to find a suitable approximation.

We shall see all of the following types of expressions of the requested function  $f$  in this book:

- exact finite expression (like the function  $f(x) = 3x + 7$  above);
- infinite expression (we shall come to that only much later in chapter 5 when introducing the limit processes);
- description of how the function's values change under a given change of the independent variable (this behaviour will be displayed under the name difference equation in a moment and under different circumstances later on);
- approximation of a not computable function with a known one (usually including some error estimates – this could be the case with the car above, say we know

second relation reduces to  $a^2 = 1/2$ , that is,  $a = \pm 1/\sqrt{2} = \pm \sqrt{2}/2 = b$ . We also see that the case  $a = -b$  is impossible; It gives  $2a^2 = -1$  which contradicts to the fact  $a \in \mathbb{R}$ . Thus  $\sqrt{i} = \pm \frac{\sqrt{2}}{2}(1 + i)$  and

$$x = -(1 + i) \pm 2\sqrt{2}(1 + i) = (-1 \pm 2\sqrt{2})(1 + i).$$

For convenience, let us verify the answer via Sage. The next commands successively written, yield the computations of the real/imaginary parts of the two complex solutions:

```
eq = x**2+2*(1+I)*x-14*I==0
sols = solve([eq], x); sols
sols[0].rhs().real_part()
sols[0].rhs().imag_part()
sols[1].rhs().imag_part()
sols[1].rhs().real_part()
```

For example, the last command returns  $2 * \text{sqrt}(2) - 1$ , as it should be, and similarly for the previous commands. As a useful remark, keep in mind that in Sage the command `sols[0]` returns the first solution, and `sols[1]` the second one. This means that Sage assigns automatically labels to these solutions, as the first two integers “0”, and “1”, respectively.  $\square$

**1.A.14. Polar form and algebraic form.** Express  $z_1 = 2 + 3i$  in polar form. Next, express  $z_2 = 3(\cos(\pi/3) + i \sin(\pi/3))$  in algebraic form.

**Solution.** As we learned from the figure in 1.A.10, the absolute value  $|z_1|$  of the complex number  $z_1$  equals to  $r = \sqrt{13}$ . Next, we need the angle (argument)  $\varphi$  of  $z_1$ , indicated in the figure. Applying the well-known rules for the trigonometric functions  $\cos$  and  $\sin$  yields  $\sin(\varphi) = 3/\sqrt{13}$  and  $\cos(\varphi) = 2/\sqrt{13}$ , respectively. Therefore, with the aid of a calculator we get

$$\varphi = \arcsin(3/\sqrt{13}) = \arccos(2/\sqrt{13}) \doteq 56.3^\circ.$$

This computation is also easy in Sage: Running the cell

```
z=2+3*I; arg(z)
```

we obtain  $\arctan(3/2)$ . Then, to translate the angle in radians or degrees we just type

```
phi = arctan(3/2)
print(N(phi,digits = 5), "radians")
print(N(phi*180/pi,digits=4), "degrees")
```

The given answer is 0.98279 radians and 56.31 degrees, respectively. Now we are able to present the polar form of  $z_1 = x + iy$ : We have  $x = \sqrt{13} \cos(\varphi)$  and  $y = \sqrt{13} \sin(\varphi)$

it goes with some known speed at the time  $t = 0$ , we break as much as possible on a known surface and we compute the decrease of speed with the help of some mathematical model);

- finding only the probability of possible values of the function. For example the function giving the length of life of a given group of still living people, in dependence of some health related parameters.

**1.1.6. Functions defined explicitly.** Let us start with the

most desirable case, when the function values are defined by a computable finite formula. Of course, we shall be interested also in the efficiency of the formulas, i.e. how fast the evaluations would be. In principle, real computations can involve only a finite number of summations and multiplications of numbers. This is how we define the *polynomials*, i.e. functions of the form  $f(x) = a_n \cdot x^n + \dots + a_1 \cdot x + a_0$ , where  $a_0, \dots, a_n$  are known scalars,  $x$  is the unknown variable whose value we can insert.  $x^n = 1 \cdot x \cdot \dots \cdot x$  means the  $n$ -times repeated multiplication of the unit by  $x$  (in particular,  $x^0 = 1$ ), and  $f(x)$  is the value of the indicated sum of products. This is fairly well computable formula for each  $n \in \mathbb{N}$ . The choice  $n = 0$  provides the constants (i.e. constant functions)  $a_0$ .

The next example is more complicated.

### FACTORIAL FUNCTION

Let  $A = \mathbb{Z}^+$  be the set of positive integers. For each  $n \in \mathbb{Z}^+$ , define the factorial function by

$$n! = n(n-1)(n-2) \dots 3 \cdot 2 \cdot 1.$$

For convenience we also define  $0! = 1$ . (We will see why this is sensible later on). It is easy to see that  $n! = n \cdot (n-1)!$  for all  $n \geq 1$ .

So  $1! = 1$ ,  $2! = 2 \cdot 1 = 2$ ,  $3! = 3 \cdot 2 \cdot 1 = 6$ ,  $6! = 720$  etc.

The latter example deserves more attention. Notice that we could have defined the factorial by setting  $A = B = \mathbb{N}$  and giving the equation  $f(n) = n \cdot f(n-1)$  for all  $n \geq 1$ . This does not yet define  $f$ , but for each  $n$ , it does determine what  $f(n)$  is in terms of its predecessor  $f(n-1)$ . This is sometimes called a *recurrence relation*. After choosing  $f(0) = 1$ , the recurrence now determines  $f(1)$  and hence successively  $f(2)$  etc., and so a function is defined. It is the factorial function as described above.

## 2. Difference equations

The factorial function is one example of a function which can be defined on the natural numbers by means of a recurrence relation. Such a situation can often be seen when formulating mathematical models that describe real systems in practice.

We will observe here only a few simple examples and return to this topic in chapter 3.

which gives

$$\begin{aligned} z_1 &= \sqrt{13} \left( \frac{2}{\sqrt{13}} + i \cdot \frac{3}{\sqrt{13}} \right) \\ &= \sqrt{13} \left( \cos \left( \arccos \left( \frac{2}{\sqrt{13}} \right) \right) + i \sin \left( \arcsin \left( \frac{3}{\sqrt{13}} \right) \right) \right). \end{aligned}$$

Transition from polar form to algebraic form is even simpler:

$$z_2 = 3 \left( \cos \left( \frac{\pi}{3} \right) + i \sin \left( \frac{\pi}{3} \right) \right) = 3 \left( \frac{1}{2} + i \cdot \frac{\sqrt{3}}{2} \right). \quad \square$$

**1.A.15. Remark.** In principle, the argument  $\arg(z) = \varphi$  of a complex number  $z$  is only defined up to “modulo  $2\pi$ ”. That is, for any integer  $k \in \mathbb{Z}$ , the angle  $\varphi + 2k\pi$  would serve as well (since full circle rotations do not change the point). Therefore, in the previous exercise we have essentially defined the so-called *principal (value of the) argument* of  $z$ .

**1.A.16.** (a) Is it true that the (principal) argument of a positive real number is zero and of a negative one is  $\pi$ ?

(b) Is it true that the (principal) argument of the imaginary number  $i$  is  $\pi/2$ , while of  $-2i$  is  $-\pi$ ? ○

**1.A.17.** Express  $z = 1 + \cos \frac{\pi}{3} + i \sin \frac{\pi}{3}$  in polar form. ○

**1.A.18. De Moivre’s theorem applied.** Simplify the expression  $(5\sqrt{3} + 5i)^n$  for  $n = 2$  and  $n = 12$ .

**Solution.** Using the binomial theorem for  $n = 2$  we see that

$$(5\sqrt{3} + 5i)^2 = 75 + 10\sqrt{3} \cdot 5i - 25 = 50 + 50\sqrt{3}i.$$

For  $n = 12$  it is shorter (and wiser) to express first the complex number in polar form:

$$5\sqrt{3} + 5i = 10 \left( \frac{\sqrt{3}}{2} + \frac{i}{2} \right) = 10 \left( \cos \frac{\pi}{6} + i \sin \frac{\pi}{6} \right).$$

Then, an application of the de Moivre’s formula presented in 1.1.4, gives the following:

$$(5\sqrt{3} + 5i)^{12} = 10^{12} \left( \cos \frac{12\pi}{6} + i \sin \frac{12\pi}{6} \right) = 10^{12}. \quad \square$$

**1.A.19.** Compute the expression  $(\cos \frac{\pi}{6} + i \sin \frac{\pi}{6})^{31}$  by applying the de Moivre’s theorem. ○

**1.A.20.** Use de Moivre’s theorem to prove the identities

$$\begin{aligned} \cos(3\varphi) &= 4 \cos^3(\varphi) - 3 \cos(\varphi), \\ \sin(3\varphi) &= 3 \sin(\varphi) - 4 \sin^3(\varphi). \end{aligned} \quad \circ$$

The beauty of complex numbers is also linked to the “fundamental theorem of algebra”, see 12.4.20. In fact, complex numbers arose from the need to solve cubic equations (without meaning that the solutions must be complex). Next we describe a procedure, which was developed during the 16th century by S. del Ferro (1465-1526), G. Cardano (1501-1576), N. F. Tartaglia (1500-1557), and possibly others. Unlike the

**1.2.1. Linear difference equations of first order.** A general *difference equation of the first order* (or *first order recurrence*) is an expression of the form

$$f(n+1) = F(n, f(n)),$$

where  $F$  is a known function with two arguments (independent variables). If we know the “initial” value  $f(0)$ , we can compute  $f(1) = F(0, f(0))$ , then  $f(2) = F(1, f(1))$  and so on. Using this, we can compute the value  $f(n)$  for arbitrary  $n \in \mathbb{N}$ .

An example of such an equation is provided by the factorial function  $f(n) = n!$  where:

$$(n+1)! = (n+1) \cdot n!, \quad f(0) = 1.$$

In this way, the value of  $f(n+1)$  depends on both  $n$  and the value of  $f(n)$ , and formally we would express this recurrence in the form  $F(x, y) = (x+1)y$ .

A very simple example is  $f(n) = C$  for some fixed scalar  $C$  and all  $n$ . Another example is the *linear difference equation of first order*

$$(1) \quad f(n+1) = a \cdot f(n) + b,$$

where  $a \neq 0$  and  $b$  are fixed scalars.

Such a difference equation is easy to solve if  $b = 0$ . Then it is the well-known recurrent definition of the geometric progression. We have

$$f(1) = af(0), \quad f(2) = af(1) = a^2f(0),$$

and so on. Hence for all  $n$  we have

$$f(n) = a^n f(0).$$

This is also the relation for the *Malthusian population growth model*. This is based on the assumption that population size grows with a constant rate when measured at a sequence of fixed time intervals.

It is time to prove our first mathematical theorem. We deduce a general result for first order equations with variable coefficients, namely:

$$(2) \quad f(n+1) = a_n \cdot f(n) + b_n.$$

We use the usual notation for sum  $\sum$ , and the similar notation for the product  $\prod$ . We use also the convention that when the index set is empty, then the sum is zero and the product is one.

**1.2.2. Proposition.** *The general solution of the first order difference equation (2) from the previous paragraph with the initial condition  $f(0) = y_0$  is for  $n \in \mathbb{N}$  given by the formula*

$$(1) \quad f(n) = \left( \prod_{i=0}^{n-1} a_i \right) y_0 + \sum_{j=0}^{n-2} \left( \prod_{i=j+1}^{n-1} a_i \right) b_j + b_{n-1}.$$

**PROOF.** We use *mathematical induction*. The result clearly holds for  $n = 1$  since  $f(1) = a_0 y_0 + b_0$ .

Assuming that the statement holds for some fixed  $n$ , we compute (do not be upset with the many brackets and remember the conventions about the empty sums and products):

quadratic equations, here we need the complex numbers even if all three solutions are real.

**1.A.21.** Express a solution of the cubic equation  $x^3 + ax^2 + bx + c = 0$  in terms of the real coefficients  $a, b$  and  $c$ .

**Solution.** The first step reduces the quadratic dependence by setting  $x := t - a/3$ . The original equation then becomes  $t^3 + pt + q = 0$ , with  $p = b - a^2/3$  and  $q = c + (2a^3 - 9ab)/27$ , respectively. The next step requires us to be more creative. We introduce new variables,  $u$  and  $v$ , satisfying the conditions

$$\{u + v = t, \quad 3uv + p = 0\}.$$

Using these terms, we can substitute the first condition into the previous equation to obtain

$$u^3 + v^3 + (3uv + p)(u + v) + q = 0.$$

Next, use the second equation to eliminate  $v$ . This yields

$$u^6 + qu^3 - \frac{p^3}{27} = 0,$$

which is a quadratic equation in the unknown  $s = u^3$ . Hence

$$u = \sqrt[3]{-\frac{q}{2} \pm \sqrt{\frac{q^2}{4} + \frac{p^3}{27}}}.$$

Finally, by back substitution we obtain the desired answer:

$$x = -p/3u + u - a/3.$$

Observe that in order to obtain all three solutions, one has to work with complex roots. This is because the equation  $x^3 = a$ , with  $a \neq 0$ , has exactly three solutions over  $\mathbb{C}$  (according to the fundamental theorem of algebra). If one needs all the three solutions, the Sage cell given below provides an answer (though the expressions are complicated enough and hence not presented here).

```
x, a, b, c=var("x, a, b, c")
assume(a, b, c, "real")
solve(x**3+a*x**2+b*x+c==0, x) □
```

**1.A.22.** Solve the equation  $x^3 + x^2 - 2x - 1 = 0$ . ○

*A series of additional tasks related to complex numbers is presented in the end of this chapter. In fact, once we provide a systematic treatment of basic linear algebra in Chapter 2, we will be able to demonstrate how to treat complex numbers via matrices. This takes place in paragraph ??.*

### B. Difference equations

*Difference equations (also called recurrence relations) are rules which determine the values of elements of a sequence in terms of previous elements. Solving a difference equation means finding an explicit formula for an arbitrary element of the sequence. If each element of the sequence is determined only by the previous element, we talk about first order difference equations. As we will see below, and also in Chapter 3, this*

$$\begin{aligned} f(n+1) &= a_n \left( \prod_{i=0}^{n-1} a_i \right) y_0 + \sum_{j=0}^{n-2} \left( \prod_{i=j+1}^{n-1} a_i \right) b_j + b_{n-1} \\ &\quad + b_n \\ &= \left( \prod_{i=0}^n a_i \right) y_0 + \sum_{j=0}^{n-1} \left( \prod_{i=j+1}^n a_i \right) b_j + b_n, \end{aligned}$$

as can be seen directly by multiplying out. □

Note that for the proof, we did not use anything about the scalars except for the properties of commutative ring.

There is another approach to the proof which explains the name "linear". First observe that with all  $b_n = 0$ , the formula from the proposition is obvious. Next observe, that dealing with two sequences  $y_n, y'_n$  solving 1.2.2(2), their difference  $z_n = y_n - y'_n$  must be a solution to the "homogenized" equation  $f(n+1) = a_n \cdot f(n)$ . On the contrary, knowing such sequences  $z_n$  and  $y_n$ , then their sum  $y'_n = z_n + y_n$  must be a solution of 1.2.2(2). Thus, we could just guess and check that the second and third terms of (1) solve our equation. In particular, the following corollary can be proved very easily this way. Try to complete this line of arguments in detail!

**1.2.3. Corollary.** *The general solution of the linear difference equation (1) from 1.2.1 with  $a \neq 1$  and initial condition  $f(0) = y_0$  is*

$$(1) \quad f(n) = a^n y_0 + (1 + \dots + a^{n-1})b = a^n y_0 + \frac{1 - a^n}{1 - a} b.$$

**PROOF.** If we set  $a_i$  and  $b_i$  to be constants and use the general formula 1.2.2(1), we obtain

$$f(n) = a^n y_0 + b \left( 1 + \sum_{j=0}^{n-2} a^{n-j-1} \right).$$

We observe that the expression in the bracket is  $(1 + a + \dots + a^{n-1})$ . The sum of this geometric progression follows from  $1 - a^n = (1 - a)(1 + a + \dots + a^{n-1})$ . □

The proof of the former proposition is a good example of a mathematical result, where the verification is quite easy, as soon as someone tells us the theorem. Mathematical induction is a natural method of proof.

Note that for calculating the sum of a geometric progression we silently assumed the existence of the inverse element for non-zero scalars. But actually, we derived the formula in a way manifesting that the division is always possible if our scalars do not allow for divisors of zero.

In particular, notice that the formula (1) is valid with integer coefficients  $a, b$  and integer initial conditions. Here, we know in advance that each  $f(n)$  is an integer. Thus our formula necessarily gives correct integer solutions, although living in the extension of  $\mathbb{Z}$  to the rational numbers  $\mathbb{Q}$ .

type of recurrence relations are often induced by problems appearing in our everyday life.

**1.B.1.** Michael wants to buy a great new car, which costs € 30 000. He wants to take out a loan and pay it off under a fixed month repayment agreement. The car company offers him a loan with yearly interest of 6%, with first repayment in the end of the first month of the loan. Specify the exact amount of the monthly payment, under the assumption that Michael aims to redeem the loan in three years.

**Solution.** Let us denote by  $P$  the sum that Michael has to pay per month, and by  $d_k$  the amount of the remaining loan after  $k$  months. Set also  $C = 30000$  and  $u = \frac{0.06}{12}$  (the latter represents the monthly interest rate). We have  $d_0 = C = 30000$ , and after the first month we see that  $d_1 = C - P + u \cdot C$ . After the  $k$ th month we compute

$$d_k = d_{k-1} - P + u d_{k-1} = (1 + u)d_{k-1} - P. \quad (*)$$

In order to solve (\*) we may apply the statement of Corollary 1.2.3. In terms of this result we have  $a = 1 + u$ ,  $b = -P$ , and thus the solution takes the form

$$d_k = d_0 a^k - P \left( \frac{a^k - 1}{a - 1} \right).$$

Paying off the loan in three years means  $d_{36} = 0$ . This gives

$$P = 30000 \cdot \left( \frac{(1 + u)^{36} u}{(1 + u)^{36} - 1} \right) = 912,7.$$

Thus, approximately Michael should pay the amount of €913 per month.  $\square$

**1.B.2.** Consider the task in 1.B.1. For how long will Michael pay, if the monthly dose of the loan is €500?  $\circ$

**1.B.3.** Determine the sequence  $\{y_n\}_{n=1}^\infty$ , which satisfies the following recurrence relation

$$y_{n+1} = \frac{3y_n}{2} + 1, \quad n \geq 1, \quad y_1 = 1.$$

Next verify your answer via Sage.

**Solution.** We can apply again the Corollary 1.2.3. We have  $a = 3/2$ ,  $b = 1$  and  $y_0 = 0$  (such that  $y_1 = 1$ ). Hence, according to the given formula we deduce that

$$y_n = (3/2)^n \cdot 0 + \frac{1 - (3/2)^n}{1 - \frac{3}{2}} \cdot 1 = -2 + 2(3/2)^n.$$

Let us explain the procedure via Sage, which has a very friendly package to treat recurrence relations. An appropriate function that one can load is the function `rsolve` (from the pure Python package `sympy` which is for symbolic computations). This can deal with linear recurrence relations and initially we type the following code:

```
from sympy import Function, rsolve
from sympy.abc import n
y = Function("y")
```

The next step is to type the relation that we want to solve and the initial conditions:

The linear difference equation 1.2.1(1) can be neatly interpreted as a mathematical model for finance, e.g. savings or loan payoff with a fixed interest rate  $a$  and fixed repayment  $b$ . (The cases of savings and loans differ only in the sign of  $b$ ).

With varying parameters  $a$  and  $b$  we obtain a similar model with varying interest rate and repayment. We can imagine for instance that  $n$  is the number of months,  $a_n$  is the interest rate in the  $n$ th month,  $b_n$  the repayment in the  $n$ th month.

**1.2.4. A nonlinear example.** When discussing linear difference equations, we mentioned a very primitive population growth model which depends directly on the momentary population size  $p$ . At first sight, it is clear that such a model with  $a > 1$  leads to a very rapid and unbounded growth.

A more realistic model has such a population change  $\Delta p(n) = p(n + 1) - p(n)$  only for small values of  $p$ , that is  $\Delta p/p \sim r > 0$ . Thus if we want to let the population grow by 5% for a time interval only for small  $p$ , then we choose  $r$  to be 0.05. For some limiting value  $p = K > 0$  the population may not grow. For even greater values it may even decrease, for instance if the resources for the feeding of the population are limited, or if individuals in a large population are obstacles to each other etc.

Assume that the values  $y_n = \Delta p(n)/p(n)$  change linearly in  $p(n)$ . Graphically we can imagine this dependence as a line in the plane of the variables  $p$  and  $y$ . This line passes through the point  $[0, r]$ , so that  $y = r$  when  $p = 0$ . This line also passes through  $[K, 0]$  since this gives the second condition, namely that when  $p = K$  the population does not change. Thus we set

$$y = -\frac{r}{K}p + r.$$

By setting  $y = y_n = \Delta p(n)/p(n)$  and  $p = p(n)$  we obtain

$$\frac{p(n + 1) - p(n)}{p(n)} = -\frac{r}{K}p(n) + r.$$

By multiplying, we obtain a difference equation of first order with  $p(n)$  present as both a first and a second power.

$$(1) \quad p(n + 1) = p(n) \left( 1 - \frac{r}{K}p(n) + r \right).$$

```
f = y(n+1) - 3*y(n)/2 - 1
initial = {y(1):1, y(2):5/2}
```

To get the solution we finally type `rsolve(f, y(n), initial)`. This gives the answer  $2 * (3/2) * n - 2$ .<sup>5</sup> □

In Chapter 3 we will study recurrences in a more systematic way. Now we continue our observations with a very characteristic example, the Fibonacci numbers, which we will meet several times, see e.g., 3.B.1.

These numbers are defined by the recurrence relation using two preceding values:  $F_n = F_{n-1} + F_{n-2}$  ( $n \geq 3$ ) with the initial conditions  $F_1 = 1$  and  $F_2 = 1$  (or the same with  $F_0 = 0$ ). Hence the very first numbers in the Fibonacci sequence  $(F_n)_{n \in \mathbb{N}}$  are 0, 1, 1, 2, 3, 5, 8, 13, 21, 34, 55, 89, etc.<sup>6</sup>

We shall call such equations (second order) linear difference equation with constant coefficients in Chapter 3, and we will learn how to solve them.

**1.B.4. Fibonacci numbers.** A 2-composition of a positive integer  $n$  is a representation of  $n$  as an ordered sum of numbers 1 and 2. Notice that the order indeed matters; For instance  $3 = 1 + 1 + 1$ ,  $3 = 1 + 2$  and  $3 = 2 + 1$ , hence the integer 3 has three distinct 2-compositions. Let  $C_n$  be the number of 2-compositions of  $n \in \mathbb{N}$ . Show that  $C_n = F_{n+1}$  for  $n \in \mathbb{N}$ . Having Sage as a tool, test (or prove) the claim, too.

**Solution.** Notice,  $C(0) = 1 = F(1)$  due to our conventions, since there is only the empty sum of interest providing the result. Thus, we may omit  $n = 0$  from our considerations. Let us denote by  $C_n(1)$  and  $C_n(2)$  the number of 2-compositions of  $n$ , ending with 1 and 2, respectively. For  $n = 1$  we have  $C_1(1) = 1$  and  $C_1(2) = 0$ , so  $C_1 = C_1(1) + C_1(2) = 1 + 0 = 1 = F_2$ . For  $n = 2$  we have  $C_2(1) = 1$  and  $C_2(2) = 1$ , so  $C_2 = C_2(1) + C_2(2) = 1 + 1 = 2 = F_3$ . Hence the claim holds for  $n = 1, 2$ . Suppose now that the integer  $n$  satisfies  $n \geq 3$ . Assume first that the 2-composition of  $n$  ends to 1. In this case, we can determine a 2-composition of the integer  $n - 1$  by deleting this 1. However, by adding a 1 in a 2-composition of  $n - 1$ , we will get a 2-composition of  $n$  that ends by 1. Thus we conclude that  $C_n(1) = C_{n-1}$ . Similarly, if the 2-composition of  $n$  ends by 2, then we get a 2-composition of the integer  $n - 2$  by deleting this 2. However, by adding a 2, or two ones, in the end of a 2-composition of  $n - 2$  we will result to a 2-composition of  $n$  ending either with 2 or with 1. Since the latter case has been counted already above, we conclude  $C_n(2) = C_{n-2}$ . Altogether we

<sup>5</sup>Recall that `a * n` in Sage means  $a^n$ .

<sup>6</sup>The Fibonacci numbers have a long and rich history, and they appear in many applications. These numbers were first discussed by Acharya Pingala, an Indian poet and mathematician (around 200 BC) when counting the possible patterns for poetry forms based on syllables of two lengths. The Italian mathematician Leonardo di Pisa (also called Bonacci, Pisano, or Fibonacci) explained them in his famous book Liber Abaci to the western community in 1202. Here these numbers were used to explain the rabbit reproduction question. They also arise in combinatorics and graph theory, and we shall meet them several times, e.g. in Chapters 3 and 13.

Try to think through the behaviour of this model for various values of  $r$  and  $K$ . In the diagram we can see the results for parameters  $r = 0.05$  (that is, five percent growth in the ideal state),  $K = 100$  (resources limit the population to the size 100), and as  $p(0) = 2$  we have initially two individuals.

Note that the original almost exponential growth slows down later. The population size approaches the desired limit of 100 individuals. For  $p$  close to one and  $K$  much greater than  $r$ , the right side of the equation (1) is approximately  $p(n)(1 + r)$ . That is, the behaviour is similar to that of the Malthusian model. On the other hand, if  $p$  is almost equal to  $K$ , the right hand side of the equation is approximately  $p(n)$ . For an initial value of  $p$  greater than  $K$  the population size will decrease. For an initial value of  $p$  less than  $K$  the population size will increase.<sup>1</sup>

### 3. Combinatorics

A typical “combinatorial” problem is to count in how many ways something can happen. For instance, in how many ways can we choose two different sandwiches from the daily offering in a grocery shop?

In this situation we need first to decide what we mean by different. Do we then allow the choice of two “identical” sandwiches? Many such questions occur in the context of card games and other games.

The solution of particular problems, usually involves either some multiplication of particular results (if the individual possibilities are independent) or some addition (if their appearance is disjoint). This is demonstrated in many examples in the problem column (cf. several problems starting with 1.D.2).

**1.3.1. Permutations.** Suppose we have a set of  $n$  (distinguishable) objects, and we wish to arrange them in some order. We can choose a first object in  $n$  ways, then a second in  $n - 1$  ways, a third in  $n - 2$  ways, and so on, until we choose the last object for which there is only one choice. The total number of possible arrangements is the product of these, hence there are exactly  $n! = n(n - 1)(n - 2) \dots 3 \cdot 2 \cdot 1$  distinct orders of the objects. Each ordering of the elements of a set  $S$  is called a *permutation* of the elements of  $S$ . The number of permutations on a set with  $n$  elements is  $n!$ .

We can identify the elements in  $S$  by numbering them (using the digits from one to  $n$ ), that is, we identify  $S$  with the set  $S = \{1, \dots, n\}$  of  $n$  natural numbers. Then the permutations correspond to the possible orderings of the numbers from one to  $n$ . Thus we have an example of a simple mathematical theorem and this discussion can be considered to be its proof.

<sup>1</sup>This model is called the *discrete logistic model*. Its continuous version was introduced already in 1845 by Pierre François Verhulst. Depending on the proportions of the parameters  $r$ ,  $K$  and  $p(0)$ , the behaviour can be very diverse, including chaotical dynamics. There is much literature on this model.

get  $C_n = C_n(1) + C_n(2) = C_{n-1} + C_{n-2}$ , and this coincides with the Fibonacci recurrence. Thus, the difference may be only in the initial conditions, but we have verified already  $C_1 = F_2$  and  $C_2 = F_3$ , and this concludes the proof.

To test  $C_n = F_{n+1}$  via Sage we will use the observed recurrence relation together with the initial conditions, which we present via Sage. Notice, how Sage imports tools from Python packages. Here Sage learns how to solve recurrences. Of course,  $c(n)$  would be listed very fast, after being resolved in the 6th line:

```
from sympy import Function, rsolve
from sympy.abc import n
a = Function("a")
f = a(n)-a(n-1)-a(n-2)
initial = {a(1):1, a(2):2}
c(n)=rsolve(f, a(n), initial)
k=var("k")
bool(c(k)==fibonacci(k+1)
    for k in (0 .. 120))
```

This returns True and so verifies our claim. Inside the cell we used the function `fibonacci(n)`, which returns the  $n$ th Fibonacci number, and the class `bool`, which is for comparing logical propositions. Later in 1.G.20 the reader can find a visual presentation of  $C_n$ .  $\square$

*Recurrence relations can be much more complicated than those of first or second order. To highlight the case, we present an example of order 3 and another one including more equations with more variables. In the latter case, although we are not able to evaluate the arbitrary term in the presented sequence  $P_{(k,l)}$  explicitly, we succeed in answering the question using the relevant recurrence relations. This is an example of the so called partial difference equations, since the terms of the sequence are indexed by two independent variables  $k, l$ .*

*Further applications of recurrence relations are in the final section of this chapter.*

**1.B.5.** How many words of length 12 can be constructed by using only the letters  $A$  and  $B$ , under the assumption that they do not contain a sentence of the form  $BBB$ ?

**Solution.** Let  $a_n$  denote the number of words of length  $n$  consisting of the letters  $A$  and  $B$ , but without  $BBB$  as a sentence in between. The words of length  $n > 3$  that satisfy the given condition, either end with one letter  $A$ , or with two letters  $AB$ , or with three letters  $ABB$  (notice that the  $AA$  two letters end has been covered, the  $ABB$  end is the only option for the  $BB$  end, while the remaining  $BAB$  three last letters are covered already). We enumerate  $a_{n-1}$  words ending with an  $A$  (observe that preceding the last  $A$ , it can be an arbitrary word of length  $n - 1$  satisfying our condition). Analogously for the two remaining groups. Thus  $a_n$  ( $n > 3$ ) satisfies the recurrence relation

$$a_n = a_{n-1} + a_{n-2} + a_{n-3}$$

NUMBER OF PERMUTATIONS

**Proposition.** The number  $p(n)$  of distinct orderings of a finite set with  $n$  elements, is given by the factorial function:

$$(1) \quad p(n) = n!$$

Suppose  $S$  is a set with  $n$  elements. Suppose we wish to choose and arrange in order just  $k$  of the members of  $S$ , where  $1 \leq k \leq n$ . This is called a  $k$ -permutation without repetition of the  $n$  elements. The same reasoning as above shows that this can be done in

$$v(n, k) = n(n-1)(n-2) \cdots (n-k+1) = \frac{n!}{(n-k)!}$$

ways. The right side of this result also makes sense for  $k = 0$ , (there is just one way of choosing nothing), and for  $k = n$ , since  $0! = 1$ .

Now we modify the problem, this time where the order of selection is immaterial.

**1.3.2. Combinations.** Consider a set  $S$  with  $n$  elements. A  $k$ -combination of the elements of  $S$  is a selection of  $k$  elements of  $S$ ,  $0 \leq k \leq n$ , when order does not matter.

For  $k \geq 1$ , the number of possible results of a subsequential choosing of our  $k$  elements, is  $n(n-1)(n-2) \cdots (n-k+1)$  (a  $k$ -permutation). We obtain the same  $k$ -tuple in  $k!$  distinct orders. Hence the number of  $k$ -combinations is

$$\frac{n(n-1)(n-2) \cdots (n-k+1)}{k!} = \frac{n!}{(n-k)!k!}$$

If  $k = 0$ , the same formula is still true, since  $0! = 1$ , and there is just one way to select all  $n$  elements.

COMBINATIONS

**Proposition.** The number  $c(n, k) = \binom{n}{k}$  of combinations of  $k$ -th degree among  $n$  elements, where  $0 \leq k \leq n$ , is

$$(1) \quad c(n, k) = \frac{n(n-1) \cdots (n-k+1)}{k(k-1) \cdots 1} = \frac{n!}{(n-k)!k!}$$

We pronounce the *binomial coefficient*  $\binom{n}{k}$  as “ $n$  over  $k$ ” or “ $n$  choose  $k$ ”. The name stems from the *binomial expansion*, which is the expansion of  $(a+b)^n$ . If we expand  $(a+b)^n$ , the coefficient of  $a^k b^{n-k}$  is the number of ways to choose a  $k$ -tuple from  $n$  parentheses in the product (from these parentheses, we take  $a$ , from the others, we take  $b$ ). Therefore we have

$$(2) \quad (a+b)^n = \sum_{k=0}^n \binom{n}{k} a^k b^{n-k}$$

Note that only distributivity, commutativity and associativity of multiplication and summation was necessary. The formula (2) therefore holds in every commutative ring.

with  $a_1 = 2$ ,  $a_2 = 4$ , and  $a_3 = 7$ . Using this relation we can now compute  $a_{12}$ . The answer is 1705. Of course, we can get this by simple modification of the previous Sage cell, give it a try!  $\square$

**1.B.6.** After the first quarter, the score of a basketball match between the national teams of Russia and the Czech Republic is 12 : 9 for the Czech team. In how many ways could the score have developed?

**Solution.** We can divide all possible evolutions of the quarter with the final score  $k : l$  into six mutually exclusive possibilities, according to which team scored, and how much was it worth (1, 2 or 3 points). If we denote by  $P_{(k,l)}$  the number of ways in which the score could have developed for a quarter that ended with  $k : l$ , then for  $k, l \geq 3$  the following recurrence relation holds:

$$P_{(k,l)} = P_{(k-3,l)} + P_{(k-2,l)} + P_{(k-1,l)} + P_{(k,l-1)} + P_{(k,l-2)} + P_{(k,l-3)}.$$

Using the symmetry of the problem,  $P_{(k,l)} = P_{(l,k)}$ . In addition, for  $k \geq 3$  we see that

$$\begin{aligned} P_{(k,2)} &= P_{(k-3,2)} + P_{(k-2,2)} + P_{(k-1,2)} + P_{(k,1)} + P_{(k,0)}, \\ P_{(k,1)} &= P_{(k-3,1)} + P_{(k-2,1)} + P_{(k-1,1)} + P_{(k,0)}, \\ P_{(k,0)} &= P_{(k-3,0)} + P_{(k-2,0)} + P_{(k-1,0)}. \end{aligned}$$

These relations, along with the initial condition, give  $P_{(0,0)} = 1$ ,  $P_{(1,0)} = 1$ ,  $P_{(2,0)} = 2$ ,  $P_{(3,0)} = 4$ ,  $P_{(1,1)} = 2$ , and

$$\begin{aligned} P_{(2,1)} &= P_{(1,1)} + P_{(0,1)} + P_{(2,0)} = 5, \\ P_{(2,2)} &= P_{(0,2)} + P_{(1,2)} + P_{(2,1)} + P_{(2,0)} = 14. \end{aligned}$$

Therefore, by repeatedly using the above equations, we arrive at nearly 500 million options, since  $P_{(12,9)} = 497178513$ .  $\square$

### C. Combinatorics

*In this section we use natural numbers to label items that may or may not be distinguishable and address questions about the number of ways certain events can occur. Let us begin with a straightforward problem involving permutations, which will demonstrate the usefulness of mathematical software packages, such as Matlab, Maple, Sage, etc.*

*We expect the reader to be familiar with the basic concepts as permutations, combinations, etc., as wells as adding or multiplying the numbers of independent options. If not, have a look into the other column in 1.3.1.*

We present a few simple propositions about binomial coefficients – another simple example of a mathematical proof. If needed, we define  $\binom{n}{k} = 0$  whenever  $k < 0$  or  $k > n$ .

**1.3.3. Proposition.** For all non negative integers  $n$ , we have

- (1)  $\binom{n}{k} = \binom{n}{n-k} \quad 0 \leq k \leq n.$
- (2)  $\binom{n+1}{k+1} = \binom{n}{k} + \binom{n}{k+1} \quad 0 \leq k \leq n - 1.$
- (3)  $\sum_{k=0}^n \binom{n}{k} = 2^n$
- (4)  $\sum_{k=0}^n k \binom{n}{k} = n2^{n-1}.$

**PROOF.** The first formula in the proposition is immediate directly from the formula 1.3.2(1). If we expand the right-hand side of (2), we obtain

$$\begin{aligned} \binom{n}{k} + \binom{n}{k+1} &= \frac{n!}{k!(n-k)!} + \frac{n!}{(k+1)!(n-k-1)!} \\ &= \frac{(k+1)n! + (n-k)n!}{(k+1)!(n-k)!} \\ &= \frac{(n+1)!}{(k+1)!(n-k)!} \end{aligned}$$

which is the left-hand side of (2).

In order to prove (3), we use *mathematical induction* again. Mathematical induction consists of two steps. In the initial step, we establish the claim for  $n = 0$  (in general, for the smallest  $n$  the claim should hold for). In the inductive step we assume that the claim holds for some  $n$  (and all smaller numbers). We use this to prove that this implies the claim for  $n + 1$ . The principle of *mathematical induction* then asserts that the claim holds for every  $n$ .

The claim (3) clearly holds for  $n = 0$ , since  $\binom{0}{0} = 1 = 2^0$ . It holds also for  $n = 1$ . Now assume that the claim holds for some  $n \geq 1$ . We must prove the corresponding claim for  $n + 1$  using the claims (2) and (3). We calculate

$$\begin{aligned} \sum_{k=0}^{n+1} \binom{n+1}{k} &= \sum_{k=0}^{n+1} \left( \binom{n}{k-1} + \binom{n}{k} \right) \\ &= \sum_{k=-1}^n \binom{n}{k} + \sum_{k=0}^{n+1} \binom{n}{k} = 2^n + 2^n = 2^{n+1}. \end{aligned}$$

Note that the formula (3) gives the number of all subsets of an  $n$ -element set, since  $\binom{n}{k}$  is the number of all subsets of size  $k$ . Note also that (3) follows from 1.3.2(2) by choosing  $a = b = 1$ .

To prove (4) we again employ induction, as we did in (3). For  $n = 0$  the claim clearly holds. The inductive assumption says that (4) holds for some  $n$ . We calculate the corresponding sum for  $n + 1$  using (2) and the inductive assumption. We obtain

the number of permutations of seven elements. By symmetry, the number of all orderings where A speaks directly after B is also 7!. Since the number of all possible orderings of eight speakers is 8!, the solution is  $8! - 2 \cdot 7!$ .  $\square$

**1.C.3.** How many rearrangements of the letters of the word “problem” are there, such that:

- (a) The letters b, r are next to each other;
- (b) The letters b, r are not next to each other.  $\circ$

**1.C.4.  $k$ -permutations and  $k$ -combinations.** Determine the number of different permutations that admits a code with 5 digits in a specific order, under the assumption that every digit can be used only once. Deduce that 5-digit codes of such type are much more secure than the corresponding 4-digit codes. Finally, what is the situation if the order of digits in the code does not matter?

**Solution.** We are interested in codes with 5 digits, where the order of the digits is crucial and every digit appears only once. In other words, we have the set of digits, say  $S = \{0, 1, \dots, 9\}$ , and we want to choose and arrange in order 5 elements of  $S$ . In terms of the paragraph 1.3.4, this is a 5-permutation of 10 elements without repetition, which can be done in

$$u(10, 5) = \frac{10!}{(10-5)!} = 10 \cdot 9 \cdot 8 \cdot 7 \cdot 6 = 30240$$

ways. In Sage we can compute  $u(10, 5)$  by typing

```
factorial(10)/factorial(5)
```

For a 4-digit code with the same characteristics, the corresponding number of permutations is given  $u(10, 6) = 5040$ , hence the claim. (Of course, we see from the formula that the letter number must be 6 times smaller than the first one!)

Assume now that the order does not play some role. Then, codes of the form 12345 and 54123, for instance, represent the same code, hence finally one will get much less possible permutations (codes of this type are very unsafe). In particular, this case yields the definition of a 5-combination of 10 elements, whose number according to 1.3.2 is given by

$$c(10, 5) = \binom{10}{5} = \frac{10!}{5!(10-5)!} = \frac{30240}{120} = 252.$$

Sage provides the command `binomial(n,k)` for the  $k$ -combination of  $n$  elements which in our case applies as

```
binomial(10, 5)
```

In such terms, the very first result about  $u(10, 5)$  appears also by the command `binomial(10,5) * factorial(5)`.  $\square$

**1.C.5. Remark.** Notice that Sage does not have a direct command for  $k$ -permutations. Let us construct one, by introducing a function called `uperm(n, k)`:<sup>7</sup>

<sup>7</sup>Note that usually the cells that we provide in Sage can be copy-pasted without extra editing being necessary in the editor of Sage. However, when we introduce functions as below, the reader should be careful and type the command in the editor exactly as it appears here, since the spaces play some role.

$k$ -PERMUTATIONS WITH REPETITIONS

$$V(n, k) = n^k.$$

If we are interested in a choice of  $k$  elements without taking care of order, we speak of  $k$ -combinations with repetitions. At first sight, it does not seem to be easy to determine the number. We reduce the problem to another problem we have already solved, namely combinations without repetitions:

COMBINATIONS WITH REPETITIONS

**Theorem.** The number of  $k$ -combinations with repetitions from  $n$  elements equals for every  $k \geq 0$  and  $n \geq 1$

$$\binom{n+k-1}{k}.$$

**PROOF.** Label the  $n$  elements as  $a_1, a_2, \dots, a_n$ . Suppose each element labeled  $a_i$  is selected  $k_i$  times,  $0 \leq k_i \leq k$ , so that  $k_1 + k_2 + \dots + k_n = k$ . Each such selection can be paired with the sequence of symbols  $*$  and  $|$  where each  $*$  represents one selection of an element and individual boxes are separated by  $|$  (therefore there are  $n-1$  of them).

The number of  $*$  in the  $i$ th box is equal to  $k_i$ , so we obtain the sequence

$$\underbrace{* \dots *}_{k_1} | \underbrace{* \dots *}_{k_2} | \dots | \underbrace{* \dots *}_{k_n}.$$

The other way around, from any such sequence we can determine the number of selections of any element (e.g. the number of  $*$  before first  $|$  determines  $k_1$ ).

Having altogether  $k$  symbols  $*$  and  $n-1$  separators  $|$  we see that there are

$$\binom{n+k-1}{n-1} = \binom{n+k-1}{k}$$

possible sequences and therefore also the same number of the required selections.  $\square$

4. Probability

Now we are going to discuss the last type of function description, as listed in the very end of the subsection 1.1.5. Thus, instead of assigning explicit values of a function, we shall try to describe the probabilities of the individual options.

**1.4.1. What is probability?** As a simple example we can use common six-sided dice throwing, with sides labelled as

- 1, 2, 3, 4, 5, 6.

If we describe the mathematical model of such throwing with a “fair” dice, we expect by symmetry that every side occurs with the same frequency. We say that “every side occurs with the probability  $1/6$ ”.

```
def uperm (n, k) :
    a = factorial (k) * binomial (n, k)
    return (a)
```

In such terms we can directly compute  $u(n, k)$  for any  $n, k$ , with  $k = 0, 1, 2, \dots$ , by typing in the editor of Sage the command `uperm(n, k)`. For instance, the command `uperm(10, 5)` returns 30240, `uperm(10, 1)` returns 10, `uperm(10, 2)` returns 90, `uperm(10, 11)` returns 0 (as it should be since  $k > n$  in this case), etc.

**1.C.6.** Determine the number of 4-digit codes, composed of the digits 1, 3, 5, 6, 7 and 9, under the condition that no digit occurs more than once.

**Solution.** We have 6 distinct letters at our disposal, and we ask: How many distinct (ordered) 4-tuples can be chosen from them? Obviously the result is

$$u(6, 4) = \frac{6!}{(6-4)!} = 6 \cdot 5 \cdot 4 \cdot 3 = 360.$$

The reader may verify the computation in Sage with the function `uperm(n, k)` constructed above, that is, via the command `uperm(6, 4)`.  $\square$

**1.C.7.** Six men in a meeting shake mutually their hands. How many handshakes will happen in total?

**Solution.** We understand that each couple of men shake their hands. Thus, the number of handshakes equals the number of ways of choosing an unordered pair among 6 elements, this is the combinations  $c(6, 2)$ . Let us present the answer via Sage:

```
c62=binomial(6, 2); c62
```

which gives 15.  $\square$

*To summarize,  $k$ -permutations  $u(n, k)$  take care of the order while combinations  $c(n, k)$  do not. Moreover,  $u(n, k) = c(n, k)k!$ . We have noticed that permutations and combinations are most useful when counting possibilities. Let us finalize this paragraph by treating examples where repetitions occur. Notice how the principle of “inclusion and exclusion” may be useful.*

**1.C.8.  $k$ -permutations with repetition.** The Greek alphabet consists of 24 letters. How many words of exactly five letters can be composed in it? (Disregarding whether the words have some actual meaning or not).

**Solution.** For each of the five positions in the word we have 24 possibilities, since the letters can repeat. According to the discussion in 1.3.4, this is nothing but a 5-permutation with repetitions. Hence the total number of words that can be composed is given by  $V(24, 5) = 24^5 = 7962624$ . In Sage we compute this by typing `24 ^ 5` or `24 * * 5`.  $\square$

But throwing some less symmetric version of a dice with six faces, the actual probabilities of the individual results might be quite different. Let us build a simple mathematical model for this. We shall work with the parameters  $p_i$  for the probabilities of individual sides with two requirements. These probabilities have to be non-negative real numbers and their sum is one, i.e.

$$p_1 + p_2 + p_3 + p_4 + p_5 + p_6 = 1.$$

At this time, we are not concerned about the particular choice of the specific values  $p_i$ , they are given to us. Later on, in chapter 10, we shall link probability with mathematical statistics and then we shall introduce methods how to discuss reliability of such a model for a specific real dice.

**1.4.2. Classical probability.** Let us come back to the mathematical model for the fair dice. We consider the sample space  $\Omega = \{1, 2, 3, 4, 5, 6\}$  of all possible elementary events (each of them corresponding to one possible result of the experiment of throwing the dice). Then we can consider any event as a given subset  $A$  of  $\Omega$ . For example  $A = \{1, 3, 5\}$  describes the result of getting odd number on the resulting side (we count the labels on the sides of the dice). Similarly, the set  $B = A^c = \{2, 4, 6\} = \Omega \setminus A$  is the complementary event of getting even numbered points. The probability of both  $A$  and  $B$  will be  $1/2$ . Indeed,  $|A|/|\Omega| = 1/2$ , where  $|A|$  means the number of elements of a set  $A$ .

This leads to the following obvious generalization:

#### CLASSICAL PROBABILITY

Let  $\Omega$  be a finite set with  $n = |\Omega|$  elements. The *classical probability* of the event corresponding to any subset  $A \subset \Omega$  is defined as

$$P(A) = \frac{|A|}{|\Omega|}.$$

Such a definition immediately allows us to solve problems related to throwing several fair dice simultaneously. Indeed, we may treat this as throwing independently one dice many times and thus multiplying the probabilities. For example, the event of getting an odd sum of points on two dice is given by adding the probabilities of having an even number on the first one and odd number on the second one and vice versa. Thus the probability will be twice  $1/2 \cdot 1/2$ , which is  $1/2$  as expected.

**1.4.3. Probability space.** Next, we formulate a more general concept of probability covering also the unfair dice example above.

We shall need a finite set  $\Omega$  of all possible states of a system (e.g. results of an experiment), which we call the *sample space*.

Further, the space of all possible *events* is given as the set  $\mathcal{A}$  of all subsets in  $\Omega$ . Finally, we need the function describing the probabilities of occurrence of individual events:

**1.C.9.** In how many ways can we insert five golf balls into five holes, with one ball into every hole, assuming that we have four identical white balls, four identical blue balls and three identical red balls?

**Solution.** First it is convenient to solve the problem for the case where we have five balls of every colour. This amounts to a free choice of five elements from three possibilities (there is a choice out of three colours for every hole), that is, permutations with repetitions. So the total ways are given by  $V(3, 5) = 3^5 = 243$ . Next, to answer our task it is sufficient to subtract the configurations which are excluded:

- all chosen balls are of one colour; there are 3 such cases,
  - exactly four red balls were chosen; there are  $2 \cdot 5 = 10$ .
- Indeed, in the latter event, one first fixes the colour of the non-red ball (two options), and then the hole where this ball is in (five independent options). Hence, in total there are  $3^5 - 3 - 10 = 230$  possible ways.  $\square$

**1.C.10.** Determine the number of ways of placing the white tower and black tower on the chessboards (of size  $8 \times 8$ ), that are neither in the same column nor in the same row.  $\circ$

**1.C.11.  $k$ -combinations with repetition.** In how many ways can we equip three distinct envelopes with five identical stamps and five identical letters. (Yes, we may glue many or no stamps onto the same envelop, etc.) Next provide an answer for the same task, under the condition that no envelope stays empty.

**Solution.** First compute the number of choices ignoring the non-emptiness condition. It is an example of 5-combinations with repetition from 3 elements, and since we glue the stamps and insert the letters independently, we have got  $C(3, 5) \cdot C(3, 5) = c(7, 2)^2 = 441$  different ways.

Next we have to subtract the choices with exactly one envelope empty, and finally with two empty ones (we still may distribute the stamps freely). We thus obtain (in the second term we choose the empty envelop and distribute the letters, and we have to correct the multiple appearances)  $C(3, 5) - 3(C(2, 5) + 3) - 3C(3, 5) = \binom{7}{2} - 3\binom{6}{1} + 3 = 6$ . Thus the resulting number is  $6C(3, 5) = 126$ .

If our interpretation was that the stamps are glued only on the non-empty envelopes, the result would be the square of the latter number of choices for envelopes, i.e., 36.  $\square$

### D. Probability

*We proceed with simple exercises related to the concept of classical probability. In many cases we are dealing with experiments having only a finite number of outcomes and we are interested in whether or not the outcome belongs to a subset of favourable outcomes. Then, the probability we are trying to determine equals the number of favourable outcomes divided by the total number of all possible outcomes. Classical probability can be used when we assume, or know, that each*

### PROBABILITY FUNCTION

Let us consider a non-empty fixed sample space  $\Omega$ . The probability function  $P : \mathcal{A} \rightarrow \mathbb{R}$  satisfies

- (1)  $P(\Omega) = 1$
- (2)  $0 \leq P(A)$  for all events  $A$
- (3)  $P(A \cup B) = P(A) + P(B)$  whenever  $A \cap B = \emptyset$ .

Notice that the intersection  $A \cap B$  describes the simultaneous appearance of both events, while the union  $A \cup B$  means that at least one of events  $A$  and  $B$  appear. The event  $A^c = \Omega \setminus A$  is called the *complementary event*.

### PROBABILITY

$$P(A \cup B) = P(A) + P(B \setminus A)$$

There are some further straightforward consequences of the definition for all events  $A, B$ :

- (4)  $P(A) = 1 - P(A^c)$
- (5)  $P(\emptyset) = 0$
- (6)  $P(A) \leq 1$  for all events  $A$
- (7)  $P(A) \leq P(B)$  whenever  $A \subset B$
- (8)  $P(A \cup B) = P(A) + P(B) - P(A \cap B)$

The proofs are all elementary. For example,  $A \cup (A^c) = \Omega$  and thus (3) implies (4).

Similarly, we can write  $A = (A \setminus B) \cup (A \cap B)$  and  $A \cup B = (A \setminus B) \cup (B \setminus A) \cup (A \cap B)$  with disjoint unions of sets on the right hand sides. Thus,  $P(A) = P(A \setminus B) + P(A \cap B)$  and  $P(A \cup B) = P(A \setminus B) + P(B \setminus A) + P(A \cap B)$  by (3), which implies the last equality. The remaining three claims are even simpler.

All these properties correspond exactly to our intuition how probability should behave. Probability should be always a real number between zero and one. The event  $\Omega$  includes all possible results of the experiment, so it must have probability one. No result appears with probability zero, the probabilities of disjoint events should add, etc.

Of course, the classical probability on the sample space  $\Omega$  is an example of a probability function. In our more general model, the set of all subsets  $\mathcal{A}$  is closed upon union, intersection and taking the complement, and this has been essential

outcome has the same probability of happening (for instance, fair dice throwing, etc).

**1.D.1.** Prove that the following two events can happen with the same probability (independently of each other):

- (a) The roll of a dice results in a number greater than 4;
- (b) Throwing two dice, and assuming that their total sum equals to 7, at least one resulted in four.

**Solution.** For the first case, there are six possible outcomes (the set  $\{1, 2, 3, 4, 5, 6\}$ ). Two are favourable ( $\{5, 6\}$ ). Thus the probability is  $2/6 = 1/3$ . For the second event, one can apply classical probability (where the condition is interpreted as restriction of the probability space). The space has 6 elements, and exactly 2 of those are favourable to the given event. Thus, the answer is again  $2/6 = 1/3$ .

Notice, that if we treat rolling of two dices as two independent rolling of one, and view the results independent of the order (i.e., just the total), then the probability of the sums is not equal. For instance 12 and 2 have got probability  $1/36$  while 10 appears with probability  $3/36$ , etc. Thus, throwing two dices is not a classical probability case in general, but we were right with treating the resulting sum 7 as classical probability anyhow. Why?  $\square$

**1.D.2.** Helen wants to give to John and Mary five pears and six apples. If we consider the pears to be indistinguishable and the same for the apples, what is the probability that either John or Mary get nothing?

**Solution.** Let us assume that the pears and apples are distributed independently and each option has the same probability. Of course, one of the two mentioned persons could then get nothing. We have to count in how many ways the distributions happen.

The five pears can be divided in six ways (it is determined by the number of pears given to John, the rest goes to Mary.) Similarly, the six apples can be divided in seven ways. These divisions are independent, hence we can apply the product rule, which states that the frequency of two independent events occurring together can be calculated by multiplying the individual values, i.e., we have got  $6 \cdot 7 = 42$  options in total. Two of them result in John or Mary getting nothing. Thus the probability is  $1/21$  (relatively high).

Notice, how much different this is from dealing with 11 distinguishable objects, where 11 independent tosses of the same coin with always the same result would result in probability  $2 \cdot 2^{-11}$  (extremely low).  $\square$

**1.D.3.** We choose randomly a group of five people from a group of eight men and four women. What is the probability that there are at least three women in the chosen group?  $\circ$

**1.D.4. Remark.** The classical probability concept can be often applied, but we have to be careful. Imagine we should compute the probability that the reader of this remark will win at least 25 million euro in EuroLotto during the next week. First, notice the formulation of the problem is incomplete. For

in our exposition above. This will continue in all our discussion on probability in the sequel, where we shall have to allow for more general spaces of events  $\mathcal{A}$  in the sets of all subsets in the sample space. We will return to this and more serious generalizations in chapter 10.

**1.4.4. Summing probabilities.** By using mathematical induction, the additivity of probability is easily extended to any (finite) number of mutually exclusive events  $A_i \subset \Omega$ ,  $i = 1, \dots, n$ . That is,

$$P(\cup_{i \in I} A_i) = \sum_{i=1}^n P(A_i),$$

whenever  $A_i \cap A_j = \emptyset$ , for all  $i \neq j$ ,  $i, j = 1, \dots, n$ . Indeed, 1.4.3(3) is the result for  $n = 2$ . If we assume the validity of the formula for some fixed  $n$ , then the union of any  $n + 1$  events  $A_0, A_1, \dots, A_n$  can be split into the union of  $A_0$  and  $A_1 \cup \dots \cup A_n$ . Then by the induction assumption, together with 1.4.3(3) again, the result follows.

In general, the summing of probabilities of event occurrences is much more difficult. The problem is that whenever the events are mutually compatible, the possible results in their intersection are counted multiple times.

We have seen the simplest case of two mutually compatible events  $A$  and  $B$  in 1.4.3(8). For classical probability, it reduces just to counting elements in subsets. Indeed, those elements that belong to both the sets  $A$  and  $B$  count in the formula  $P(A \cup B) = P(A) + P(B) - P(A \cap B)$  twice and thus we have to subtract them once.

Now, we look at the general case. The approach of interactive inclusion and exclusion (potentially too many) elements in some count is a standard method in combinatorics known as the *inclusion-exclusion principle*. We shall exploit this method in our general finite probability spaces.

As we shall see, this is an example of a mathematical theorem, where the hard part is to understand (and find) the formulation of the result. The proof is then relatively simple.

INCLUSION-EXCLUSION PRINCIPLE

The diagram explains the situation for three sets  $A, B, C$  for classical probability:

$$P(A \cup B \cup C) = P(A) + P(B) + P(C) - P(A \cap B) - P(A \cap C) - P(B \cap C) + P(A \cap B \cap C).$$

Clearly, the probabilities are given by first counting the elements in each set and adding. Then we subtract the sum

example, we could impose that the sample space is just “win” and “not win”, with the same probability 1/2. In reality, the basic condition for the classical probability is not valid (every elementary event must have the same probability), but even the elementary event has not been defined sufficiently yet.

Instead, suppose that EuroLotto has a daily draw with a jackpot of €25 000 000 for choosing 5 correct numbers in  $1, \dots, 50$ . Let us simplify our problem and assume we want to win the €25 000 000 jackpot at least once. Thus we want to see the probability that the elementary event, a single lotto card with 5 numbers winning a jackpot happens. We assume that all quintuples are drawn with the same probability.

Assuming for instance that the reader submits  $k$  lotto cards every day of the week, the probability of winning at least one jackpot during the week is  $\frac{7k}{\binom{50}{5}} = \frac{7k}{2118760}$ . For instance, for  $k = 7$  via Sage and the command

```
N(49/2118760)
```

we get the very small number 0.0000231267345050879.

**1.D.5.** There are  $2n$  seats in a row in a cinema. We randomly seat  $n$  men and  $n$  women in the row. What is the probability that no two persons of the same sex sit next to each other?

**Solution.** There are  $(2n)!$  possible seatings. We assume, each of them comes with the same probability. The number of seatings satisfying the given condition is  $2(n!)^2$ . For we have two ways for choosing the positions for men and thus also for women: either all men sit on odd-numbered places, and thus the women sit on even-numbered places, or vice versa. Among these places, both men and women are seated arbitrarily. Therefore, the resulting probability is

$$P(n) = \frac{2(n!)^2}{(2n)!}.$$

In particular,  $P(2) = 1/3$ ,  $P(5) = 1/126$  and  $P(8) = 1/6435$ . To verify this computation by Sage we use the cell:

```
n=var("n")
P(n) = 2*factorial(n)**2/factorial(2*n)
```

Typing  $P(2)$ ,  $P(5)$ , etc, we obtain the given values. □

**1.D.6.** Five persons enter an elevator in a building with eight floors. Each of them leaves the elevator at any floor with the same probability. What is then the probability, that

- all of them leave at sixth floor;
- all of them leave at the same floor;
- each of them leaves at a different floor.

**Solution.** The sample space of possible events (see 1.4.3), is the space of all possible ways of leaving the elevator by 5 people. There are  $8^5$  of them. Hence, in the first case there is only one favourable outcome, thus the probability is  $\frac{1}{8^5}$ . In the second case there are eight favourable outcomes, thus the probability is  $8 \frac{1}{8^5} = \frac{1}{8^4}$ . In the third case, the number of favourable outcomes is given by a five-element variation of eight elements (we choose five floors among eight where

of those in intersections of pairs of sets, since those elements are counted twice. But we must then add in the number of elements in the intersection of all three.

We shall now follow the same idea in order to write down the formula in the following theorem. It seems plausible that such a formula should work with proper coefficients of the sums of probabilities of intersections of more and more events among  $A_1, \dots, A_k$ , at least in the case of classical probability. The reader will perhaps appreciate that a quite straightforward mathematical induction will verify the theorem in full generality.

**1.4.5. Theorem.** Let  $A_1, \dots, A_k \in \mathcal{A}$  be arbitrary events over the sample space  $\Omega$  with a set of events  $\mathcal{A}$ . Then

$$\begin{aligned} P(\cup_{i=1}^k A_i) &= \sum_{i=1}^k P(A_i) - \sum_{i=1}^{k-1} \sum_{j=i+1}^k P(A_i \cap A_j) \\ &\quad + \sum_{i=1}^{k-2} \sum_{j=i+1}^{k-1} \sum_{\ell=j+1}^k P(A_i \cap A_j \cap A_\ell) \\ &\quad - \dots \\ &\quad + (-1)^{k-1} P(A_1 \cap A_2 \cap \dots \cap A_k). \end{aligned}$$

**PROOF.** For  $k = 1$  the claim is obvious. The case  $k = 2$  is the same as the equality 1.4.3(8), which we have already proved.

Assume that the theorem holds for any number of events up to  $k$ , where  $k \geq 1$ . Now we can work in the induction step with the formula for  $k + 1$  events, where the union of the first  $k$  of them are considered to be the  $A$  in the equation 1.4.3(8) and the remaining event is considered to be the  $B$ :

$$\begin{aligned} P(\cup_{i=1}^{k+1} A_i) &= P((\cup_{i=1}^k A_i) \cup A_{k+1}) \\ &= \sum_{j=1}^k \left( (-1)^{j+1} \sum_{1 \leq i_1 < \dots < i_j \leq k} P(A_{i_1} \cap \dots \cap A_{i_j}) \right) \\ &\quad + P(A_{k+1}) - P((A_1 \cup \dots \cup A_k) \cap A_{k+1}). \end{aligned}$$

This already resembles the formula for  $k + 1$  summed events. But in the first term, expressions containing  $A_{k+1}$  are missing. Also absent is a term allowing for the probability that all the events happen. On the other hand, the last expression should not be there. We can replace it by the expression

$$-P((A_1 \cap A_{k+1}) \cup \dots \cup (A_k \cap A_{k+1}))$$

and for this we can again use the induction, that is, the formula in the statement of the theorem. With a little patience (and a piece of paper long enough to write down all the expressions) we can check that this adds all the missing pieces. □

**1.4.6. Inclusion-exclusion principle.** As we have mentioned already, a special case of the previous theorem is the one of classical probability. There the probability of an event  $A$  is strictly proportional to the number of elements in  $A$  (which is just divided by the total size  $n$  of the sample space).

some person leaves the elevator and then we choose the order in which they leave the chosen floors). The probability is then

$$\frac{8 \cdot 7 \cdot 6 \cdot 5 \cdot 4}{8^5} \doteq 0.20508.$$

In Sage we can obtain this result by using the function `uperm` introduced above. We present the corresponding cell:

```
def uperm(n, k):
    a = factorial(n)/factorial(n-k)
    return a
p=uperm(8,5)/8**5
print("Probability of each of them leaving
at a different floor:", round(p,5))
```

It returns (the round function rounds a number to a given precision in decimal digit):

```
Probability of each of them leaving
at a different floor: 0.20508
```

□

**1.D.7.** In a particular state there is a parliament with 200 members. Two major political parties in this state flip a coin during an “election” for every seat in the parliament. Each of the parties has associated one side of the coin. What is the probability that each of the parties gains 100 seats, assuming that the coin is “fair”?

**Solution.** There are  $2^{200}$  of possible results of the elections (considered to be a sequence of 200 results of flips). If each party is to obtain 100 seats, then there are exactly 100 tails and 100 heads in the sequence. There are  $\binom{200}{100}$  such sequences (since the sequence is uniquely determined by choosing 100 members of 200 possible, which will result in, say, tails). The resulting probability is

$$\frac{\binom{200}{100}}{2^{200}} = \frac{200!}{100! \cdot 100!} \doteq 0.0563.$$

In Sage we can do this computation by using the `binomial` and `round` functions.

```
ans = binomial(200, 100) / (2**200)
print(round(ans, 4))
```

□

**1.D.8.** In a box there are 9 red and 7 white balls. Sequentially we draw three balls (without returning). Determine the probability that the first two are red and the third is white. ○

*In many problems we use the “rule of complement”, computing the size of the complements of the desired subsets. This principle generalizes to the notion of “inclusion-exclusion principle”. Iterating, we add too much, push out unwanted counts, etc., see 1.4.6.*

Thus, in the formula from the previous theorem, all the probabilities give the sizes of the subsets involved, up to a common factor  $\frac{1}{n}$ .

In this way we can extract from the theorem 1.4.5 the following claim for the size of a general finite set  $M$  and its subsets  $A_1, \dots, A_k$ . As usual we let  $|M|$  denote the number of elements of the set  $M$ .

Of course for every finite set  $M$  and its subsets,

$$|M \setminus (\cup_{i=1}^k A_i)| = |M| - |\cup_{i=1}^k A_i|.$$

Now we use the previous theorem, and express the size of the union on the right side, and we obtain the theorem that is usually called

PRINCIPLE OF INCLUSION-EXCLUSION

$$|M \setminus (\cup_{i=1}^k A_i)| = |M| + \sum_{j=1}^k (-1)^j \sum_{1 \leq i_1 < \dots < i_j \leq k} |A_{i_1} \cap \dots \cap A_{i_j}|$$

The meaning of this result for the special case  $n = 3$  can be visualized easily, see the diagram in 1.4.5.

**1.4.7. Independent events.** Next, we wish to express possible dependencies among events in a given sample space  $\Omega$  with the probability function  $P$ . We say that the events  $A$  and  $B$  are *stochastically independent* if

$$P(A \cap B) = P(A) \cdot P(B).$$

This definition may remind us of our experiences in combinatorics when counting possibilities for independent choices. For example, dealing with a fair dice, we can define events  $A$  “odd number occurs”,  $B$  “the result is at least 3” and  $C$  “the result is at most 3”. The probabilities are  $P(A) = \frac{1}{2}$ ,  $P(B) = \frac{2}{3}$ ,  $P(C) = \frac{1}{2}$ ,  $P(A \cap B \cap C) = \frac{1}{6} = \frac{1}{2} \cdot \frac{2}{3} \cdot \frac{1}{2} = P(A) \cdot P(B) \cdot P(C)$ , and taking pairs we have  $P(A \cap C) = \frac{1}{3} \neq \frac{1}{2} \cdot \frac{1}{2}$ ,  $P(A \cap B) = \frac{1}{3} = \frac{1}{2} \cdot \frac{2}{3}$ ,  $P(B \cap C) = \frac{1}{6} \neq \frac{2}{3} \cdot \frac{1}{2}$ . Notice, that the stochastic dependence of the pairs  $A, C$  and  $B, C$  corresponds well to our intuition (e.g. there are more odd numbers between the values 1, 2, 3 than between the numbers 4, 5, 6).

This example also shows that we have to be careful with more events. In general, mutually independent sets are defined in this way:

**Definition.** Consider an arbitrary probability function  $P$  on sample space  $\Omega$  and  $k$  events  $A_1, \dots, A_k$  in that space. We say that these events are *stochastically independent* (with respect to the probability function  $P$ ), if for any chosen events  $A_{i_1}, \dots, A_{i_\ell}$ ,  $1 \leq \ell \leq k$  we have

$$P(A_{i_1} \cap \dots \cap A_{i_\ell}) = P(A_{i_1}) \cdot \dots \cdot P(A_{i_\ell}).$$

Every subset of a set of stochastically independent events is also stochastically independent. Further, for any two

**1.D.9. Inclusion-exclusion principle.** A secretary has to send six letters to six different people. She puts the letters in the envelopes randomly. What is the probability that at least one person receives the correct intended letter?

**Solution.** We compute the probability of the complementary event, which is “no person receives the correct letter”. The sample space corresponds to all possible orderings of six envelopes. Let us denote both the letters and the envelopes by numbers from one to six. Then, all the favourable events (no letter is assigned to the corresponding envelope) correspond to such orderings of six elements, where the  $i$ th element is not at the  $i$ th place, for  $i = 1, \dots, 6$ . These are the permutations without a fixed point.

One can compute the number of such orderings using the so-called *inclusion-exclusion principle*, see Theorem 1.4.5 and its corollary 1.4.6. Here we will use the same notation. Let us denote by  $M_i$  the set of permutations, such that  $i$  is a fixed point (note that permutations in  $M_i$  can also have other fixed points). In such terms, the resulting number  $d$  of permutations without a fixed point is

$$d = 6! - |M_1 \cup \dots \cup M_6|.$$

On the other hand, the number of elements in the intersection  $M_{i_1} \cap \dots \cap M_{i_k}$ ,  $k = 1, \dots, 6$ , equals to  $(6-k)!$  (note that the order of the elements  $i_1, \dots, i_k$  is fixed, while the remaining  $6-k$  can be ordered arbitrarily). The inclusion-exclusion principle states that

$$|M_1 \cup \dots \cup M_6| = \sum_{k=1}^6 (-1)^{k+1} \binom{6}{k} (6-k)!.$$

Hence, we can compute the number  $d$ :

$$\begin{aligned} d &= 6! - \sum_{k=1}^6 (-1)^{k+1} \binom{6}{k} (6-k)! \\ &= \sum_{k=0}^6 (-1)^k \binom{6}{k} (6-k)! = 6! \sum_{k=0}^6 \frac{(-1)^k}{k!}. \end{aligned}$$

We deduce that the probability that no person receives “his” letter is  $\sum_{k=0}^6 \frac{(-1)^k}{k!} = \frac{53}{144}$ , and thus the probability we were asked for equals to  $1 - \frac{53}{144} = \frac{91}{144}$ . More than one half!  $\square$

**1.D.10.** Approximately 1200 persons die per year at the roads of the Czech Republic. Determine the probability that some person of a chosen group of 500 people will die in the following ten years in a traffic accident (assume that the total population is 10 million and every person has the same probability of dying in a traffic accident during one year).

**Solution.** Let us first count the probability that one randomly chosen person will not die in ten years in a traffic accident. The probability that he/she will not die in one year is  $(1 - \frac{12}{10^5})$ . Thus, the probability that he/she will not die in ten years is  $(1 - \frac{12}{10^5})^{10}$ . We deduce that the probability that in ten years

stochastically independent events we compute

$$\begin{aligned} P(A \cap B^c) &= P(A \setminus B) = P(A) - P(A \cap B) = \\ &= P(A)(1 - P(B)) = P(A)P(B^c). \end{aligned}$$

From there we can show that by exchanging one or more events in a set of stochastically independent events by their complements, we again obtain a set of stochastically independent sets.

Sometimes we need to compute the probability that at least one of the stochastically independent set of events occurs. That is, we want to compute  $P(A_1 \cup \dots \cup A_k)$ . In such a situation we can use the De Morgan laws for sets (check them yourselves!)

$$(\cup_{i \in I} A_i)^c = \cap_{i \in I} A_i^c, \quad (\cap_{i \in I} A_i)^c = \cup_{i \in I} A_i^c.$$

We obtain

$$\begin{aligned} P(A_1 \cup \dots \cup A_k) &= 1 - P(A_1^c \cap \dots \cap A_k^c) \\ &= 1 - (1 - P(A_1)) \cdot \dots \cdot (1 - P(A_k)) \\ &= 1 - \prod_{j=1}^k (1 - P(A_j)). \end{aligned}$$

**1.4.8. Conditional probability.** Often we want to restrict our attention only to events, which lie in a subspace  $H \subset \Omega$ . This means that the events in question will be the intersections  $A \cap H$  of the original events  $A$  with the subset  $H$ . Thus our new probabilities should be proportional to  $P(A \cap H)$ . We would like to have  $H$  in the role of the new sample space.

As an example, we might look again at the model of a fair dice and ask the question “what is the probability that by throwing two dice the result is twice 5, if we know that the sum of the results is 10?”. Of course, we are now having only the possibilities  $4 + 6$  (two times) and  $5 + 5$  (once). So the probability should be  $\frac{1}{3}$ , much greater then the probability  $\frac{1}{36}$  of the same event without any further condition.

Similar situations are reflected in the following definition:

#### CONDITIONAL PROBABILITY

**Definition.** Let  $H$  be an event with non-zero probability in the sample space  $\Omega$  with the probability function  $P$ . The *conditional probability*  $P(A|H)$  of the event  $A$  given  $H$  is defined by the formula

$$P(A|H) = \frac{P(A \cap H)}{P(H)}.$$

The event  $H$  is sometimes called the *hypothesis*.

As it is obvious from the definition, the hypothesis  $H$  with non-zero probability and the event  $A$  are (stochastically) independent if and only if  $P(A) = P(A|H)$ . The definition also directly implies the “theorem for product of probabilities”

none of the given 500 people will not die, occurs by the product rule. This is because the events are independent, hence we obtain  $(1 - \frac{12}{10^5})^{5000}$ . It follows that the probability of the complementary event, that is, some of the chosen people will die, equals to  $1 - (1 - \frac{12}{10^5})^{5000} \doteq 0.4512$ .  $\square$

**Remark.** The model we have used in the previous exercise to describe the given situation is only approximate. The complication arises from the condition that every person in the sample has the same probability of dying, and the probabilities are derived from the total number of deaths per year. However, the number of deaths changes yearly and also the population changes. We may handle one of the possible inaccuracies as follows. Suppose that 1200 persons per year die, so in ten years 12000 persons die. The probability that a certain person dies in ten years is estimated by  $12000/10^7$ . Thus, the probability that a specific person will not die in ten years is  $(1 - \frac{12}{10^4})$  (first two members of binomial expansion of  $(1 - \frac{12}{10^5})^{10}$ ). In total, we obtain the following estimate of the probability  $1 - (1 - \frac{12}{10^4})^{500} \doteq 0.4514$ . Observe that both estimates are very close one to each other.

We already met probabilities based on assumptions that other events have happened, we say “under certain hypothesis”. We talk about conditional probability, see 1.4.8. As we will see below, such estimates can be successfully derived also via Sage (which is also related to “Monte Carlo” computational method, cf. 1.4.10).

**1.D.11. Sage simulation.** What is the probability that when rolling two dice the sum is 7, if we know that neither of the rolls resulted in a 2? Estimate the solution via Sage.

**Solution.** Let  $B$  be the event that neither of the rolls results into 2, and let  $A$  be the event “sum is 7”. The set of all possible outcomes is again denoted by  $\Omega$ . Then

$$P(A|B) = \frac{P(A \cap B)}{P(B)} = \frac{\frac{|A \cap B|}{|\Omega|}}{\frac{|B|}{|\Omega|}} = \frac{|A \cap B|}{|B|}.$$

Now, the number 7 can appear as a sum in four ways if there is no 2, that is,  $|A \cap B| = 4$ ,  $|B| = 5 \cdot 5 = 25$ . Thus

$$P(A|B) = \frac{4}{25} = 0.16.$$

Observe that  $P(A) = \frac{1}{6}$ , that is  $A$  and  $B$  are *not* stochastically independent.

Let us now run the simulation to estimate the resulting probability via Sage. Initially we use the parameter `num_rolls` and the method `random_element` (be careful that after copying-pasting the cells below, one needs to re-edit the functions to keep the spaces that appearing below, etc).

```
num_rolls = 100_000
die1=[IntegerRing().random_element(x=1,
    y=7) for _ in range(num_rolls)]
die2=[IntegerRing().random_element(x=1,
    y=7) for _ in range(num_rolls)]
```

– if we have two events  $A_1, A_2$  satisfying  $P(A_1 \cap A_2) > 0$ , then

$$P(A_1 \cap A_2) = P(A_2)P(A_1|A_2) = P(A_1)P(A_2|A_1).$$

All these numbers express (in a different manner) the probability that both events  $A_1$  and  $A_2$  occur. For instance, in the last case we first look whether the first event occurred. Then, assuming that the first has occurred, we look whether the second also occurs. Similarly, for three events  $A_1, A_2, A_3$  satisfying  $P(A_1 \cap A_2 \cap A_3) > 0$  we obtain

$$P(A_1 \cap A_2 \cap A_3) = P(A_1)P(A_2|A_1)P(A_3|A_1 \cap A_2).$$

The probability that three events occur simultaneously can be computed as follows. Compute the probability that the first occurs, then compute the probability that the second occurs under the assumption that the first has occurred. Then compute the probability that the third occurs under the assumption that both the first and the second have occurred. Finally, multiply the results together.

In general, if we have  $k$  events  $A_1, \dots, A_k$  satisfying  $P(A_1 \cap \dots \cap A_k) > 0$ , then the theorem says

$$P(A_1 \cap \dots \cap A_k) = P(A_1)P(A_2|A_1) \cdots P(A_k|A_1 \cap \dots \cap A_{k-1}).$$

Notice that our condition that  $P(A_1 \cap \dots \cap A_k) > 0$  implies that all the hypotheses in the latter formula have got non-zero probabilities and thus all the conditional probabilities make sense. Indeed, each  $A_i$  is at least as big as the intersection and thus its probability is at least as big, see 1.4.3(7).

**1.4.9. Geometric probability.** In practical problems, the sample space may not be a finite set. The set  $\mathcal{A}$  of all events may not be the entire set of all subsets in  $\Omega$ . To generalise probability to such situations is beyond our scope now, but we can at least give a simple illustration.

Consider the plane  $\mathbb{R}^2$  of pairs of real numbers and a subset  $\Omega$  with known area  $|\Omega|$ . Events are represented by subsets  $A \subset \Omega$  (again with known areas). For the event set  $\mathcal{A}$  we consider some suitable system of subsets for which we can determine the area. An event  $A$  then occurs if a randomly chosen point from  $\Omega$  belongs to the subregion determined by  $A$ , otherwise the event does not occur.

Consider the problem of randomly choosing two numbers  $a < b$  in the interval  $[0, 1] \subset \mathbb{R}$ . All values  $a$  and  $b$  are chosen with equal probability. The question is “what is the probability that the interval  $(a, b)$  has length at least one half?” The choice of points  $(a, b)$  is actually the choice of a point  $[a, b]$  inside of the triangle  $\Omega$  with vertex points  $[0, 0]$ ,  $[0, 1]$ ,  $[1, 1]$  (see the diagram below).

We can imagine this as a description of a problem where a very tired guest at a party tries to divide a sausage with two cuts into three pieces for himself and his two friends. What is the probability that the middle part will be at least half of the sausage?

We select only rolls where neither dice resulted in a 2.

```
good_rolls = []
for x, y in zip(die1, die2):
    if x != 2 and y != 2:
        good_rolls.append((x, y))
```

Next we calculate the number of rolls with sum 7:

```
count_sum_7 = 0
for x, y in good_rolls:
    if x + y == 7:
        count_sum_7 += 1
```

The final probability is given by the ratio

```
result=count_sum_7/len(good_rolls)
print(n(result))
```

Sage’s output is 0.162572964225857 (this will slightly differ each time you run the code!), hence our estimate given by Sage has been close to the correct answer. □

**1.D.12.** Michael has two mailboxes, one at gmail.com and the other one at hotmail.com. His username is the same at both servers, but the passwords are different. He does not remember which password corresponds to which server. When typing in the password for accessing his mailbox, he makes a typo with probability 5% (i.e., if he tries to type in a specific password, he types what he intended with probability 95%). At the server hotmail.com, Michael typed in the username and a password, but the server told him that something is wrong. What is the probability that he chose the correct password but just mistyped? (we assume that the username is always typed correctly and that making a typo cannot turn a wrong password into a right one.)

**Solution.** Let  $A$  be the event that Michael typed in a wrong password at hotmail.com. This event is the union of two disjoint events:

- $A_1$ : he wanted to type in the correct password and mistyped;
- $A_2$ : he wanted to type in the wrong password (the one from gmail.com) and either mistyped it or not.

We are looking for a conditional probability  $P(A_1|A)$  which according to the paragraph 1.4.8 is given by

$$\frac{P(A_1 \cap A)}{P(A)} = \frac{P(A_1)}{P(A_1 \cup A_2)} = \frac{P(A_1)}{P(A_1) + P(A_2)}.$$

Here, we have used the fact that  $P(A_1 \cup A_2) = P(A_1) + P(A_2)$ , since  $A_1$  and  $A_2$  are disjoint. So, we only need to compute the probabilities  $P(A_1)$  and  $P(A_2)$ . The event  $A_1$  is the intersection of two independent events: Michael wanted to type in a correct password and Michael mistyped. According to the problem statement, the probability of the first event is  $1/2$  and the probability of the second event is  $1/20$ . In total, and since the events are independent, we get  $P(A_1) = \frac{1}{2} \cdot \frac{1}{20} = \frac{1}{40}$ . In addition,  $P(A_2) = \frac{1}{2}$ , and thus

Thus we need to determine the area of the subset which corresponds to points with  $b \geq a + \frac{1}{2}$ , that is, the interior of the triangle  $A$  bounded by the points  $[0, \frac{1}{2}]$ ,  $[0, 1]$ ,  $[\frac{1}{2}, 1]$ . We find  $P(A) = (1/8)/(1/2) = \frac{1}{4}$ .

Similarly, if we ask for the probability that some of the three guests will get at least half of the sausage, then we have to add the probabilities of two other events:  $B$  saying  $a \geq 1/2$  and  $C$  given as  $b \leq 1/2$ . Clearly they correspond to the lowest and the most right top triangles and thus they have got probabilities  $1/4$ , too. Thus the requested probability is  $3/4$ .

Equivalently we could have asked for the complementary event “all of them get less than a half” which clearly corresponds to the middle triangle and thus has probability  $1/4$ .

Try to answer on your own the question “what is the minimal prescribed length  $\ell$  such that the probability of choosing an interval  $(a, b)$  of length at least  $\ell$  is one half?”

**1.4.10. Monte Carlo methods.** One efficient method for computing approximate values is simulation by the relative occurrence of a chosen event.

We present an example. Let  $\Omega$  to be the unit square with vertices at  $[0, 0]$ ,  $[1, 0]$ ,  $[0, 1]$ , and  $[1, 1]$ . Let  $A$  be the intersection of  $\Omega$  with the unit disk centred at the origin. Then  $\text{area } A = \frac{1}{4}\pi$ . Suppose we have a reliable generator of random numbers  $a$  and  $b$  between zero and one. We then compute relative frequencies of how often  $a^2 + b^2 < 1$ . That is, that  $[a, b] \in A$ . Then the result (after a large number of attempts) should approximate the area of a quarter unit circle, that is  $\pi/4$  quite well. (Draw a picture yourselves!)

Of course, the well-known formula for the area of a circle with radius  $r$  is  $\pi r^2$ , where  $\pi = 3.14159\dots$ . It is an interesting question – why should the area of a circle be a constant multiple of the square of its radius? We will be able to prove this later. But experimentally, we can hint at this by the approach as above using squares of different sizes.

Numerical approaches based on such probabilistic principle are called *Monte Carlo methods*.

## 5. Plane geometry

So far we have been using elementary notions from the geometry of the real plane in an intuitive way. Now we will investigate in more detail how to deal with the need to describe “position in the plane” and to find some relation between positions of distinct points in the plane.

$P(A) = P(A_1) + P(A_2) = \frac{1}{40} + \frac{1}{2} = \frac{21}{40}$ . This gives

$$P(A_1|A) = \frac{P(A_1)}{P(A)} = \frac{\frac{1}{40}}{\frac{21}{40}} = \frac{1}{21}.$$

With the Sage cell

```
PA1=1/2*1/20; PA2=1/2; PA=PA1+PA2
PA1condA=PA1/PA
print("P(A1|A)=", PA1condA)
```

we obtain the verification  $P(A_1|A) = 1/21$ . □

**1.D.13.** Consider a deck of 32 cards. If we draw twice one card, what is the probability that the second drawn card is an ace, if we return the first card; and when we don't return the first card (then there are 31 cards in the deck).

**Solution.** If we return the card in the deck, we are just repeating the experiment, which has 32 possible results (having the same probability), and exactly four of them are favourable. Thus we see that the probability is  $p = 1/8$ . In the second case when we do not return the card, the probability is the same. Indeed, notice that when drawing all the cards one by one, the probability of an ace as the first card is identical to the probability getting an ace in the second draw.

We can also apply the conditional probability, splitting the event into two disjoint options of drawing or not drawing an ace as the first card:  $p = \frac{4}{32} \cdot \frac{3}{31} + \frac{28}{32} \cdot \frac{4}{31} = \frac{1}{8}$ . □

*The concept of geometric probability is useful if we can identify individual events with positions on a line, in a plane, in a space, etc., while the sample space  $\Omega$  is a region with known length, area, volume, respectively. The favorable positions are then represented by measurable objects, too. In analogy to the classical probability, we define the probability as the ratios of length, areas, volumes, etc., to those of  $\Omega$ , see ???. This reflects the idea that all subregions of the same measure are hit with the same probability. We present one example (and we include more of them in the final section of this chapter, starting at page 61).*

**1.D.14.** In a certain country, a bus departs from town A to town B once a day at a random time between eight a.m. and eight p.m. Once a day in the same time interval another bus departs in the opposite direction. The trip in either direction takes five hours. Compute the probability that the buses meet, assuming they use the same route.

**Solution.** The sample space is a square  $12 \times 12$ . If we denote the time of the departure of the buses as  $x$  and  $y$  respectively, then they meet on the trail if and only if  $|x - y| \leq 5$ . This inequality determines the region in the square of "favourable events". This is a complement to the union of two right-angled isosceles triangles with legs of length 7, see also the figure below.

Our tools will be mappings. We will mainly consider mappings  $F$  which, to (ordered) pairs of values  $(x, y)$ , assign pairs  $(w, z) = F(x, y)$ . Such a mapping will consist of two functions  $w(x, y)$  and  $z(x, y)$ , each depending on two arguments  $x, y$ . This will also serve as a gentle introduction to the part of mathematics called *Linear algebra*, with which we will deal in the subsequent three chapters.

**1.5.1. Vector space  $\mathbb{R}^2$ .** We view the "plane" as a set of pairs of real numbers  $(x, y) \in \mathbb{R}^2$ . We will call these pairs *vectors* in  $\mathbb{R}^2$ . For such vectors we can define addition "coordinate-wise", that is, for vectors  $u = (x, y)$  and  $v = (x', y')$  we set

$$u + v = (x + x', y + y').$$

Since all the properties of commutative groups hold for individual coordinates, these hold for our new vector addition too. In particular there exists a *zero vector*  $0 = (0, 0)$ , such that  $v + 0 = v$ . We use the same symbol 0 for the vector and for the number zero on purpose. The context will always make it clear which "zero" it is.

Next we define scalar multiplication of vectors. For  $a \in \mathbb{R}$  and  $u = (x, y) \in \mathbb{R}^2$ , we set

$$a \cdot u = (ax, ay).$$

Usually we will omit the symbol  $\cdot$  and use the juxtaposition of the symbols  $av$  to denote the scalar multiple of a vector.

We can directly check other properties for scalar multiplication by  $a$  or  $b$  and addition of vectors  $u$  and  $v$ . For instance  $a(u+v) = au + av$ ,  $(a+b)u = au + bu$ ,  $a(bu) = (ab)u$ .

We use the same symbol  $+$  for both vector addition and scalar addition.

Now we take a very important step. Define vectors  $e_1 = (1, 0)$  and  $e_2 = (0, 1)$ . Every vector can then be written uniquely as

$$u = (x, y) = x e_1 + y e_2.$$

The expression on the right is called a *linear combination of vectors  $e_1$  and  $e_2$*  (with coefficients  $x$  and  $y$ ). The pair of vectors  $\underline{e} = (e_1, e_2)$  is called the *standard basis* of the vector space  $\mathbb{R}^2$ .

As shown on the picture, these operations are easy to imagine if we consider the vectors  $v$  to be arrows starting at the origin  $0 = (0, 0)$  and ending at the position  $(x, y)$  in the plane.

Its area in total is 49, so the area of the “favourable part” is  $144 - 49 = 95$ . The probability is  $p = \frac{95}{144} \doteq 0.66$ .  $\square$

### E. Plane geometry

*In this section we handle elementary geometric objects in the real plane  $\mathbb{R}^2$ , including points, vectors, lines, circles, and polygons. Our explanation will be supported by Sage. We begin with a series of standard tasks related to the fundamental notion of lines. Recall that a line in the plane is given “implicitly” by the equation  $ax + by = c$  (the line is the set of all points  $[x, y]$  given by the solutions with fixed parameters  $a, b, c$ ). We shall mostly write  $\ell, p, q$  for lines. Lines can be also “parametrized” using equations of the form  $x = x_0 + tv_1$  and  $y = y_0 + tv_2$ , where  $P = [x_0, y_0]$  is a point on the line,  $(v_1, v_2)$  is the direction vector, and  $t \in \mathbb{R}$  is a parameter, see 1.5.3 for more details.*

**1.E.1. Points versus vectors.** Points in the plane will be denoted with capital letters, as  $P = [x, y]$ , where  $x, y \in \mathbb{R}$  are the coordinates, while the vectors shifting  $P$  to  $Q = [x + u_1, y + u_2]$  will be written as  $u = (u_1, u_2)$ . This follows the needs to distinguish the “position in the plane”  $P$  and the “change of the position”  $u$ . Notice, the same notation is used for closed and open intervals on a real line, cf. Chapter 5, but we do not see much space for confusion here. The reader is advised to look carefully at the explanation starting in 1.5.2, to fully appreciate working with both concepts as couples of reals, as soon as we fix our coordinates. This approach will be crucial when dealing with affine and Euclidean geometries in Chapter 4.

We shall also adopt the matrix calculus which brings the notation for both points and vectors in the form of columns, i.e., instead of  $u = (x, y)$  or  $P = [x, y]$ , we often write  $\begin{pmatrix} x \\ y \end{pmatrix}$ .

**1.E.2.** Determine the line  $\ell$  given by  $\{x = 2 - t, y = 1 + 3t : t \in \mathbb{R}\}$  implicitly. Next present an illustration of  $\ell$  using Sage for those  $x$  with  $-5 \leq x \leq 5$ .

**Solution.** We need to find the implicit representation of  $\ell$ , and this can be done by eliminating the parameter  $t$ . Solving the first equation with respect to  $t$  gives  $t = 2 - x$ . Replacing this in the second equation gives  $y = 1 + 3(2 - x)$ , that is  $y + 3x - 7 = 0$ , which is the solution. To present a line via Sage, there are many alternatives. Here we use the implicit form  $y = -3x + 7$ , and then the code can be

The addition of two such arrows is then given by the parallelogram law: Given two arrows starting at the origin, their sum is the arrow given by the diagonal arrow (also starting at the origin) of the parallelogram with the two given arrows as adjacent sides. Multiplication by a scalar  $a$  corresponds to stretching the arrow to its  $a$ -multiple. This includes negative scalars, where the direction of the vector is reversed.

If we choose any two non-zero vectors  $u, v$  such that neither of them is a multiple of the other, then they form a basis of  $\mathbb{R}^2$ , too, i.e. each other vector can be (uniquely) written as a linear combination of these. This seems to be clear from the picture, and we may easily write down the two equations for the coefficients and to solve them (as we shall deduce in a while).

**1.5.2. Points in the plane.** In geometry, we should distinguish between the points in the plane (as for instance the chosen origin  $O$  above), and the vectors as the arrows describing the difference between two such points. We will work in fixed standard coordinates, that is, with pairs of real numbers, but for better understanding we will now distinguish vectors written in parentheses and denoted for a moment by bold face letters like  $\mathbf{u}, \mathbf{v}$ , instead of brackets (which we use for coordinates of points in the plane). Points themselves are denoted by capital latin letters.

Even if we view the entire plane as pairs of real numbers in  $\mathbb{R}^2$ , we may understand adding two such couples as follows. The first couple of coordinates describes a point  $P = [x, y]$ , while the other one denotes a vector  $\mathbf{u} = (u_1, u_2)$ . Their sum  $P + \mathbf{u}$  corresponds to adding the (arrow) vector  $\mathbf{u}$  to the point  $P$ . If we fix the vector  $\mathbf{u}$ , we call the resulting mapping

$$P = [x, y] \mapsto P + \mathbf{u} = [x + u_1, y + u_2]$$

the *shift of the plane* (or *translation*) by the vector  $\mathbf{u}$ .

Thus, the vectors in  $\mathbb{R}^2$  can be understood in more abstract way as the shifts in the plane (sometimes called the *free vectors* in elementary geometry texts).

The standard coordinates on  $\mathbb{R}^2$ , understood as pairs of real numbers are not the only ones. We can put a coordinate system on the plane with our choosing.

```
e11=-3*x+7
plot(e11, -5, 5, color="black", thickness=2)
```

Or simply type `e11 = -3 * x + 7; plot(e11, -5, 5)`, or `plot(-3 * x + 7, -5, 5)`, without the options for the colour and the thickness of the line. The figure that Sage returns via the very first choice is given here:

□

**1.E.3.** Consider the lines  $p, q$  given in the form  $[2, 0] + t(3, 2)$ , and  $[-1, 2] + s(1, 3)$ , with  $t, s \in \mathbb{R}$ , respectively. Present them in implicit form, and next examine if they intersect. In positive case, determine explicitly the (unique) intersection point. Verify your answer via Sage.

**Solution.** The coordinates of the points on the first line are given by the parametric equations  $\{x = 2 + 3t, y = 0 + 2t\}$ . Eliminating  $t$  from the equations we obtain the implicit form of  $p$ :  $2x - 3y - 4 = 0$ . Similarly, the points on the line  $q$  are given by  $\{x = -1 + s, y = 2 + 3s\}$ .

By eliminating  $s$ , we get the implicit form of  $q$ , namely  $3x - y + 5 = 0$ . The unique solution  $(x^*, y^*)$  of the system of the equations  $\{2x - 3y - 4 = 0, 3x - y + 5 = 0\}$ , if any, determines the coordinates of the unique intersection point  $P = (x^*, y^*)$  of  $p, q$ , if any. We compute  $P = [-\frac{19}{7}, -\frac{22}{7}]$ . As we have seen, Sage offers the command `solve`. Here its application comes with the cell

```
x, y=var("x, y")
eq1=2*x-3*y-4; eq2=3*x-y+5
solve([eq1==0, eq2==0], x, y)
```

which returns  $[[x == (-19/7), y == (-22/7)]]$ . As for the given plot that joins both lines, we have applied the Sage cell

COORDINATES IN THE PLANE  $\mathbb{R}^2$

Choose any point in the plane, and call it the origin  $O$ . All other points  $P$  in the plane can be identified with the vectors (arrows)  $\overrightarrow{OP}$  with their tails at the origin.

Choose any point other than  $O$  and call it  $E_1$ . This defines the vector  $e_1 = \overrightarrow{OE_1} = (1, 0)$ . Choose any other point  $E_2$  so that  $O, E_1, E_2$  are distinct and not collinear. This defines the vector  $e_2 = \overrightarrow{OE_2} = (0, 1)$ .

Then every point  $P = (a, b)$  in the plane can be described uniquely as  $P = O + a e_1 + b e_2$  for real  $a, b$ , or in vector notation,  $\overrightarrow{OP} = a e_1 + b e_2$ .

Translation, by adding a fixed vector, can be used either to shift the coordinate system (including the origin), or to shift sets of points in the plane. Notice that the vector corresponding to the shift of the point  $P$  into the point  $Q$  is given as the difference  $Q - P$  (in any coordinates). Thus we shall also use this notation for the vector  $\overrightarrow{PQ} = Q - P$ .

For each choice of coordinates, we have two distinct lines for the two axes. The origin is the point of intersection. Other way round, each choice of two non-parallel lines, together with the scales on each of them defines coordinates in the plane. They are called *affine coordinates*.

Clearly each nontrivial triangle in the plane with vertices  $O, E_1, E_2$  defines coordinates where this triangle is defined by points  $[0, 0], [1, 0], [0, 1]$ . Thus we may say that in the geometry of plane, "all nontrivial triangles are the same, up to a choice of coordinates".

**1.5.3. Lines in the plane.** Every line is parallel to a (unique) line through the origin. To define a line, we therefore need two ingredients. One is a non-zero vector which describes the direction of the line. Call it  $\mathbf{v} = (v_1, v_2)$ . The other is a point  $P_0 = [x_0, y_0]$  on the line. Every point on the line is then of the form

$$P(t) = P_0 + t\mathbf{v}, \quad t \in \mathbb{R}.$$

PARAMETRIC DESCRIPTION OF A LINE

We may understand the line  $p$  as the set of all multiples of the vector  $v$ , shifted by the vector  $(x_0, y_0)$ . This is called the *parametric description* of the line:

$$p = \{P \in \mathbb{R}^2; P = P_0 + t\mathbf{v}, t \in \mathbb{R}\}.$$

The vector  $v$  is called *direction vector* of the line  $p$ .

LINE EQUATION

```
z=var("z")
y1=(2/3)*z-(4/3); y2=3*z+5
P = plot([],figsize=(4,4))
P += plot(y1,z,(-4,4), color="black")
P += plot(y2,z,(-4,4), color="black")
P += point((-19/7, -22/7), size=50,
           color="black"); show(P)
```

**1.E.4. Remark.** In 1.E.3 you can also solve the problem by substituting the parametric equations of the line  $q$  into the implicit equation of  $p$ , which gives  $2(-1+s)-3(2+3s)-4 = 0$ . This equation has the unique solution  $s = -12/7$ , hence returning back to the parametric equation of  $q$  we obtain the coordinates of  $P$  as previously mentioned.

In Sage you can directly plot a line given in parametric form using the `parametric_plot` command. For example, to plot the lines from 1.E.3 you can use the following Sage cell (check the resulting figure in your editor). Sage can also find the intersection point by solving the systems of the two equations for the parameters  $s, t$  - try it out yourselves!

```
t = var("t")
P1= parametric_plot((2+3*t, 2*t), (t, -3, 3),
                   color="blue", legend_label="line p")
P2= parametric_plot((-1+t, 2+3*t), (t, -3,
3), color="black", legend_label="line q")
Q= point((-19/7, -22/7), size=70)
PL=P1+P2+Q; show(PL)
```

**1.E.5.** Determine the intersection of the lines  $x + y - 4 = 0$  and  $\{x = -1 + 2t, y = 2 + t : t \in \mathbb{R}\}$ .

**1.E.6.** Find the line  $p$  which passes through the point  $P = [2, 3] \in \mathbb{R}^2$  and is parallel to line  $q$  given by  $x - 3y + 2 = 0$ . Provide a figure in Sage illustrating the situation.

**Solution.** On the real plane for two parallel lines there are two chances: either they overlap, or they have no intersection. Since the line  $p$  should pass from the point  $[2, 3]$  and this point does not belong to  $q$  (since it does not satisfy its equation), we deduce that  $p, q$  have no intersection.

This means that  $p$  is of the form  $x - 3y + c = 0$ , for some  $c \in \mathbb{R}$ , with  $c \neq 2$ . To find  $c$ , we substitute the coordinates of the point  $P$  into this equation. It reveals  $c = 7$ , which means that  $p$  is implicitly given by  $y = \frac{1}{3}x + \frac{7}{3}$ . For the figure presented above, we have used the cell

```
x=var("x")
y1=(1/3)*x+(2/3)
y2=(1/3)*x+(7/3)
a = plot([],figsize=(4,4))
```

In the chosen coordinates, the point  $P(t) = [x(t), y(t)]$  is given as

$$x = x(t) = x_0 + t v_1, \quad y = y(t) = y_0 + t v_2$$

We can eliminate  $t$  from these two equations to obtain

$$-v_2x + v_1y = -v_2x_0 + v_1y_0.$$

Since the vector  $v = (v_1, v_2)$  is non-zero, at least one of the numbers  $v_1, v_2$  is non-zero. If one of the coordinates  $v_1$  or  $v_2$  is zero, then the line is parallel to one of the coordinate axis.

#### IMPLICIT DESCRIPTION OF A LINE

The general equation of the line in the plane is

$$(1) \quad ax + by = c,$$

with  $a$  and  $b$  not both zero. The relation between the pair of numbers  $(a, b)$  and the direction vector of the line  $\mathbf{v} = (v_1, v_2)$  is

$$(2) \quad av_1 + bv_2 = 0.$$

We can view the left hand side of the equation (1) as a function  $z = f(x, y)$  mapping each point  $[x, y]$  of the plane to a scalar and the line corresponds to the prescribed constant value of this function. We shall see soon that (2) says the vector  $(a, b)$  is perpendicular to the direction of the line.

#### GRAPH OF A FUNCTION $f(x, y)$

Suppose we have two lines  $p$  and  $q$ . We ask about their intersection  $p \cap q$ . That is a point  $[x, y]$  which satisfies the equations of both lines simultaneously. We write them as

$$(3) \quad \begin{aligned} ax + by &= r \\ cx + dy &= s. \end{aligned}$$

Again, we can view the left side as a mapping  $F$ , which to every pair of coordinates  $[x, y]$  of the point  $P$  in the plane assigns a vector of values of two scalar functions  $f_1$  and  $f_2$  given by the left sides of the particular equations (3). Hence we can write our two scalar equations as one vector equation  $F(\mathbf{v}) = \mathbf{w}$ , where  $\mathbf{v} = (x, y)$  and  $\mathbf{w} = (r, s)$ .

Notice that the two lines are not parallel if and only if they have a unique point in their intersection.

```
a += plot(y1, x, (-4, 4), thickness=2)
a += plot(y2, x, (-4, 4), thickness=2)
a += point((2, 3), size=70);show(a)
```

Observe that in this case we asked a different size for the thickness of lines, in comparison with the previous figures.  $\square$

**1.E.7.** Consider the following lines in  $\mathbb{R}^2$ :

$$\begin{aligned} p_1 : 2x + 3y - 4 &= 0, & p_2 : x - y + 3 &= 0, \\ p_3 : -2x + 2y &= -6, & p_4 : -x - \frac{3}{2}y + 2 &= 0, \\ p_5 : x = 2 + t, & y = -2 - t, & t \in \mathbb{R} \end{aligned}$$

Determine which lines are parallel to each other.  $\circ$

**1.E.8.** Find a parametric equation of the line  $\ell$  which goes through the points  $P_1 = [1, 3]$  and  $P_2 = [-2, 1]$  on  $\mathbb{R}^2$ . What is the corresponding implicit equation of  $\ell$ ?

**Solution.** The parametric equation of a line  $\ell$  on the Euclidean plane passing through two points  $P_1 = [u_1, v_1]$  and  $P_2 = [u_2, v_2]$  on  $\mathbb{R}^2$  is given by

$$P_1 + t\overrightarrow{P_1P_2} = P_1 + t(P_2 - P_1),$$

where  $\overrightarrow{P_1P_2} := P_2 - P_1 = (u_2 - u_1, v_2 - v_1)$  is the displacement vector from  $P_1$  to  $P_2$ . Applying this rule for the given points, we get  $P_2 - P_1 = (-3, -2)$  and so the parametric equation of  $\ell$  is given by  $[1, 3] + t(-3, -2) = [1, 3] - t(3, 2)$ , with  $t \in \mathbb{R}$ . Hence we have  $x = 1 - 3t$  and  $y = 3 - 2t$ . By eliminating  $t$  we get  $y = \frac{2}{3}x + \frac{7}{3}$ . As a verification one can check that both the points  $P_1, P_2$  satisfy the equation of  $\ell$ .  $\square$

**1.E.9.** Planar soccer player shoots a ball from the point  $F = [1, 0]$  in the direction of the vector  $u = (3, 4)$  hoping to hit the goal which is a line segment from the point  $A = [23, 36]$  to  $B = [26, 30]$ . Does the ball fly towards the goal?

**Solution.** The ball travels along the line  $[1, 0] + t(3, 4)$ . The line segment joining  $A$  and  $B$ , has the parametrization  $[23, 36] + s(3, -6)$ . The intersection of these lines is given by equations  $1 + 3t = 23 + 3s$  and  $4t = 36 - 6s$ , with the solution  $t = 8, s = 2/3$ . As  $0 < 2/3 < 1$  the intersection is in the line segment between  $A$  and  $B$ , and so the ball hits the goal.

Another approach (closed to the function of our vision) is based on the slopes of the vectors  $\overrightarrow{FA}, u = (3, 4)$ , and  $\overrightarrow{FB}$  (i.e. the ratio of the coordinates, we shall come back to that later). Since  $\frac{36}{22} > \frac{4}{3} > \frac{30}{25}$ , the player scores.  $\square$

*Next, we shall touch the basic computational tools in the entire Mathematics, the matrix calculus. For now, we shall restrict our attention to tasks in the plain only, and the reader can find introductory concepts from the so called "linear algebra" in 1.5.4, also restricted to the real plane  $\mathbb{R}^2$ . Below we will first experience the operations of addition and multiplication of matrices, and exercise how to compute with them more or less exactly as with scalars. We shall return to the geometry of the plane with the new tools at hand later.*

**1.5.4. Linear mappings and matrices.** Mappings  $F$  with

which we have worked with when describing intersection of lines have one very important property in common: they preserve the operations of addition and multiplication with vectors and scalars, that is they preserve linear combinations:

$$F(a \cdot \mathbf{v} + b \cdot \mathbf{w}) = a \cdot F(\mathbf{v}) + b \cdot F(\mathbf{w})$$

for all  $a, b \in \mathbb{R}, \mathbf{v}, \mathbf{w} \in \mathbb{R}^2$ . We say that  $F$  is a *linear mapping* from  $\mathbb{R}^2$  to  $\mathbb{R}^2$ , and write  $F: \mathbb{R}^2 \rightarrow \mathbb{R}^2$ . This can be also described with words — linear combination of vectors maps to the same linear combination of their images, that is linear mappings are those mappings which preserve linear combinations.

We have already encountered the same behaviour in the equation 1.5.3(1) for the line, where the linear mapping in question was  $f: \mathbb{R}^2 \rightarrow \mathbb{R}$  and its prescribed value  $c$ . That is also the reason why the values of the mapping  $z = f(x, y)$  are on the image depicted as a plane in  $\mathbb{R}^3$ .

We can write such a mapping using *matrices*. By a matrix we mean a rectangular array of numbers, for instance

$$A = \begin{pmatrix} a & b \\ c & d \end{pmatrix} \quad \text{or} \quad \mathbf{v} = \begin{pmatrix} x \\ y \end{pmatrix}.$$

We speak of a (square  $2 \times 2$ ) matrix  $A$  and (column) vector  $\mathbf{v}$ . Multiplication of matrices, row by column, is defined as follows:

$$A \cdot \mathbf{v} = \begin{pmatrix} a & b \\ c & d \end{pmatrix} \cdot \begin{pmatrix} x \\ y \end{pmatrix} = \begin{pmatrix} ax + by \\ cx + dy \end{pmatrix}.$$

We introduce some more tools for vectors and matrices. Our goal is to compute with matrices in a similar way as we do it with scalars.

We define the product  $C = A \cdot B$  of two square matrices  $A$  and  $B$  applying the above formulas to individual columns of the matrix  $B$  and writing the resulting column vectors again as columns in the matrix  $C$ .

In order to multiply two vectors  $\mathbf{w}$  and  $\mathbf{v}$  in a similar way, we can write the vector  $\mathbf{w}$  as a row of numbers (the transposed vector)  $\mathbf{w}^T$ . Then the product of  $\mathbf{w}^T$  and  $\mathbf{v}$  is

$$\mathbf{w}^T \cdot \mathbf{v} = (r \quad s) \cdot \begin{pmatrix} x \\ y \end{pmatrix} = rx + sy.$$

This is the *scalar product of vectors*  $\mathbf{v}$  and  $\mathbf{w}$  introduced a while ago.

We can easily check the associativity of multiplication (do it for general matrices  $A, B$  and a vector  $\mathbf{v}$  in detail):

$$(A \cdot B) \cdot \mathbf{v} = A \cdot (B \cdot \mathbf{v}).$$

Instead of a vector  $\mathbf{v}$  we can write any  $(2 \times 2)$  matrix  $C$ . In a similar way, distributivity also holds:

$$\begin{aligned} A \cdot (B + C) &= A \cdot B + A \cdot C \\ (A + B) \cdot C &= A \cdot C + B \cdot C. \end{aligned}$$

**1.E.10. Quick comments on notation.** In order to simplify our notation, for the multiplication of two matrices  $A, B$  (of appropriate size) we just write  $AB$ , instead of  $A \cdot B$  (which is the complete notation we use in the other column, but only in this chapter). Later on we shall use the operator “ $\cdot$ ” for the scalar product  $u \cdot v$  between two vectors  $u, v$  (which we do in the other column as well).

In the sequel, we shall write  $\text{Mat}_{m,n}(\mathbb{R})$  for the set of all  $m \times n$  real matrices (so in this section both  $m$  and  $n$  will be either 1 or 2). For  $m = n$ , i.e., square matrices, we will use the notation  $\text{Mat}_n(\mathbb{R})$ . If  $m = 1, n = 2$ , the object is a couple of scalars written in a row, if  $n = 1$  and  $m = 2$ , we deal with a vector written as a column (while  $\text{Mat}_1(\mathbb{R})$  coincides with  $\mathbb{R}$ ). Moreover, for  $A = \begin{pmatrix} \alpha & \beta \\ \gamma & \delta \end{pmatrix} \in \text{Mat}_2(\mathbb{R})$  we denote by  $\det(A)$  and  $\text{tr}(A)$  the determinant and trace of  $A$ , which are the real numbers defined by  $\det(A) = \alpha\delta - \beta\gamma$  and  $\text{tr}(A) = \alpha + \delta$ , respectively. On all matrices, there is the transposition operation,  $A \mapsto A^T$  swapping rows and columns, and the product by scalars  $cA$ , for  $c \in \mathbb{R}$ . In Chapter 2, we will extend the matrix calculus to general positive integers  $m$  and  $n$ , and general scalars.

**1.E.11.** Let  $A, B$  be two real square matrices. How many arithmetic operations do we need to compute the product  $AB$ ?

**Solution.** Given  $A, B \in \text{Mat}_2(\mathbb{R})$ , each entry of the product  $AB$  requires 2 multiplications and  $2 - 1 = 1$  addition. Since there are  $2^2 = 4$  entries in  $AB$ , we need  $4(2 + 1) = 12$  operations in total.

We may notice, that the same operation of “multiplying” rows and columns for general  $A, B \in \text{Mat}_n(\mathbb{R})$  requires  $n$  multiplications and  $n - 1$  additions for each term in the result. Thus, we shall see in the next chapter that in total we need  $n^2(n+n-1) = n^2(2n-1)$  arithmetic operations to compute  $AB$  for two real square matrices  $A, B$ .<sup>8</sup> □

**1.E.12.** Compute  $v = 2(A - B)^T C u$ , for  $A = \begin{pmatrix} 0 & 5 \\ -2 & 2 \end{pmatrix}$ ,  $B = \begin{pmatrix} 2 & 0 \\ -1 & 1 \end{pmatrix}$ ,  $C = \begin{pmatrix} 2 & -2 \\ 4 & 5 \end{pmatrix}$ , and  $u = (3, 2)^T$ , respectively. ○

**1.E.13. Matrices in Sage.** Our aim is to compute with matrices and vectors just like with scalars. Sage can do this. Let us look at simple computations like in 1.E.12. We have to tell Sage to use the objects of the right class. The commands `matrix` and `vector` do that for us. Let us type

```
A = matrix([[0, 5], [-2, 2]])
B = matrix([[2, 0], [-1, 1]])
C = matrix([[2, -2], [4, 5]])
u = vector([3, 2])
v = 2*transpose(A-B)*C*u; print(v)
```

<sup>8</sup>This means, that the complexity of matrix multiplication is “polynomial”, essentially of the size of  $n^3$ . With big matrices, this is an essential issue in theoretical computer science to make the power lower. Volker Strassen introduced his famous algorithm reaching the complexity of the size  $n^{2.807}$  in 1969, and as of July 2023, the fastest known algorithm performs with the complexity size of  $n^{2.371866}$ .

But the commutativity does not hold. For example,

$$\begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix} \cdot \begin{pmatrix} 0 & 0 \\ 0 & 1 \end{pmatrix} = \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix},$$

$$\begin{pmatrix} 0 & 0 \\ 0 & 1 \end{pmatrix} \cdot \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix} = \begin{pmatrix} 0 & 0 \\ 0 & 0 \end{pmatrix}.$$

This last product also shows the existence of divisors of zero.

Notice that the mapping defined by multiplication of vectors with a fixed matrix is a linear mapping, i.e. it respects linear combinations. On the other hand, every linear mapping  $F$  has to be completely given by its values on the two vectors  $e_1 = (1, 0)$  and  $e_2 = (0, 1)$  in the standard basis and these values appear in the columns of the matrix  $A$ , which expresses  $F$  as matrix multiplication (check this observation carefully!).

With matrices and vectors we can write the equations for lines and points respectively as

$$\mathbf{u}^T \cdot \mathbf{v} = (a \ b) \cdot \begin{pmatrix} x \\ y \end{pmatrix} = c$$

$$A \cdot \mathbf{v} = \begin{pmatrix} a & b \\ c & d \end{pmatrix} \cdot \begin{pmatrix} x \\ y \end{pmatrix} = \begin{pmatrix} r \\ s \end{pmatrix} = \mathbf{w}.$$

**1.5.5. Determinant of matrix.** The procedure of finding the intersection of lines described in 1.5.3 fails in some special cases. For instance the intersection of two parallel lines is either empty (when the lines are parallel but distinct) or the line itself (when the lines are identical). This condition occurs when the ratios  $a/c$  and  $b/d$  are the same, that is

$$(1) \quad ad - bc = 0.$$

Note that this expression already takes care of the cases, where either  $c$  or  $d$  is zero.

The expression on the left in (1) is called the *determinant* of the matrix  $A$ . We write it as

$$\det A = \begin{vmatrix} a & b \\ c & d \end{vmatrix} = ad - bc.$$

Our discussion can be now expressed as follows:

**Proposition.** *The determinant is a real valued function  $\det A$  defined for all square  $2 \times 2$  matrices  $A$ . The (vector) equation  $A \cdot \mathbf{v} = \mathbf{u}$  has a unique solution for  $\mathbf{v}$  if and only if  $\det A \neq 0$ .*

So far, we have worked with pairs of real numbers in the plane. Equally well we might pose exactly the same questions for points with integer coordinates and lines with equations with integer coefficients. Notice that the latter requirement is equivalent to considering rational coefficients in the equations. We have to be careful which properties of the scalars we exploit.

In fact, we needed all the properties of the field of scalars when discussing the solvability of the system of two equations — try to think it through. At least, we can be sure that the intersection of two non-parallel lines with rational coefficients is a point with rational coefficients again. The case of integer coefficients and coordinates is more difficult. We shall come

Notice, Sage does all the multiplications properly (including multiplying correctly all the components by 2), and returns the components  $(-52, 64)$  of the vector  $v$ . The methods of addition and multiplication are appropriately used for the objects, with the same symbols as with scalars. Of course, we may introduce a matrix with other scalar type of entries. For example, the real float type entries are invoked by  $A = \text{matrix}(\text{RR}, [[0, 5], [-2, 2]])$  (recall that  $\text{RR}$  indicates the field of float type real numbers in Sage), and similarly with  $\text{CC}$  for complex float type. Sage also offers the methods  $\text{transpose}(A)$  and  $\text{determinant}(A)$  (or write  $A.\text{transpose}()$  and  $A.\text{determinant}()$ , respectively), which return the transpose and determinant of a matrix  $A$ . Further methods and comments will appear when using Sage below.

**1.E.14.** Prove the statements listed below, where  $A, B, C$  are the matrices from 1.E.12:

- (a)  $(A - B)^2 \neq A^2 - 2AB + B^2$ ;
- (b)  $D := 2ABC - BCA - CAB \neq 0$ ;<sup>9</sup>
- (c)  $\frac{c(AB) - (c(AB))^T}{\sqrt{2}} = \frac{11\sqrt{2}c}{2} \begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix}$ , with  $c \neq 0$ ;
- (d)  $\det(AB) - \det(A)\det(B) = 0$ ;
- (e) The determinant of the matrix

$$F := \det(A)B - \det(B)A - \text{tr}(C)C$$

is an integer divisible by the numbers 1, 2, 19 and 38.

**1.E.15.** Give an example of matrices  $A$  and  $B$  for which

- (a)  $(A + B)(A - B) \neq A^2 - B^2$ .
- (b)  $(A + B)(A + B) \neq A^2 + 2AB + B^2$ .

The so called “affine geometry” of the real plane is characterized by the concept of “going straight with constant velocity” from a given point, i.e., along a line. The mappings  $F : \mathbb{R}^2 \rightarrow \mathbb{R}^2$  of the plane which preserve this feature are called “affine”. Those fixing the origin  $O = [0, 0]$  are just the “linear ones”,

$$F(au + bv) = aF(u) + bF(v),$$

for all  $a, b \in \mathbb{R}$  and  $u, v \in \mathbb{R}^2$ . Remarkably, all affine maps are obtained by additionally allowing the “shifts”  $P \mapsto P + u$ ,  $P \in \mathbb{R}^2$ , for some fixed vectors  $u$ .

In coordinates, the linear mappings are given by matrix multiplication, while the affine mapping include also addition of constant vectors. See the detailed explanation in the other column, e.g., 1.5.6. Due to the associativity of matrix multiplication, composition of mappings corresponds to multiplication of matrices, too. Moreover, invertible affine mappings are also understood as changes of coordinates, see 1.5.6, thus we call them affine transformations.

<sup>9</sup>Here we denote by  $0$  the zero  $2 \times 2$  matrix.

back to this in the next chapter. In particular we shall see that the equation 1.5.3(3) with fixed integer coefficients  $a, b, c, d$  has a unique integer solution for all integer values  $(r, s)$  if and only if the determinant is  $\pm 1$ .

**1.5.6. Affine mappings.** We now investigate how the matrix notation allows us to work with simple mappings in the affine plane. We have seen that matrix multiplication defines a linear mapping. Shifting  $\mathbb{R}^2$  by a fixed vector  $\mathbf{w} = (r, s) \in \mathbb{R}^2$  in the affine plane can be also easily written in matrix notation:

$$P = \begin{pmatrix} x \\ y \end{pmatrix} \mapsto P + \mathbf{w} = \begin{pmatrix} x + r \\ y + s \end{pmatrix}.$$

If we add a fixed vector to the result of a linear mapping then we have the expression

$$\mathbf{v} = \begin{pmatrix} x \\ y \end{pmatrix} \mapsto A \cdot \mathbf{v} + \mathbf{w} = \begin{pmatrix} ax + by + r \\ cx + dy + s \end{pmatrix}.$$

In this way we have described all affine mappings of the plane to itself.

Such mappings allow us to recompute coordinates which arise by different choices of origins or bases. We shall come back to this in detail later.

**1.5.7. The distance and angle.** Now we consider distance. We define the length of the vector  $\mathbf{v} = (x, y)$  to be

$$\|\mathbf{v}\| = \sqrt{x^2 + y^2}.$$

Immediately we can define notions of distance, angle and rotation in the plane.

DISTANCE IN THE PLANE

The distance between the points  $P, Q$  in the plane is given as the length of the vector  $\overrightarrow{PQ}$ , i.e.  $\|Q - P\|$ . Obviously, the distance does not depend on the ordering of  $P$  and  $Q$  and it is invariant under shifts of the plane by any fixed vector  $\mathbf{w}$ .

The Euclidean plane is an affine plane with distance defined as given above.

**1.E.16.** Decide whether the mappings  $F, G : \mathbb{R}^2 \rightarrow \mathbb{R}^2$  given by

$$F : (x, y) \mapsto (7x - 3y, -2x + 5y),$$

$$G : (x, y) \mapsto (2x + 2y - 4, 4x - 9y + 3),$$

are linear. Write them via matrix multiplication, analyze the meaning of the individual columns, and check that their composition is expressed via matrix multiplication, too.  $\circ$

*Affine transformations play a crucial role in computer graphics and computer vision. Computer graphics involve creating and manipulating images, displayed or animated on a computer screen. Modern computer-aided design (CAD) programs and tools like LibreCAD have a wide range of applications, from designing satellites to creating computer games and educational software. Thus these tools are particularly valuable for engineers and designers working in various industries.*

*Below we will explore how to manipulate affine transformations on the plane, which will enhance our understanding of their mathematical significance in practical applications. Using Sage to illustrate these concepts, we will focus on two-dimensional graphics (2D graphics) through the problems analyzed below. For additional learning and Sage examples, refer to the tasks outlined in 1.G.52, 1.G.53, and ??.*

**1.E.17. Affine transformations.** Find the matrix representation for simple affine transformations on the plane, as: shifts, homotheties, stretching in only one direction, shears, rotations, and reflections.

**Solution.** In order to talk about matrix representation, we need to fix the coordinates, see 1.5.2. We shall work with the standard ones, that is, with the vectors  $e_1 = (1, 0)$ ,  $e_2 = (0, 1)$ , identifying the plane with  $\mathbb{R}^2$  explicitly.

- “Identity transformation.” The simplest affine transformation is the identity, the relevant matrix is the identity matrix  $E = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}$ . Clearly  $Eu = u$ , for all  $u \in \mathbb{R}^2$ .

- “Shifts.” The shift (or translation)  $\tau_w$  by a vector  $w = r e_1 + s e_2 = (r, s)^T \in \mathbb{R}^2$  is given by applying the matrix  $E$  and adding the vector  $w$ , i.e.,  $(x, y)^T \mapsto (x, y)^T + (r, s)^T = (x+r, y+s)^T$ , or in other words  $\tau_w(u) = u+w$ . For instance, if  $w = (3, 0)^T$ , then applying  $\tau_w$  to an image will shift it to the right by 3. Notice that when we want to shift a point  $P$  to the origin, we will also write  $\tau_{-P}$  for the relevant translation.

With the aim to illustrate a translation (and also the rest transformations), we will use a triangle  $ABC$ , with vertices the points  $A = [1, 0]$ ,  $B = [4, -2]$ , and  $C = [2, -2]$ . In the figures we have coloured these vertices by blue, green and red, respectively. The new coordinates are also painted by the corresponding colour, with the hope to get a better visualization of how the given transformation acts. For instance, let us present the illustration of the translation  $\tau_{(3,0)}$  applied to  $ABC$ :

Angles are a matter of vectors rather than points in Euclidean geometry. Let  $\mathbf{u}$  be a vector of length 1, at angle  $\varphi$  measured counter-clockwise from the vector  $(1, 0)$ . In coordinates,  $\mathbf{u}$  is at the unit circle and has first and second coordinates  $\cos \varphi, \sin \varphi$  respectively (this is one of the elementary definitions of the sine and cosine functions). That is,

$$\mathbf{u} = (\cos \varphi, \sin \varphi).$$

This is compatible with  $-1 \leq \sin \varphi \leq 1$  satisfying

$$(\cos \varphi)^2 + (\sin \varphi)^2 = 1.$$

ANGLE BETWEEN VECTORS

The angle  $\varphi$  between two vectors  $\mathbf{v}$  and  $\mathbf{v}'$  can be in general described using their coordinates  $\mathbf{v} = (x, y)$ ,  $\mathbf{v}' = (x', y')$  like this:

$$(1) \quad \cos \varphi = \frac{xx' + yy'}{\|\mathbf{v}\| \|\mathbf{v}'\|}$$

with  $0 \leq \varphi \leq \pi$ .

In our special case  $\mathbf{v} = (1, 0)$ , the more general equation gives

$$\cos \varphi = \frac{x'}{\|\mathbf{v}'\|},$$

which is just the definition of the function  $\cos \varphi$ . The general case can be always reduced to this special one. First we notice that the angle  $\varphi$  between two vectors  $\mathbf{u}, \mathbf{v}$  is always the same as the angle between the *normalized vectors*  $\frac{1}{\|\mathbf{u}\|} \mathbf{u}$  and  $\frac{1}{\|\mathbf{v}\|} \mathbf{v}$ . Thus we can restrict ourselves to two vectors on the unit circle. Then we can rotate our coordinates in such a way that the first of the vectors will become  $(1, 0)$ . This means, it is enough to show that the scalar product  $xx' + yy'$ , as well as the length of vectors are invariant with respect to rotations. We shall come back to this in a moment.

In the special case, when the scalar product is zero, we say that the vectors are *perpendicular* and this corresponds to  $\varphi = \pi/2$  as expected. Of course the best example of perpendicular vectors of length 1 are the standard basis vectors  $(1, 0)$  and  $(0, 1)$ .

Notice that our formula for the angle between the vectors is symmetric in the two vector arguments, thus we have to take the smaller of the possible angles between two vectors and  $\varphi$  is always between 0 and  $\pi$ .

We can easily imagine that not all affine coordinates are adequate for expressing the distance and thus for use in the Euclidean plane. Indeed, although we may choose any point  $O$  as the origin again, we want also the basis vectors  $\mathbf{e}_1 = \overrightarrow{OE_1}$  and  $\mathbf{e}_2 = \overrightarrow{OE_2}$  to be perpendicular and of length one. Such

• “Homotheties.” A homothety  $h_c$  is a constant rescaling of all vectors by a factor  $c \in \mathbb{R}$ . Thus the relevant matrix is a multiple of  $E$  and hence diagonal,  $A = cE = \begin{pmatrix} c & 0 \\ 0 & c \end{pmatrix}$ . As a result, a homothety with  $c > 1$  will stretch a figure. Let us illustrate this, by using the triangle  $ABC$  and the homothety  $h_c((x, y)^T) = (\frac{3x}{2}, \frac{3y}{2})^T$ , i.e.,  $c = 3/2$ :

In the opposite, a homothety  $h_c$  with  $0 < c < 1$  will shrink the figure, try to present examples yourselves.

In case we want to apply a homothety with another fixed point  $P = [a, b]$  in  $\mathbb{R}^2$  (thus rescaling the differences  $Q - P$  for all points  $Q$ ), then we can first translate  $P$  to the origin, then to employ the usual homothety and then to shift the plane back:

$$\begin{pmatrix} x \\ y \end{pmatrix} \mapsto \begin{pmatrix} x - a \\ y - b \end{pmatrix} \mapsto \begin{pmatrix} c(x - a) \\ c(y - b) \end{pmatrix} \mapsto \begin{pmatrix} c(x - a) + a \\ c(y - b) + b \end{pmatrix}.$$

Imagine what is happening with the plane under the three transformations on the way.

• “Rotations.” If we rotate by angle  $\theta$  counterclockwise, we get  $e_1 \mapsto (\cos \theta, \sin \theta)$  (this is the elementary definition of the goniometric functions), while  $e_2 \mapsto (-\sin \theta, \cos \theta)$  (look at the picture in 1.5.8). Thus, the rotation matrix has the form

$$R_\theta = \begin{pmatrix} \cos \theta & -\sin \theta \\ \sin \theta & \cos \theta \end{pmatrix}.$$

For instance, for  $\theta = \pi/2$ , we get  $R_{\pi/2} = \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix}$ , and hence in this case the rotation takes  $(x, y)^T$  to  $(-y, x)^T$ :

$$\begin{pmatrix} x \\ y \end{pmatrix} \mapsto R_{\pi/2} \begin{pmatrix} x \\ y \end{pmatrix} = \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix} \begin{pmatrix} x \\ y \end{pmatrix} = \begin{pmatrix} -y \\ x \end{pmatrix}.$$

The figure below illustrates the result of  $R_{\pi/2}$  on the triangle  $ABC$  used above.<sup>10</sup>

<sup>10</sup>Notice a rotation preserves both the lengths of vectors and the angles.

basis will be called *orthonormal*. We shall see that the angles and distances computed in such coordinates will always be the same no matter which coordinates are used.

**1.5.8. Rotation around a point in the plane.** As we saw, the matrix of any given linear mapping  $F : \mathbb{R}^2 \rightarrow \mathbb{R}^2$  is easy to guess. If the mapping works applying the matrix with columns  $(a, c)$  and  $(b, d)$ , then the first column  $(a, c)$  is obtained by multiplying this matrix with the basis vector  $(1, 0)$  and the second is the evaluation at the second basis vector  $(0, 1)$ .

ROTATION AROUND A POINT IN THE PLANE

We can see from the picture that the columns of the matrix corresponding to rotating counter-clockwise through the angle  $\psi$  are computed as follows:

$$\begin{pmatrix} a & b \\ c & d \end{pmatrix} \begin{pmatrix} 1 \\ 0 \end{pmatrix} = \begin{pmatrix} \cos \psi \\ \sin \psi \end{pmatrix}, \quad \begin{pmatrix} a & b \\ c & d \end{pmatrix} \begin{pmatrix} 0 \\ 1 \end{pmatrix} = \begin{pmatrix} -\sin \psi \\ \cos \psi \end{pmatrix}$$

The counter-clockwise direction is called the *positive direction*, the other direction is the negative direction.

ROTATION MATRIX

Rotation through a given angle  $\psi$  in the positive direction about the origin is given by the matrix  $R_\psi$ :

$$\mathbf{v} = \begin{pmatrix} x \\ y \end{pmatrix} \mapsto R_\psi \cdot \mathbf{v} = \begin{pmatrix} \cos \psi & -\sin \psi \\ \sin \psi & \cos \psi \end{pmatrix} \cdot \begin{pmatrix} x \\ y \end{pmatrix}.$$

Now, since we now know how the matrix of the rotation in the plane looks like, we can check that rotation preserves distances and angles (defined by the equation (1) in 1.5.7).

Denote the image of a vector  $\mathbf{v}$  as

$$\mathbf{v}' = \begin{pmatrix} x' \\ y' \end{pmatrix} = R_\psi \cdot \mathbf{v} = \begin{pmatrix} x \cos \psi - y \sin \psi \\ x \sin \psi + y \cos \psi \end{pmatrix},$$

and similarly  $\mathbf{w}' = R_\psi \cdot \mathbf{w}$  for  $\mathbf{w} = (r, s)^T$ , and  $\mathbf{w}' = (r', s')^T$ .

A straightforward expansion (exploiting  $(\cos \psi)^2 + (\sin \psi)^2 = 1$ ) checks the expected equalities  $\|\mathbf{v}'\|^2 = \|\mathbf{v}\|^2$ , and that  $x'r' + y's' = xr + ys$ .

The previous expression can be written using vectors and matrices as follows:

$$(R_\psi \cdot \mathbf{w})^T (R_\psi \cdot \mathbf{v}) = \mathbf{w}^T \mathbf{v}.$$

• “Stretching by a parameter  $c$ ”. Let us stretch the plane only in the direction of the first basis vector  $e_1$ . Then, the relevant matrix  $A_c$  is diagonal, obtained by multiplying the first row in the identity matrix by the stretching parameter  $c$ , i.e.,  $A_c = \begin{pmatrix} c & 0 \\ 0 & 1 \end{pmatrix}$ . The figure below shows the stretching of our triangle  $ABC$  in the direction of  $e_1$  with  $c = 3/2$ , hence the particular linear transformation has the form

$$\begin{pmatrix} x \\ y \end{pmatrix} \mapsto \begin{pmatrix} 3/2 & 0 \\ 0 & 1 \end{pmatrix} \begin{pmatrix} x \\ y \end{pmatrix} = \begin{pmatrix} 3x/2 \\ y \end{pmatrix}.$$

Applying the same stretching but in direction of  $e_2$ , will force only the  $y$ -coordinates to be transformed, as we see here:

If we want to employ the same operation with a general fixed point  $P$  belonging in a line  $\ell$ , and along this line, we may again compose three transformations: first shift by  $\tau_{-P}$ , then find the angle  $\theta$  of  $\ell$  with the direction of  $e_1$  and use the  $R_{-\theta}$  matrix, then apply the above stretching and next move the plane back, i.e., apply  $R_\theta$  and  $\tau_P$ .

• “Shears.” The horizontal shear is a linear transformation keeping the  $y$ -coordinate fixed, and the entire “ $x$ -coordinate axes” (this is the line  $y = 0$ ), is fixed, too. In other words a horizontal shear takes the point  $(x, y)$  to the point  $(x + ay, y)$  for some  $a$ . Similarly, vertical shears are the transformations with the properties of the components swapped. Thus, the relevant matrices have the following

The transposed vector  $(R_\psi \cdot \mathbf{w})^T$  equals  $\mathbf{w}^T \cdot R_\psi^T$ , where  $R_\psi^T$  is the so-called transpose of the matrix  $R_\psi$ . That is a matrix, whose rows consist of the columns of the original matrix and similarly the columns consist of the rows of the original matrix. Therefore we see that the rotation matrices satisfy the relation  $R_\psi^T \cdot R_\psi = I$ , where the matrix  $I$  (sometimes we denote this matrix just as 1 and mean by this the unit in the ring of matrices) is the *unit matrix*

$$I = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}.$$

This leads us to a remarkable observation — the matrix  $X$  with the property that  $X \cdot R_\psi = I$  (we will call such a matrix the *inverse matrix to the rotation matrix*  $R_\psi$ ) is the transpose of the original matrix. This makes sense, since the inverse mapping to the rotation through the angle  $\psi$  is again a rotation, but through the angle  $-\psi$ . That is, the inverse matrix of  $R_\psi^T$  equals the matrix

$$R_{-\psi} = \begin{pmatrix} \cos(-\psi) & -\sin(-\psi) \\ \sin(-\psi) & \cos(-\psi) \end{pmatrix} = \begin{pmatrix} \cos \psi & \sin \psi \\ -\sin \psi & \cos \psi \end{pmatrix}.$$

It is easy to write the rotation around a point  $P = O + \mathbf{w}$ ,  $P = [r, s]$  again using matrices. One just has to note that instead of rotating around the given point  $P$ , we can first shift  $P$  into the origin, then do the rotation and then do the inverse shift.

We calculate:

$$\begin{aligned} \mathbf{v} = \begin{pmatrix} x \\ y \end{pmatrix} &\mapsto \mathbf{v} - \mathbf{w} \mapsto R_\psi \cdot (\mathbf{v} - \mathbf{w}) \\ &\mapsto R_\psi \cdot (\mathbf{v} - \mathbf{w}) + \mathbf{w} = \\ &\begin{pmatrix} \cos \psi (x - r) - \sin \psi (y - s) + r \\ \sin \psi (x - r) + \cos \psi (y - s) + s \end{pmatrix}. \end{aligned}$$

**1.5.9. Reflections.** Another well-known example of a length preserving mapping is *reflection through a line*. It is enough to understand reflection through a line that goes through the origin  $O$ . All other reflections can be derived using shifts. Thus, we look first for a matrix  $Z_\psi$  of reflection with respect to the line through the origin and through the point  $(\cos \psi, \sin \psi)$ .

Notice that

$$Z_0 = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}.$$

form:

$$H_a = \begin{pmatrix} 1 & a \\ 0 & 1 \end{pmatrix}, \quad V_a = \begin{pmatrix} 1 & 0 \\ a & 1 \end{pmatrix}.$$

Let us illustrate a shear in the  $x$ -direction for the values  $a = \pm 3$ . We get the transformations

$$\begin{pmatrix} x \\ y \end{pmatrix} \mapsto \begin{pmatrix} 1 & \pm 3 \\ 0 & 1 \end{pmatrix} \begin{pmatrix} x \\ y \end{pmatrix} = \begin{pmatrix} x \pm 3y \\ y \end{pmatrix},$$

so the triangle  $ABC$  is transformed as follows:

Case  $a = 3$ :

Case  $a = -3$ :

- “Reflections.” Finally, let us deal with reflections.

They actually appeared above as stretching along one direction, with the parameter  $c = -1$ . Thus, stretching along the direction of  $e_1$  with  $c = -1$  gives a reflection with respect to the  $y$ -axis, where the matrix representation is  $\begin{pmatrix} -1 & 0 \\ 0 & 1 \end{pmatrix}$ . Repeating, using instead of  $e_1$  the vector  $e_2$ , we get a reflection with respect to the  $x$ -axis, where the matrix presentation is  $\begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}$ . Below we illustrate the reflection of our triangle  $ABC$  with respect to the  $y$ -axis:

For an illustration of a reflection in the plane with respect to  $x$ -axis, see 1.G.51.

On the other hand, the reflection in the plane through the line  $y = x$ , sends the  $x$ -axis into the  $y$ -axis, and vice versa. Hence it is also referred to as the “axial symmetry”. Obviously, its matrix presentation is given by  $\begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}$ , hence for example it transforms the given triangle as follows (see 1.G.52 for another example).

Any line going through the origin can be rotated so that it has the direction  $(1, 0)$  and thus we can write general reflection matrix as

$$Z_\psi = R_\psi \cdot Z_0 \cdot R_{-\psi},$$

where we first rotate via the matrix  $R_{-\psi}$  so that the line is in “zero” position, reflect with the matrix  $Z_0$  and return back with the rotation  $R_\psi$ .

Therefore we can calculate (by associativity of matrix multiplication):

$$\begin{aligned} Z_\psi &= \begin{pmatrix} \cos \psi & -\sin \psi \\ \sin \psi & \cos \psi \end{pmatrix} \cdot \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix} \cdot \begin{pmatrix} \cos \psi & \sin \psi \\ -\sin \psi & \cos \psi \end{pmatrix} \\ &= \begin{pmatrix} \cos \psi & \sin \psi \\ \sin \psi & -\cos \psi \end{pmatrix} \cdot \begin{pmatrix} \cos \psi & \sin \psi \\ -\sin \psi & \cos \psi \end{pmatrix} \\ &= \begin{pmatrix} \cos^2 \psi - \sin^2 \psi & 2 \sin \psi \cos \psi \\ 2 \sin \psi \cos \psi & -(\cos^2 \psi - \sin^2 \psi) \end{pmatrix} \\ &= \begin{pmatrix} \cos 2\psi & \sin 2\psi \\ \sin 2\psi & -\cos 2\psi \end{pmatrix}. \end{aligned}$$

The last equality follows from the usual formulas for trigonometric functions:

$$(1) \quad \begin{aligned} \sin 2\psi &= 2 \sin \psi \cos \psi \\ \cos 2\psi &= \cos^2 \psi - \sin^2 \psi. \end{aligned}$$

Notice that the product  $Z_\psi \cdot Z_0$  gives:

$$\begin{pmatrix} \cos 2\psi & \sin 2\psi \\ \sin 2\psi & -\cos 2\psi \end{pmatrix} \cdot \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix} = \begin{pmatrix} \cos 2\psi & -\sin 2\psi \\ \sin 2\psi & \cos 2\psi \end{pmatrix}.$$

This observation can be formulated as follows:

**Proposition.** A rotation through the angle  $\psi$  can be obtained by two subsequent reflections through the lines that have the angle  $\frac{1}{2}\psi$  between them.  $\square$

**1.E.18.** Show that every rotation can be obtained as a composition of three shears.<sup>11</sup>

**Solution.** This is a little more demanding exercise.

But we may experiment with the abilities of Sage and this makes our life really easy. We would add the lines in the following session following partial results. Composing horizontal shears gives again a horizontal shear (and similarly for the vertical ones):

$$\begin{pmatrix} 1 & a \\ 0 & 1 \end{pmatrix} \begin{pmatrix} 1 & b \\ 0 & 1 \end{pmatrix} = \begin{pmatrix} 1 & a+b \\ 0 & 1 \end{pmatrix}.$$

Thus we try to combine horizontal and vertical ones to get a rotation by an angle  $\theta$ .

```
# introduce three shear matrices with
# variable parameters a,b,c
a,b,c=var("a,b,c")
A = matrix([[1,a],[0,1]]); B = matrix(
[[1,0],[b,1]]); C=matrix([[1,c],[0,1]])
# take the general transformation X
# obtained by composition
X = C*B*A; print(X)
# notice that one of the conditions on X
# to be a rotation indicates a=c
X = X.substitute(c=a)
eq1 = X[0,0]^2+X[1,0]^2-1;
eq2 = X[1,0]+X[0,1];
# eq3 = X[0,0]-X[1,1] == 0 is already
# fulfilled; solve the system
sol = solve([eq1,eq2],[a,b]); print(sol)
```

The final line returns the two solutions:

$$a = (\sqrt{-r_1^2 + 1} - 1)/r_1, \quad b = r_1,$$

or

$$a = -(\sqrt{-r_2^2 + 1} + 1)/r_2, \quad b = r_2.$$

This means that  $b$  is a free parameter and from the printed form of  $X$ , we learn that  $b$  plays the role of  $\sin \theta$ . The graphical illustration of this compositions is given in ??.

**1.E.19. Change of coordinates.** Look at picture in 1.5.6 and assume that, in the standard coordinates,  $O' = [1, 5]$ ,  $P = O' + e'_1 = [2, 3]$ ,  $Q = O' + e'_2 = [2, 7]$  and these define the “girl’s” coordinate system. Consider the two options that the meeting point  $M = [2, 1]$  is given (a) by the boy, or (b) by the girl, in their own coordinate system. What does it mean for the other one? Find the answer first for the situation where at least the origins of the coordinate systems coincide!

**Solution.** If the boy and girl have got at least the same origin of coordinate systems, then the transformation of coordinates is simple. The girl’s basis is already expressed in the standard coordinates (the boy’s ones). Thus the matrix  $T$  with columns

<sup>11</sup>This is actually of high interest for pixel based computer graphics: A horizontal or vertical shear is a very quick operation consisting of constant shifting of individual rows or columns of pixels, while implementing a rotation directly is much more time consuming! It seems that the first algorithm based on this was introduced by Alan Paeth in 1986.

In fact we can prove the previous proposition purely by geometrical argumentation, as shown in the above picture (try to be a “synthetic geometer” when reflecting  $A$  to  $A'$  and then  $A'$  to  $A''$ ). If we believe in this proof “by picture”, then the above computational derivation of the proposition provides the proof of the standard double angle formulas (1).

**1.5.10.** The following is a recapitulation of previous ideas.

MAPPINGS THAT PRESERVE LENGTH

**Theorem.** A linear mapping of the Euclidean plane is composed of one or more reflections if and only if it is given by a matrix  $R$  which satisfies

$$R = \begin{pmatrix} a & b \\ c & d \end{pmatrix}, \quad ab + cd = 0, \quad a^2 + c^2 = b^2 + d^2 = 1.$$

This happens if and only if the mapping preserves length. Rotation is such a mapping if and only if the determinant of the matrix  $R$  equals one, which corresponds to an even number of reflections. When there is an odd number of reflections, the determinant equals  $-1$ .

**PROOF.** We calculate how a general matrix  $A$  might look, when the corresponding mapping preserves length. That is, we have a mapping

$$\begin{pmatrix} x \\ y \end{pmatrix} \mapsto \begin{pmatrix} a & b \\ c & d \end{pmatrix} \cdot \begin{pmatrix} x \\ y \end{pmatrix} = \begin{pmatrix} ax + by \\ cx + dy \end{pmatrix}.$$

Preserving length thus means that for every  $x$  and  $y$ , we have

$$\begin{aligned} x^2 + y^2 &= (ax + by)^2 + (cx + dy)^2 \\ &= (a^2 + c^2)x^2 + (b^2 + d^2)y^2 + 2(ab + cd)xy. \end{aligned}$$

Since this equation is to hold for every  $x$  and  $y$ , the coefficients of the individual powers  $x^2$ ,  $y^2$  and  $xy$  on the left and right side of the equation must be equal. Thus we have calculated that the conditions put on the matrix  $R$  in the first part

$e'_1$  and  $e'_2$  yields the linear mapping providing the boy's coordinate expression of the girl's vectors. In order to go in the opposite direction, we just take the inverse matrix  $T^{-1}$ . Thus,

$$T = \begin{pmatrix} 1 & 1 \\ 2 & -2 \end{pmatrix}, \quad \text{and} \quad T^{-1} = \begin{pmatrix} 1/2 & -1/4 \\ 1/2 & 1/4 \end{pmatrix},$$

and the boy knows that the girl means him to be at  $[3, -2]$ , while the girl knows that boy's  $[2, 1]$  would be  $[3/4, 5/4]$ .

In the general case, we must consider the shifts of the origin, evaluated in the right coordinates. We shall again use Sage to compute:

```
# go to the new affine coordinates
O=vector([0,0]);e1=vector([1,0]);
e2=vector([0,1]);
OO=vector([1,5]);ee1=vector([2,3])-OO;
ee2 = vector([2,7])-OO;
# define the relevant transformations
T=matrix([ee1,ee2]); T=T.transpose();
print(T); print(T.inverse())
def change_girl_to_boy(coordinates):
    position = vector(coordinates)
    return T*position + OO
def change_boy_to_girl(coordinates):
# [0,0] = a[1,-2]+b[1,2]+[1,5] =>
# a-b=5/2, a+b=-1 => a=3/4, b=-7/4
    position = vector(coordinates)
    return T.inverse()*position
    + vector([3/4,-7/4])
print(change_girl_to_boy(vector([2,1])))
print(change_boy_to_girl(vector([2,1])))
# tests
OO+2*ee1+1*ee2 == O+4*e1+3*e2 and
O+2*e1+1*e2 == OO+3/2*ee1-1/2*ee2
```

The linear parts of the transformations are still  $T$  and  $T^{-1}$ , the right shifts are added. The last two prints give the answer: the girl's meeting point  $[2, 1]$  means the boy should go to position  $[4, 3]$ , while if it is the boy who tells his meeting point, then the girl should look for him at  $[3/2, -1/2]$  in her coordinates. The final line confirms this by returning "True".  $\square$

*Let us now move to Euclidean tasks. In addition, there is the concept of the norm (size) of a vector, allowing us to measure distances between points. We have already seen this in case of complex numbers, viewing  $\mathbb{C}$  as the real plane with standard coordinates. As we will see below, we are then also able to measure angles between vectors and areas of polygonal objects.*

- 1.E.20.** (a) Find the norms, the scalar product and the angle of the vectors  $u = (-3, -2)$  and  $v = (-2, 3)$ .  
 (b) Prove that the triangle with vertices  $P = [2, 2], Q = [3, 0], R = [4, 3]$  is isosceles.

**Solution.** (a) We shall work with the standard Euclidean norm on  $\mathbb{R}^2$  (which we may identify with  $\mathbb{C}$ ), as we did in 1.A.8. The norm of a vector  $w = (x, y)$  is given by

of the theorem we are proving are equivalent to the property that the given mapping preserves length.

Because  $a^2 + c^2 = 1$ , we can assume that  $a = \cos \varphi$  and  $c = \sin \varphi$  for a suitable angle  $\varphi$ . As soon as we choose the first column of the matrix  $R$ , the relation  $ab + cd = 0$  determines the second column up to a multiple. But we also know that the length of the vector in the second column is one, and thus we have only two possibilities for the matrix  $R$ , namely:

$$\begin{pmatrix} \cos \varphi & -\sin \varphi \\ \sin \varphi & \cos \varphi \end{pmatrix}, \quad \begin{pmatrix} \cos \varphi & \sin \varphi \\ \sin \varphi & -\cos \varphi \end{pmatrix}.$$

In the first case, we have a rotation through the angle  $\varphi$ , in the second case we have a rotation composed with the reflection through the first coordinate axis. As we have seen in the previous proposition 1.5.8, every rotation corresponds to two reflections. The determinant of the matrix  $R$  is in these two cases either one or minus one and distinguishes between these two cases by the parity of the number of reflections.  $\square$

Notice, we have now proved our earlier claim on the invariance of formulae for distance and angle in any orthonormal coordinates. Moreover, we have seen that all euclidean affine mappings are generated by translations, and reflections.

**1.5.11. Area of a triangle.** At the end of our little trip to

geometry we will focus on the *area* of planar objects. For us, triangles will be sufficient. Every triangle is determined by a pair of vectors  $\mathbf{v}$  and  $\mathbf{w}$ , which, if translated so that they start from one vertex  $P$  of the triangle, determine the remaining two vertices. We would like to find a formula (scalar function area), which assigns the number  $\text{area } \Delta(\mathbf{v}, \mathbf{w})$  equal to the area of the triangle  $\Delta(\mathbf{v}, \mathbf{w})$  defined in the aforementioned way. By translating, we can place  $P$  at the origin since translation should not change the area.

*area of  $\Delta = 1/2$  area of  $\square$*

We can see from the picture that the desired value is half of the area of the parallelogram spanned by the vectors  $\mathbf{v}$  and  $\mathbf{w}$ . It is easy to calculate (using the well-known formula: base times corresponding height), or simply observe from the picture that the following holds

$$\begin{aligned} \text{area } \Delta(\mathbf{v} + \mathbf{v}', \mathbf{w}) &= \text{area } \Delta(\mathbf{v}, \mathbf{w}) + \text{area } \Delta(\mathbf{v}', \mathbf{w}) \\ \text{area } \Delta(a\mathbf{v}, \mathbf{w}) &= a \text{ area } \Delta(\mathbf{v}, \mathbf{w}). \end{aligned}$$

$\|w\| = \sqrt{x^2 + y^2}$ . Thus  $\|u\| = \sqrt{9+4} = \sqrt{13} = \|v\|$ . Their scalar product (dot product) is given by  $u \cdot v \equiv \langle u, v \rangle = (-3)(-2) + (-2)3 = 0$ , and hence  $u, v$  are orthogonal each other, i.e., their angle is  $\varphi = \pi/2$ . In Sage, we have got the method which is applied to the first vector and gets the second one as argument: `u.dot_product(v)`, see the cell

```
u = vector([-3, 2]); v = vector([-2, 3])
u.dot_product(v)
```

which returns 0. As for the norms of the vectors  $u, v$ , type

```
u.norm(); v.norm()
```

and for both cases this returns  $\sqrt{13}$ .

(b) In this case we compute

$$\begin{aligned} |\overrightarrow{PQ}| &= \|P - Q\| = \sqrt{(2-3)^2 + (2-0)^2} = \sqrt{5}, \\ |\overrightarrow{QR}| &= \|Q - R\| = \sqrt{(3-4)^2 + (0-3)^2} = \sqrt{10}, \\ |\overrightarrow{PR}| &= \|P - R\| = \sqrt{(2-4)^2 + (2-3)^2} = \sqrt{5}. \end{aligned}$$

Thus  $|\overrightarrow{PQ}| = |\overrightarrow{PR}|$  and the triangle is isosceles. □

**1.E.21.** Given the line  $\ell : 7y = 6x + 13$ , determine the line  $\ell'$  which is perpendicular to  $\ell$  and passes through the point  $P = [-6, 7] \in \mathbb{R}^2$ . Find at least two methods.

**Solution.** (1) Given a line  $\ell$  in parametric form  $P_0 + tu = [x_0, y_0] + t(x_1, y_1)$  ( $t \in \mathbb{R}$ ), it is easy to determine a line  $\ell'$  perpendicular to  $\ell$ , which goes through another point  $Q = [a, b]$ , as follows. The direction vector of  $\ell'$  must be orthogonal with the direction vector of  $\ell$ . So, if we assume that  $Q + tv$  is the parametric form of  $\ell'$ , then we should have  $u \cdot v = 0$ , where  $\cdot$  is the usual dot product on  $\mathbb{R}^2$ . Taking  $v = (-y_1, x_1)$  we see that  $(x_1, y_1) \cdot (-y_1, x_1) = 0$ , that is,  $u \perp v$ . Thus the parametric equation of  $\ell'$  is simply  $Q + tv = [a, b] + t(-y_1, x_1)$ , with  $t \in \mathbb{R}$ . To apply this in our case we need to express the initial line  $\ell$  in parametric form. The points  $[-1, 1]$  and  $[0, 13/7]$  belong to the line  $\ell$ , so the parametric form of  $\ell$  is (cf. 1.E.8)

$$[-1, 1] + t(0 - (-1), \frac{13}{7} - 1) = [-1, 1] + t(1, \frac{6}{7}).$$

As a result, the direction vector of  $\ell'$  is  $(-\frac{6}{7}, 1)$ , such that  $(1, \frac{6}{7}) \cdot (-\frac{6}{7}, 1) = 0$ , and  $\ell'$  reads by  $[-6, 7] + t(-\frac{6}{7}, 1)$ , or in other words  $x = -6 - \frac{6}{7}t$  and  $y = 7 + t$ , with  $t \in \mathbb{R}$ . For a verification we can transfer the given parametric form of  $\ell'$  to implicit form. Eliminating  $t$  from these equations gives  $x = -6 - \frac{6}{7}(y - 7)$ , which is equivalent to  $y = -\frac{7}{6}x$ .

(2) Actually, writing the equation for  $\ell$  as  $6x - 7y - 13 = 0$ , it is obvious that the coefficients  $(6, -7)$  provide just a vector perpendicular to  $\ell$ . Thus we may write the implicit equation for  $\ell'$  immediately.

(3) We may also work with the slopes. Writing  $\ell$  as  $y = \frac{6}{7}x + \frac{13}{7}$ , we get its slope  $m = 6/7$ . The line  $\ell'$ , perpendicular to the line  $\ell$  must have the slope  $m' = -\frac{7}{6}$ , such that  $mm' = -1$ .

LINEARITY IN ARGUMENT

Finally we add to the formulation of our problem a condition

$$\text{area } \Delta(\mathbf{v}, \mathbf{w}) = -\text{area } \Delta(\mathbf{w}, \mathbf{v}),$$

which corresponds to the idea that we give a sign to the area, according to the order in which we are taking the vectors.

If we write the vectors  $\mathbf{v}$  and  $\mathbf{w}$  into the columns of a matrix  $A$ , then the mapping

$$A = (\mathbf{v}, \mathbf{w}) \mapsto \det A$$

satisfies all the three conditions we wanted. How many such mappings could there possibly be? Every vector can be expressed using two basis vectors  $\mathbf{e}_1 = (1, 0)$  and  $\mathbf{e}_2 = (0, 1)$ . By linearity, area  $\Delta$  is uniquely determined by these vectors. We want

$$\text{area } \Delta(\mathbf{e}_1, \mathbf{e}_2) = \frac{1}{2}.$$

In other words, we have chosen the *orientation* and the *scale* through the choice of basis vectors, and we choose the unit square to have area equal to one.

Thus we see that the determinant gives the area of a parallelogram determined by the columns of the matrix  $A$ . The area of the triangle is thus one half of the parallelogram.

**1.5.12. Visibility in the plane.** The previous description of the value for oriented area gives us an elegant tool for determining the position of a point relative to oriented line segments. By an oriented line segment we mean two points in the plane  $\mathbb{R}^2$  with a selected order. We can imagine it as an arrow from one point to the other. Such an oriented line segment divides the plane into two half-planes. Let us call them “left” and “right”. We want to be able to determine whether a given point is in the left or right half-plane.

Such tasks are often met in computer graphics when dealing with visibility of objects. We can imagine that an oriented line segment can be “seen” from the points to the right of it and cannot be seen from the points to left of it.

Thus,  $\ell'$  is of the form  $y = -\frac{7}{6}x + b$ , and substituting the coordinates of  $P$  implies  $b = 0$ , i.e.,  $y = -\frac{7}{6}x$ .  $\square$

**1.E.22.** Verify that each affine mapping always maps parallel lines to parallel lines, but the angles and distances are changed in general.  $\circ$

**1.E.23. Remark on plots.** Sage, as well as other software, provides extensive 2D plotting functionality. However, even for drawing simple lines in the plane, we should notice several details.

First, let us look at the so called “aspect ratio” of the figures, which is governed by the option `aspect_ratio` in Sage. The aspect ratio reflects the apparent height/width ratio of a unit square. In Sage one can explicitly ask for an “automatic setup” by typing `aspect_ratio = "automatic"`. However, this does not produce always what we normally expect. Instead, the option `aspect_ratio = 1` works much better applying the same scale on both coordinates. This seems to be relevant if illustrating Euclidean properties, where we want to see the real angles and lengths, while in the affine setup we may more appreciate to choose the scales independently.

We may also adjust the size of a figure via the option `figsize`. The default `figsize` is 4, while setting `figsize = 8` makes a figure roughly twice as big. We can also request separate horizontal and vertical sizes, by typing for example `figsize = [4, 8]` (both will be measured in inches). Usually, small `figsize` values work well.

**1.E.24.** To illustrate the above situation, provide the plots of the lines appearing in Problem 1.E.21.  $\circ$

*In the next series of exercises we shall focus on applications of the linear and affine mappings. In applications, they appear either directly, or as “linear approximations”.<sup>12</sup> We already saw the simple building blocks of most of them in 1.E.17, see also the other column starting in 1.5.8.*

*We shall also include the concept of area and its link to the properties of the determinant function on matrices. We refer to the paragraphs 1.5.5 and 1.5.11 for details.*

**1.E.25.** Compute the area of the triangle  $PQR$ , if  $P = [-8, 1]$ ,  $Q = [-2, 0]$  and  $R = [5, 9]$ . What would we have to do, if the points were given in a coordinate system different to the standard Euclidean one?  $\circ$

**1.E.26.** Consider the quadrilateral  $S$  given by its vertices  $A = [1, 1]$ ,  $B = [6, 1]$ ,  $C = [11, 4]$ , and  $D = [2, 4]$ . Illustrate  $S$  via Sage and deduce that  $S$  is a trapezoid whose bases are of lengths 5 and 9, respectively, and whose height equals to 3. Next compute its area in at least two ways.  $\circ$

<sup>12</sup>While the linear approximations are the core of building models in Science and Engineering (we shall start developing the relevant methods in Chapter 5), in arts, the linearity concept is essential in finding the right proportions, helping to create structure, balance, and rhythm in compositions, guiding the viewer’s eye and effecting emotions.

We have the oriented line segment  $AB$  and are given some point  $C$ . We calculate the oriented area of the corresponding triangle determined by the vectors  $A-C$  and  $B-C$ . If the point  $C$  is to the left of the line segment, then with the usual positive orientation (counter-clockwise) we obtain the positive sign of the oriented area, while the negative sign corresponds to the points to the right.

This approach is often used for testing relative positions in 2D graphics.

## 6. Relations and mappings

In the final part of this introductory chapter, we return to the formal description of mathematical structures. We will try to illustrate them on examples we already know. We can consider this part to be an exercise in a formal approach to the objects and concepts of mathematics, i.e. the “language of mathematics”.

**1.6.1. Relations between sets.** First we define the *Cartesian product*  $A \times B$  of two sets  $A$  and  $B$ . It is the set of all ordered pairs  $(a, b)$  such that  $a \in A$  and  $b \in B$ . A *binary relation* between the two sets  $A$  and  $B$  is then a subset  $R$  of the Cartesian product  $A \times B$ .

We write  $a \simeq_R b$  to mean  $(a, b) \in R$ , and say that  $a$  is related to  $b$ . The *domain of the relation* is the subset

$$D = \{a \in A : \exists b \in B, (a, b) \in R\}.$$

Here the symbol  $\exists b$  means that there is at least one such  $b$  satisfying the rest of the claim.

Similarly, the *codomain of the relation* is the subset

$$I = \{b \in B : \exists a \in A, (a, b) \in R\}.$$

A special case of a relation between sets is a *mapping from the set  $A$  to the set  $B$* . This is the case when every element of the domain of the relation is related to exactly one element of the codomain. Examples of mappings known to us are all functions, where the codomain of the mapping is a set of numbers, for instance the set of integers or the set of real numbers, or the linear mappings in the plane given by matrices. We write

$$f : D \subseteq A \rightarrow I \subseteq B, \\ f(a) = b$$

to express the fact that  $(a, b)$  belongs to a relation, and we say that  $b$  is the value of  $f$  at  $a$ . Furthermore we say that

- mapping  $f$  of the set  $A$  to the set  $B$  is *surjective* (or *onto*), if  $D = A$  and  $I = B$ , clarify ?
- mapping  $f$  of the set  $A$  to the set  $B$  is *injective* (or *one-to-one*), if  $D = A$  and for every  $b \in I$  there exist exactly one *preimage*  $a \in A$ ,  $f(a) = b$ .

Expressing a mapping  $f : A \rightarrow B$  as a relation

$$f \subseteq A \times B, \quad f = \{(a, f(a)); a \in A\}$$

is also known as *the graph of a mapping  $f$* .

**1.E.27.** (a) An equilateral triangle with vertices  $[1, 0]$  and  $[0, 1]$  lies entirely in the first quadrant. Find the coordinates of its third vertex with the help of Sage.

(b) An equilateral triangle has vertices at  $P = [1, 1]$  and  $Q = [2, 3]$ . Its other vertex lies in the same half-plane as the point  $S = [0, 0]$ . The triangle is rotated by  $60^\circ$  in the positive direction around the point  $S$ , to produce a new triangle. Determine the coordinates of the vertices of the new triangle.

**Solution.** (a) Let us denote by  $A = [1, 0]$  and  $B = [0, 1]$  the given points. To find the coordinates  $[x, y]$  of the third vertex we are rotating the point  $A$  around the point  $B$  by an angle of  $60^\circ = \pi/3$  in the positive direction (counter clockwise direction). Thus, in Sage we can find the third vertex by typing

```
a=pi/3
M=matrix([[cos(a), -sin(a)], [sin(a), cos(a)]])
A=vector([1, 0]); B=vector([0, 1])
rot=M*(A-B)+B;
print(rot)
```

Hence we have

$$[x, y] = \begin{pmatrix} \cos(\pi/3) & -\sin(\pi/3) \\ \sin(\pi/3) & \cos(\pi/3) \end{pmatrix} (A - B) + B,$$

which gives  $[x, y] = [\frac{1}{2} + \frac{\sqrt{3}}{2}, \frac{1}{2} + \frac{\sqrt{3}}{2}]$ .

(b) Using the general rotation transformation as found in Sage above, we obtain easily the wanted points (check yourselves):

$$[-\frac{3}{2}\sqrt{3}, \sqrt{3} - \frac{1}{2}], [\frac{1}{2} - \frac{1}{2}\sqrt{3}, \frac{1}{2}\sqrt{3} + \frac{1}{2}], [1 - \frac{3}{2}\sqrt{3}, \sqrt{3} + \frac{3}{2}].$$

□

**1.E.28.** Consider a regular hexagon with vertices labeled in the positive direction, with first vertex  $A = [0, 2]$  and centre at the point  $S = [1, 0]$ . Determine the coordinates of the third vertex  $C$ . ○

**1.E.29.** Which sides of the quadrangle given by the vertices  $[-2, -2]$ ,  $[1, 4]$ ,  $[3, 3]$  and  $[2, 1]$  are “visible” from the position of the point  $X = [3, \pi - 2]$ ?

**Solution.** In the first step we order the vertices such that their order corresponds the counter-clockwise direction. We choose vertex  $A = [-2, -2]$ , the order of the remaining vertices is then  $B = [2, 1]$ ,  $C = [3, 3]$ ,  $D = [1, 4]$  (think, how to order the points without a picture; you can actually use similar procedure to what follows). First consider the side  $AB$ . It along with the point  $X = [3, \pi - 2]$  determines the matrix

$$\begin{pmatrix} -2 - 3 & 2 - 3 \\ -2 - (\pi - 2) & 1 - (\pi - 2) \end{pmatrix}$$

such that its first column is the difference  $A - X$  and the second column is  $B - X$ . Whether it can be “seen” from the point  $[3, \pi - 2]$  (i.e., is left or right of the vector  $\overrightarrow{AB}$ , see 1.5.12), is then determined by the sign of the determinant

$$\begin{vmatrix} -2 - 3 & 2 - 3 \\ -2 - (\pi - 2) & 1 - (\pi - 2) \end{vmatrix} = \begin{vmatrix} -5 & -1 \\ -\pi & 3 - \pi \end{vmatrix} < 0.$$

**1.6.2. Composition of relations and mappings.** For mappings, the concept of composition is clear. Suppose we have two mappings  $f : A \rightarrow B$  and  $g : B \rightarrow C$ . Then their composition  $g \circ f : A \rightarrow C$  is defined as

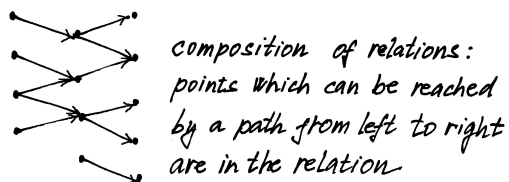

$$(g \circ f)(a) = g(f(a)).$$

Composition can also be expressed with the notation used for a relation as

$$\begin{aligned} f &\subseteq A \times B, & f &= \{(a, f(a)); a \in A\} \\ g &\subseteq B \times C, & g &= \{(b, g(b)); b \in B\} \\ g \circ f &\subseteq A \times C, & g \circ f &= \{(a, g(f(a))); a \in A\}. \end{aligned}$$

The composition of a relation is defined in a very similar way. We just add existential quantifiers to the statements, since we have to consider all possible “preimages” and all possible “images”. Let  $R \subseteq A \times B$ ,  $S \subseteq B \times C$  be relations. Then  $S \circ R \subseteq A \times C$ ,

$$S \circ R = \{(a, c); \exists b \in B, (a, b) \in R, (b, c) \in S\}.$$

A special case of a relation is the identity relation

$$\text{id}_A = \{(a, a) \in A \times A; a \in A\}$$

on the set  $A$ . It is a neutral element with respect to composition with any relation that has  $A$  as its codomain or domain.

For every relation  $R \subseteq A \times B$ , we define the inverse relation

$$R^{-1} = \{(b, a); (a, b) \in R\} \subseteq B \times A.$$

Beware, the same term is used with mappings in a more specific situation. Of course, for every mapping there is its inverse relation, but this relation is in general not a mapping. Therefore we speak about the existence of an inverse mapping if every element  $b \in B$  is an image of exactly one element in  $A$ . In such a case the inverse mapping is exactly the inverse relation.

Note that the composition of a mapping and its inverse mapping (if it exists) is the identity mapping. In general, this is not so for relations.

For the sides  $BC$ ,  $CD$  and  $DA$  we analogically obtain

$$\begin{aligned} \begin{vmatrix} 2-3 & 3-3 \\ 1-(\pi-2) & 3-(\pi-2) \end{vmatrix} &< 0, \\ \begin{vmatrix} 3-3 & 1-3 \\ 3-(\pi-2) & 4-(\pi-2) \end{vmatrix} &> 0, \\ \begin{vmatrix} 1-3 & -2-3 \\ 4-(\pi-2) & -2-(\pi-2) \end{vmatrix} &> 0. \end{aligned}$$

The determinants differ in signs, thus the point  $X$  is outside the given quadrangle and a side is visible from  $X$ , if  $X$  is left of the side. According to our convention of putting vectors  $\overrightarrow{XA}$ ,  $\overrightarrow{XB}$ ,  $\overrightarrow{XC}$ ,  $\overrightarrow{XD}$  into the determinants, the side is visible, if the corresponding determinant is negative (i.e.,  $X$  is right of the oriented side). Thus, from the point  $X$  are visible exactly the sides determined by the pairs of vertices  $A = [-2, -2]$ ,  $B = [2, 1]$  and  $B = [2, 1]$ ,  $C = [3, 3]$ .  $\square$

**1.E.30.** Given the sides of the pentagon with vertices at points  $[-2, -2]$ ,  $[-2, 2]$ ,  $[1, 4]$ ,  $[3, 1]$  and  $[2, -11/6]$ , which are visible from the point  $[300, 1]$ .  $\circ$

**1.E.31.** Let the triangle with the vertices  $P = [5, 6]$ ,  $Q = [7, 8]$ , and  $R = [5, 8]$ . Determine, which of its sides are visible from the point  $X = [0, 1]$ .  $\circ$

**F. Relations and mappings**

*We close this chapter by considering briefly some aspects of the language of mathematics. Thus, instead of the usual intuitive introduction we request the reader to have a quick look at the formal approach to the relevant concepts, beginning in 1.6.1. Note that digesting the abstract concepts of equivalence and ordering (see 1.6.3) is one of the crucial steps towards mathematical thinking.*

**1.F.1.** Determine whether the following relations on the given set  $M$  are equivalence relations:

- i)  $M = \{f : \mathbb{R} \rightarrow \mathbb{R}\}$ , where  $f \sim g$  if  $f(0) = g(0)$ .
- ii)  $M = \{f : \mathbb{R} \rightarrow \mathbb{R}\}$ , where  $f \sim g$  if  $f(0) = g(1)$ .
- iii)  $M$  is the set of lines in the plane, where two lines are related if they do not intersect.
- iv)  $M$  is the set of lines in the plane, where two lines are related if they are parallel.
- v)  $M = \mathbb{N}$ , where  $m \sim n$  if  $S(m) + S(n) = 20$ , while  $S(n)$  stands for the sum of the digits of the integer  $n$ .
- vi)  $M = \mathbb{N}$ , where  $m \sim n$  if  $C(m) = C(n)$ , where  $C(n) = S(n)$  if the sum of the digits  $S(n)$  is less than 10, otherwise we define  $C(n) = C(S(n))$  (thus we always have  $C(n) < 10$ ).

**Solution.** For each case we must check the three defining properties of equivalence relations.

- i) a) Reflexivity: for any real function  $f$ ,  $f(0) = f(0)$ .
- b) Symmetry: if  $f(0) = g(0)$ , then also  $g(0) = f(0)$ .

**1.6.3. Relation on a set.** In the case when  $A = B$  we speak about a relation on the set  $A$ . We say that the relation  $R$  is:

- reflexive, if  $\text{id}_A \subseteq R$ , that is  $(a, a) \in R$  for every  $a \in A$ ,
- symmetric, if  $R^{-1} = R$ , that is if  $(a, b) \in R$ , then also  $(b, a) \in R$ ,
- antisymmetric, if  $R^{-1} \cap R \subseteq \text{id}_A$ , that is if  $(a, b) \in R$  and if also  $(b, a) \in R$ , then  $a = b$ ,
- transitive, if  $R \circ R \subseteq R$ , that is if  $(a, b) \in R$  and  $(b, c) \in R$  implies  $(a, c) \in R$ .

A relation is called an *equivalence relation* if it is reflexive, symmetric and transitive.

A relation is called an *ordering* if it is reflexive, transitive and antisymmetric. Orderings are usually denoted by the symbol  $\leq$ , that is the fact that element  $a$  is in relation with element  $b$  is written as  $a \leq b$ .

Notice that the relation  $<$ , that is “to be strictly smaller than”, is not an ordering on the set of real numbers, since it is not reflexive. The common practice (also used in this book) is to use the sign  $<$  or  $\subset$  for orderings, too.

A good example of an ordering is set inclusion. Consider the set  $2^A$  of all subsets of a finite set  $A$ . We have a relation  $\subseteq$  on the set  $2^A$  given by the property “being a subset”. Thus  $X \subseteq Z$  if  $X$  is a subset of  $Z$ . Clearly all three conditions from the definition of ordering are satisfied: if  $X \subseteq Y$  and  $Y \subseteq X$  then necessarily  $X$  and  $Y$  must be identical. If  $X \subseteq Y \subseteq Z$  then also  $X \subseteq Z$ , and reflexivity is clear from the definition. (As mentioned above, we shall mostly use the symbol  $\subset$  without excluding equality.)

We say that an ordering  $\leq$  on a set  $A$  is *complete*, if every two elements  $a, b \in A$  are *comparable*, that is, either  $a \leq b$  or  $b \leq a$ .

If  $A$  contains more than one element, there exist subsets  $X$  and  $Y$  where neither  $X \subseteq Y$  nor  $Y \subseteq X$ , so the ordering  $\subseteq$  is not complete on the set of all subsets of  $A$ .

The set of real numbers with the usual  $\leq$  is complete. Thus the subdomains  $\mathbb{N}$ ,  $\mathbb{Z}$ ,  $\mathbb{Q}$  come equipped with a complete ordering, too. On the other hand, there is no such natural complete ordering on  $\mathbb{C}$ . The absolute value provides a partial ordering there (comparing the radii of the circles in the complex plane).

**1.6.4. Partitions of an equivalence.** Every equivalence relation  $R$  on a set  $A$  defines also a *partition* of the set  $A$ , consisting of subsets of mutually equivalent elements, namely *equivalence classes*. For any  $a \in A$  we consider the set of elements, which are equivalent with  $a$ , that is

$$[a] = R_a = \{b \in A; (a, b) \in R\}.$$

Clearly  $a \in R_a$  by reflexivity. If  $(a, b) \in R$ , then  $R_a = R_b$  by symmetry and transitivity. Furthermore, if  $R_a \cap R_b \neq \emptyset$  then there is an element  $c$  in both  $R_a$  and  $R_b$  so that  $R_a = R_c = R_b$ . It follows that for every pair  $a, b$ , either  $R_a = R_b$ , or  $R_a$  and  $R_b$  are disjoint. That is, the equivalence classes are pairwise disjoint. Finally,  $A = \cup_{a \in A} R_a$ . That is, the set  $A$  is partitioned into equivalence classes. We write  $[a] = R_a$ ,

- c) Transitivity: if  $f(0) = g(0)$  and  $g(0) = h(0)$ , then also  $f(0) = h(0)$ . We conclude that the relation is an equivalence relation.
- ii) The relation is not reflexive, since for instance for the function  $f(x) = \sin(x)$  we have  $\sin(0) \neq \sin(1)$ . Moreover, it is not transitive.
- iii) The relation is neither reflexive (every line intersects itself), nor transitive.
- iv) This is an equivalence relation whose equivalence classes are well represented by the un-oriented lines through the origin.
- v) The relation clearly is not reflexive. Neither it is transitive.
- vi) In this case the answer is positive and we leave the verification of the details to the reader. □

**1.F.2.** Consider the set  $A = \{1, 2, 3, 4\}$  and let  $R$  be the relation over  $A$  defined by

$$R = \{(0, 0), (0, 1), (0, 3), (1, 0), (1, 1), (2, 3), (3, 3)\}$$

Show that  $R$  is *not* an equivalence relation by explaining which of the defining properties of an equivalence relation are not satisfied.

**Solution.** It is easy to see that  $R$  is not reflexive, since  $2 \in A$  but  $(2, 2) \notin R$ . It is not symmetric since for example  $(3, 2) \notin R$ . Finally it is not transitive since  $(1, 0)$  and  $(0, 3)$  they both belong to  $R$  but  $(1, 3) \notin R$ . □

**1.F.3.** Over the set  $A = \{a, b, c, d\}$  consider the relation  $R_1 = \{(a, a), (b, b), (c, c), (d, d), (b, a), (b, c), (b, d)\}$ . Is  $R_1$  an equivalence relation?

**Solution.** Since  $(k, k) \in R_1$  for any  $k \in A$ , the relation is reflexive. It is also transitive. However, it is not symmetric since for example  $(b, a) \in R_1$  but  $(a, b) \notin R_1$ . Hence  $R_1$  is not an equivalence relation. □

**1.F.4.** Verify the result of the previous task in Sage. ○

**1.F.5.** Let the relation  $R$  be defined over  $\mathbb{R}^2$  such that  $((a, b), (c, d)) \in R$  for arbitrary  $a, b, c, d \in \mathbb{R}$  if and only if  $b = d$ . Determine whether or not this is an equivalence relation. In the positive case, describe geometrically the partitioning determined by  $R$ . ○

**1.F.6.** Present the domain  $D$  and the codomain  $I$  of the relation  $R = \{(a, v), (b, x), (c, x), (c, u), (d, v), (f, y)\}$  defined between the sets  $A = \{a, b, c, d, e, f\}$  and  $B = \{x, y, u, v, w\}$ . Is the relation  $R$  a mapping? Next attempt to solve the problem using Sage. ○

**1.F.7.** Determine for each of the following relations over the set  $\{a, b, c, d\}$  whether it is an ordering and whether it is complete:

$$R_1 = \{(a, a), (b, b), (c, c), (d, d), (b, a), (b, c), (b, d)\},$$

$$R_2 = \{(a, a), (b, b), (c, c), (d, d), (d, a), (a, d)\},$$

$$R_3 = \{(a, a), (b, b), (c, c), (d, d), (a, b), (b, c), (b, d)\}.$$

and by the above, we can represent an equivalence class by any one of its elements.

**1.6.5. Existence of scalars.** As before, we assume to know what sets are, and indicate the construction of the natural numbers.

We denote the empty set by  $\emptyset$  (notice the difference between the symbol 0 for the zero and the empty set  $\emptyset$ ) and define

$$(1) \quad 0 := \emptyset, \quad n + 1 := n \cup \{n\},$$

in other words

$$0 := \emptyset, \quad 1 := \{0\}, \quad 2 := \{0, 1\}, \dots, \quad n + 1 := \{0, 1, \dots, n\}.$$

This notation says that if we have already defined the numbers  $0, 1, 2, \dots, n$ , then the number  $n + 1$  is defined as the set of all previous numbers.

We have defined the set of natural numbers  $\mathbb{N}$ .<sup>3</sup> Next, we should construct the operations  $+$  and  $\cdot$  and deduct their required properties. In order to do that in detail, we would have to pay more attention to basic understanding of sets. For example, once we know what a disjoint union of sets is, we may define the natural number  $c = a + b$  as the unique natural number  $c$  having the same number of elements as the disjoint union of  $a$  and  $b$ .

Of course, formally speaking, we need to explain what does it mean for two sets to have the same number of elements. Let us notice that in general, having the two sets  $A$  and  $B$  of the same “size” should mean that there exists a bijection  $A \rightarrow B$ . This is completely in accordance with our intuition for finite sets. However, it is much less intuitive with infinite sets. For example there is the same amount of all natural numbers and those with natural square roots (the bijection  $a \mapsto a^2$ ), although the picture in the solution to 1.A.3 could be read as “many of natural numbers do not have a rational square root”. We say, that each set which is bijective to natural numbers  $\mathbb{N}$  is *countable*. Sets bijective to some natural number  $n$  (as defined above) are called *finite* (with *number of elements*  $n$ ), while the sets which are neither finite nor countable are called *uncountable*.

So adding  $a + b$  is understood as increasing  $a$  iteratively by one exactly as many time as is the number of elements in  $b$ . Similarly, we multiply  $a \cdot b$  by adding  $a$  to zero as many times as is the number of elements in  $b$ . Now we should check the axioms for scalar operations for our operations  $+$  and  $\cdot$ . The (boring but tedious) check is left to the reader.

We can also define a relation  $\leq$  on  $\mathbb{N}$  as follows:  $m \leq n$ , if either  $m \in n$  or  $m = n$ . Clearly this is a complete ordering. For instance  $2 \leq 4$ , since

$$2 = \{\emptyset, \{\emptyset\}\} \in \{\emptyset, \{\emptyset\}, \{\emptyset, \{\emptyset\}\}, \{\emptyset, \{\emptyset\}, \{\emptyset, \{\emptyset\}\}\} = 4.$$

<sup>3</sup>The concept of natural numbers based on the principle of “increasing by one” was known to all ancient civilisations, however they always had the smallest natural number one. The set theoretical approach was developed in 19th century and there zero got a logical smallest natural number as the counterpart of the empty set.

**Solution.** The relation  $R_1$  is an ordering, which is not complete (for instance neither  $(a, c) \notin R_1$  nor  $(c, a) \notin R_1$ ). The relation  $R_2$  is not anti-symmetric as it is both  $(a, d) \in R_2$  and  $(d, a) \in R_2$ , therefore it is not an ordering. The relations  $R_3$  does not define an ordering as well, since it is not transitive (for instance  $(a, b), (b, c) \in R_3$ , but  $(a, c) \notin R_3$ ).  $\square$

**1.F.8.** In the following three figures, icons are connected with lines such that people in different parts of the world could have assigned them. Determine whether the connection is a mapping, and whether it is injective, surjective or bijective.

**Solution.** In the first figure the connection is a mapping which is surjective but not injective, because both the snake and the spider are labeled as poisonous. The second figure is not a mapping but only a relation, since the dog is labeled both as a pet and as a meal. The third connection is again a mapping. This time it is neither injective nor surjective.  $\square$

**1.F.9.** Determine whether or not the mapping  $f$  is injective (one-to-one) or surjective (onto), when  $f$  is given by:

- (a)  $f : \mathbb{Z} \times \mathbb{Z} \rightarrow \mathbb{Z}, \quad f((x, y)) = x + y - 10x^2;$
- (b)  $f : \mathbb{N} \rightarrow \mathbb{N} \times \mathbb{N}, \quad f(x) = (2x, x^2 + 10).$   $\circ$

**1.F.10.** Determine the number of equivalence relations over the set  $A = \{1, 2, 3, 4\}$ .

**Solution.** We divide the sought equivalences according to the types of corresponding partitions (given by number and cardinality of equivalence classes), and we count the number of partitions of a given type:

The type of partition	number of partitions of this type
1,1,1,1	1
2,1,1	$\binom{4}{2}$
2,2	$\frac{1}{2} \binom{4}{2}$
3,1	$\binom{4}{1}$
4	1

Thus in total we have 15 different equivalences.  $\square$

**1.F.11.** Determine the number of orderings of a four-element set.

**Solution.** We will consider all possible Hasse diagrams of orderings over a four-element set  $M$ . We count how many different orderings (recall that an ordering is a subset of a set  $M \times M$ ) the given Hasse diagram has. See the diagram:

In other words, the recurrent definition itself gives the relation  $n \leq n+1$ . and transitivity then gives  $n \leq k$  for all  $k$  obtained in this manner later.

This ordering of the positive integers or natural numbers (the number  $a$  is strictly smaller than  $b$  if  $a \in b$ ) has obviously got the following striking property: *every nonempty subset in  $\mathbb{N}$  or  $\mathbb{Z}^+$  has a smallest element.*

**1.6.6. Integers and rational numbers.** With the set  $\mathbb{N}$  of positive integers together with zero, we can always add two numbers together. Also, adding zero to a number does not change it. We can also define subtraction, but the result does not always belong to  $\mathbb{N}$ .

The basic idea of construction of the integers from the natural numbers or positive integers is to add to  $\mathbb{N}$  these missing results.

This can be done as follows: instead of subtraction, we will work with ordered pairs of numbers  $(a, b)$  representing the desired result  $a - b$ . It just remains to define which such pairs are equivalent (with respect to the result of subtraction).

The necessary relation is then:

$$(a, b) \sim (a', b') \iff a - b = a' - b' \iff a + b' = a' + b.$$

Note that the expression in the middle equation may not belong to  $\mathbb{N}$ , but the expression on the right always does. It is easy to check that it really is an equivalence, and we denote its classes as the integers  $\mathbb{Z}$ .

We define addition and subtraction on  $\mathbb{Z}$  using representatives. For instance

$$[(a, b)] + [(c, d)] = [(a + c, b + d)],$$

which is clearly independent of the choice of representatives.

It is always possible to choose a representative  $(a, 0)$  for natural numbers  $a$ , and a representative  $(0, a)$  for negative numbers  $-a$ . This is probably the simplest and easiest choice.

Next, we define multiplication of integers similarly to the addition (i.e., using representatives we aim at the representative of  $(a - b) \cdot (c - d)$ )

$$(a, b) \cdot (c, d) = (ac + bd, bc + ad).$$

This is clearly commutative and obviously does not depend on the choice of representatives.

Moreover, choosing positive or negative multiplicands with their special representatives as above, we get just the standard multiplication in  $\mathbb{N}$  taking the right care for the signs.

Now it is easy to see, that we have all the properties (CG1)–(CG4) and (R1)–(R4), see the paragraph 1.1.1. For multiplication, the neutral element is one, but for all numbers  $a$  other than zero and  $\pm 1$  there does not exist an integer  $a^{-1}$  with the property  $a \cdot a^{-1} = 1$ . Thus, for multiplication, we are missing the inverse elements. However, the property of the integral domain (ID) holds. This means that if the product of two integers equals zero, then at least one of them has to be zero.

We can construct the rational numbers  $\mathbb{Q}$  by adding all the missing multiplicative inverses by a method analogous to the construction of  $\mathbb{Z}$  from  $\mathbb{N}$ .

..... 1	!.. $\frac{4!}{2}$	!! $\frac{4!}{2}$	·^ $\frac{4!}{2}$	·v $\frac{4!}{2}$	·!  4!	N 4!	X $\frac{4!}{4}$
^ $\frac{4!}{6}$	v $\frac{4!}{6}$	!  4!	!  4!	Y $\frac{4!}{2}$	^ $\frac{4!}{2}$	◇ $\frac{4!}{2}$	!  4!

In total, there are 219 orderings over a four-element set. □

Many combinatorics problems involve relations, and examples can be found in the final section with additional material (see Section G).

On the set of all ordered pairs  $(p, q)$ ,  $q \neq 0$ , of integers, we define a relation  $\sim$  so that it models our expectation of the fractions  $p/q$ :

$$(p, q) \sim (p', q') \iff p/q = p'/q' \iff p \cdot q' = p' \cdot q.$$

Again, we are not able to formulate the expected behaviour in the middle equation when we work in  $\mathbb{Z}$ , but for the equation on the right this is indeed possible. This relation is a well-defined equivalence (think it through!).

If we formally write  $p/q$  instead of pairs  $(p, q)$ , we can define the operations of multiplication and addition by the well-known formulas

$$p/q \cdot r/s = pr/qs$$

$$p/q + r/s = ps/qs + qr/qs = (ps + qr)/qs.$$

**1.6.7. Remainder classes.** Another example of equivalence

classes is the remainder classes of integers. For a fixed natural number  $k$  we define an equivalence  $\sim_k$  so that two numbers  $a, b \in \mathbb{Z}$  are equivalent if they have the same remainder when divided by  $k$ . The resulting set of equivalence classes is denoted as  $\mathbb{Z}_k$ . This procedure is simplest for  $k = 2$ . This yields  $\mathbb{Z}_2 = \{[0], [1]\}$ , where zero stands for even numbers and one for odd numbers. It is easy to see that the addition and multiplication can be defined using representatives.

REMAINDER CLASSES RINGS AND FIELDS

**Theorem.** *The remainder class  $\mathbb{Z}_k$  is always a commutative ring of scalars. It is a commutative field of scalars (that is, the property (F) from the paragraph 1.1.1 is also satisfied) if and only if  $k$  is a prime.*

*If  $k$  is not prime, then  $\mathbb{Z}_k$  contains a divisor of zero, thus it is not an integral domain.*

**PROOF.** The second part is easy to see — if  $x \cdot y = k$  for natural numbers  $x, y$ , then the result of multiplying the corresponding classes  $[x] \cdot [y]$  is zero.

On the other hand, if  $x$  and  $k$  are relatively prime, then according to the Bezout equality, (which we derive later, see 11.1.2), there are natural numbers  $a$  and  $b$  satisfying

$$ax + bk = 1,$$

which for corresponding equivalence classes gives

$$[a] \cdot [x] + [0] = [a] \cdot [x] = [1]$$

and thus  $[a]$  is the inverse element to  $[x]$ . □

**G. Additional exercises for the whole chapter**

We will now present supplementary material related to the concepts discussed so far. We begin by reviewing some key equalities and inequalities that appear throughout the book, due to their versatility in various applications.

A) MATERIAL ON NUMBERS AND FUNCTIONS

**I.G.1. (Basic arithmetic and the triangular numbers)** Recall from high-school that the principle of mathematical induction can be used to prove the following in just a few steps:

$$\Delta_n := 1 + 2 + \dots + n = \frac{n(n+1)}{2}, \quad n \in \mathbb{Z}_+.$$

The numbers  $\Delta_n$  are called *triangle numbers*. Provide a shorter proof of this summation without using induction, and illustrate your method with a figure. Next, show that the number of distinct handshakes or wine glass clinks among  $n$  people equals the triangular number  $\Delta_{n-1}$ . Finally prove that  $\Delta_n - \Delta_{n-1} = n$ , and  $\Delta_n + \Delta_{n-1} = n^2$  for any  $n$ . ○

**I.G.2. (Average speed)** A bicyclist ascends a hill at 25km/h, and descends the same hill at 75km/h. Find the bicyclist's average speed for the entire trip, assuming the length of the hill is not needed for the calculation. ○

**1.G.3. The arithmetic–geometric mean inequality (AM-GM inequality).** (a) For any two non-negative real numbers  $a, b$  prove the inequality

$$\sqrt{ab} \leq \frac{a+b}{2}, \quad \text{or equivalently} \quad (ab)^{\frac{1}{2}} \leq \frac{a+b}{2}, \quad (\dagger)$$

with equality if and only if  $a = b$  (recall that  $\sqrt{ab}$  is called the *geometric mean* of  $a, b$ , while  $\frac{a+b}{2}$  is the *arithmetic mean* of  $a, b$ ). Next use  $(\dagger)$  to prove that any four non-negative real numbers  $a, b, c, d$ , the following inequality holds:

$$(abcd)^{\frac{1}{4}} \leq \frac{a+b+c+d}{4}, \quad (\ddagger)$$

with equality if and only if  $a = b = c = d$ .

(b) Present a proof using mathematical induction for the general arithmetic–geometric mean inequality

$$\sqrt[n]{a_1 \cdot a_2 \cdot \dots \cdot a_n} \leq \frac{a_1 + a_2 + \dots + a_n}{n},$$

with equality if and only if  $a_1 = a_2 = \dots = a_n$ , where  $a_i$  are non-negative real numbers for all  $i = 1, \dots, n$ .

**Solution.** (a) There are numerous alternative proofs for the AM-GM inequality. For instance, take the square in both sides of the relation given in  $(\dagger)$ . We obtain  $ab \leq (a+b)^2/4$ , which simplifies to  $4ab \leq a^2 + 2ab + b^2$ . This is equivalent to stating that  $(a-b)^2 \geq 0$ . This last inequality is obviously true, as the square of a real number is non-negative. Moreover, equality holds if and only if  $a = b$ . Since all steps are reversible, the statement is proven.

A more geometric proof can be described using the figure below. This illustrates four rectangles, each of area  $ab$ , placed inside a square of area  $(a+b)^2$ . We observe that  $4ab$  does not exceed  $(a+b)^2$ , with the “wasted” area being the shaded region in the figure. By demonstrating that the shaded area is  $(a-b)^2$  we can conclude that equality holds if and only if  $a = b$ .

The second inequality follows directly from  $(\dagger)$ , when combined with the known properties of powers of real numbers:

$$(abcd)^{\frac{1}{4}} = \left( (abcd)^{\frac{1}{2}} \right)^{\frac{1}{2}} = \left( \sqrt{ab} \sqrt{cd} \right)^{\frac{1}{2}} \stackrel{(\dagger)}{\leq} \frac{\sqrt{ab} + \sqrt{cd}}{2} \stackrel{(\dagger)}{\leq} \frac{\frac{a+b}{2} + \frac{c+d}{2}}{2} = \frac{a+b+c+d}{4}.$$

(b) To simplify the notation, suppose that  $\mathcal{Y}(n)$  stands for the hypothesis that the given inequality is valid. Above we proved the result for  $n = 2, 4$ , that is, we have confirmed  $\mathcal{Y}(2)$  and  $\mathcal{Y}(4)$ , and in a similar way one can show that the result is valid for  $n = 8$ , that is,

$$(a_1 \cdot a_2 \cdot \dots \cdot a_8)^{\frac{1}{8}} = \left( (a_1 \cdot \dots \cdot a_4)^{\frac{1}{4}} (a_5 \cdot \dots \cdot a_8)^{\frac{1}{4}} \right)^{\frac{1}{2}} \stackrel{(\dagger)}{\leq} \frac{(a_1 \cdot \dots \cdot a_4)^{\frac{1}{4}} + (a_5 \cdot \dots \cdot a_8)^{\frac{1}{4}}}{2} \stackrel{(\dagger)}{\leq} \frac{a_1 + \dots + a_8}{8}.$$

Hence we have confirmed  $\Upsilon(2)$ ,  $\Upsilon(4)$  and  $\Upsilon(8)$ , and one can obtain the statement for any  $2^k$  with  $k \geq 1$ , that is, verify  $\Upsilon(2^k)$  for all integers  $k \geq 1$  (we leave this verification to the reader). Let us now explain how  $\Upsilon(4)$  can be used to derive  $\Upsilon(3)$ . Set

$$\mu := \frac{a_1 + a_2 + a_3}{3}$$

for the arithmetic mean of some real positive numbers  $a_1, a_2, a_3$ . A crucial but simple observation is that  $\mu$  is also the arithmetic mean of the numbers  $a_1, a_2, a_3, \mu$ , that is,

$$\frac{a_1 + a_2 + a_3}{3} = \frac{a_1 + a_2 + a_3 + \mu}{4},$$

or in other words  $\mu = \frac{a_1 + a_2 + a_3 + \mu}{4}$ . A proof of this is easy: By definition we have  $3\mu = a_1 + a_2 + a_3$ , or equivalently  $4\mu = a_1 + a_2 + a_3 + \mu$ . Then a division by 4 gives the claim. Now we can apply  $\Upsilon(4)$  on the numbers  $a_1, a_2, a_3, \mu$ :

$$\sqrt[4]{(a_1 a_2 a_3 \mu)} = (a_1 a_2 a_3 \mu)^{\frac{1}{4}} \leq \frac{a_1 + a_2 + a_3 + \mu}{4} = \mu.$$

Considering the fourth power of both sides in this inequality, we obtain  $abc\mu \leq \mu^4$  which can be rewritten as  $a_1 a_2 a_3 \leq \mu^3$ . Thus, after taking cube roots in both sides we arrive to the result, i.e.,  $(a_1 a_2 a_3)^{\frac{1}{3}} \leq \mu$ . Before describe the general step, keep in mind that  $a_1 a_2 a_3 \mu$  can be rewritten as  $a_1 a_2 a_3 \mu^{2^2-3}$  and  $a_1 + a_2 + a_3 + \mu = a_1 + a_2 + a_3 + (2^2 - 3)\mu$ , since  $2^2 - 3 = 1$ .

Now one can use  $\Upsilon(8)$ , to obtain also  $\Upsilon(5)$ ,  $\Upsilon(6)$ , and  $\Upsilon(7)$ , and so forth. However, let us explicitly present the general argument. Observe that in order to compute  $\Upsilon(3)$  from  $\Upsilon(4)$ , we extended the triple  $(a_1, a_2, a_3)$  into the quadruple  $(a_1, a_2, a_3, \mu) = (\hat{a}_1, \hat{a}_2, \hat{a}_3, \hat{a}_4)$ , so that we could apply  $\Upsilon(4)$ . We will use the analogous technique to prove  $\Upsilon(n)$  for all  $n < 2^k$ . Hence, the goal is to extend  $(a_1, a_2, \dots, a_n)$  to  $(\hat{a}_1, \dots, \hat{a}_{2^k})$ , so that we can apply  $\Upsilon(2^k)$  on the latter set. A question that may arise is how to extend this result, and the case  $n = 3$  provides the necessary motivation. Indeed, consider the following:

$$\hat{a}_j := \begin{cases} a_j, & j = 1, 2, \dots, n, \\ \mu := \frac{a_1 + a_2 + \dots + a_n}{n}, & j = n + 1, \dots, 2^k \end{cases}$$

(for  $n = 3$  this formula yields the expressions used above, and in particular we have  $k = 2$  for this case). Apply now  $\Upsilon(2^k)$  to  $(\hat{a}_1, \dots, \hat{a}_{2^k})$ . This gives

$$(a_1 \cdots a_n \mu^{2^k-n})^{\frac{1}{2^k}} \leq \frac{a_1 + \cdots + a_n + (2^k - n)\mu}{2^k} = \mu.$$

Obviously,  $(\mu^{2^k-n})^{\frac{1}{2^k}} = \mu \mu^{-\frac{n}{2^k}}$ , therefore the previous formula is also written as

$$(a_1 \cdots a_n \mu^{2^k-n})^{\frac{1}{2^k}} = (a_1 \cdots a_n)^{\frac{1}{2^k}} \mu \mu^{-\frac{n}{2^k}} \leq \mu.$$

Thus we can eliminate  $\mu$  from both sides, i.e., we have proved till now that  $(a_1 \cdots a_n)^{\frac{1}{2^k}} \mu^{-\frac{n}{2^k}} \leq 1$ . Raising both sides of this inequality to the power of  $\frac{2^k}{n}$ , yields the result:

$$(a_1 \cdots a_n)^{\frac{1}{n}} \mu^{-1} \leq 1, \quad \text{or equivalent} \quad (a_1 \cdots a_n)^{\frac{1}{n}} \leq \mu.$$

This completes the main proof, and the equality case can be easily derived. □

*The proof given above goes back almost two centuries, and is due to the French mathematician A.-L. Cauchy (1789–1856).*

*Note that this is a special kind of mathematical induction, often referred to as the “forward-backward” induction.*

*This is because we first derived the result for all the powers of 2, and next proceeded with another induction to establish it for all positive integers. As we pronounced, the AM-GM inequality admits many different proofs, most of them based on induction. There are also methods arising in term of calculus, which allow the presentation of shorter proofs. For example, much later in Chapter 8, we will provide a proof of the AM-GM inequality in terms of the so-called Lagrange multipliers.*

**1.G.4. Bernoulli inequality.** For any  $x \in \mathbb{R}$  with  $x > -1$  based on mathematical induction one can easily prove that  $(1+x)^n \geq 1+nx$  for any  $n \in \mathbb{N}$ , see also 5.4.1. This is the so called *Bernoulli inequality*. Prove that the Bernoulli inequality yields the AM-GM inequality.

**Solution.** For  $n = 1$  we have nothing to prove, so we may assume that  $n \geq 2$ . Setting  $y = x + 1$  with  $x > -1$ , so that  $y > 0$ , the Bernoulli inequality takes the form

$$y^n \geq 1 + n(y - 1). \quad (*)$$

Now, to simplify the description let us set  $A(n) = \frac{a_1 + \dots + a_n}{n}$  and  $G(n) = (a_1 \dots a_n)^{\frac{1}{n}}$ , so that the AM-GM inequality simply reads by  $G(n) \leq A(n)$ . Obviously  $\frac{A(n)}{A(n-1)} > 0$  and as  $y$  we may consider the ratio  $\frac{A(n)}{A(n-1)}$  with  $n \geq 2$ . Then, using the relation (\*) we deduce that

$$\left(\frac{A(n)}{A(n-1)}\right)^n \geq 1 + n \left(\frac{A(n)}{A(n-1)} - 1\right) = \frac{A(n-1) + nA(n) - nA(n-1)}{A(n-1)} = \frac{a_n}{A(n-1)},$$

and this can be equivalently rephrased as  $A^n(n) \geq a_n A^{n-1}(n-1)$ . Using this inequality successively we obtain

$$\begin{aligned} A^n(n) &\geq a_n A^{n-1}(n-1) \geq a_n \cdot a_{n-1} A^{n-2}(n-2) \geq \dots \geq a_n \cdot a_{n-1} \cdot \dots \cdot a_2 A^1(1) \\ &= a_n \cdot a_{n-1} \cdot \dots \cdot a_2 \cdot a_1 = G^n(n), \end{aligned}$$

that is,  $A^n(n) \geq G^n(n)$ , for any  $n \geq 2$ . Raising both sides to the power of  $\frac{1}{n}$  we obtain the desired  $A(n) \geq G(n)$ .  $\square$

**1.G.5. Symbolic computations with Sage and polynomials.** In SageMath, for a series of applications as doing symbolic computations, solving equations, plotting functions, etc. are available the so called *symbolic variables*. Symbolic variables are often used to represent "indeterminates," which are variables that do not have a fixed value. This concept is frequently employed in mathematical problem-solving to allow for general solutions and manipulations, such as simplifying expressions, solving equations, and performing symbolic differentiation and integration (see Chapter 5 and Chapter 6, respectively). By using indeterminates, we can explore mathematical relationships and derive formulas that hold true for any value of the variable, providing a powerful tool for both theoretical and applied mathematics.

On the other hand, polynomials form a fundamental component of algebra and calculus, and symbolic computation provides a powerful toolset for examining their properties and behavior. Let us explain how using symbolic variables, we can manipulate polynomials easily. First, to establish a symbolic variable we type `t = var("t")`, or simply `var("t")`, or

```
t=SR.var("x"); t
```

which returns a symbolic variable, named `t` by Sage. We stress that Sage does this *automatically* for the variable `x`, but not for other variables. Thus, given the cell

```
y=var("y"); x-y
```

Sage will understand `x - y` as an expression of two variables `x, y`. In the opposite, typing directly `x - y` an error will be printed out, declaring that the name "y" is not defined. It is also possible to create more than one symbolic variable, in a row. This for example allows to use expressions depending either on many variables, or both on variables and parameters, as in the examples below:

```
x, y, z=var("x, y, z"); x+y+z
t, a, b, c=var("t, a, b, c"); a*t**2+b*t+c
```

The cell

```
var("a, b, c"); f=a*x**2+b*x+c; print([f.coefficient(x**2), f.coefficient(x)])
```

returns the coefficients of the terms  $x^2$  and  $x$ , respectively, as `[a, b]`, which can be useful in complicated expressions. Of course, if you want to solve the equation  $ax^2 + bx + c = 0$  with  $a > 0$ , then type

```
x, a, b, c=var("x, a, b, c"); assume(a>0); show(solve(a*x**2+b*x+c==0, x))
```

In this case Sage returns the known solutions in terms of `a, b, c`, check the output yourselves. An alternative to introduce symbolic variables is the command `x = SR.var("x", n)`. This creates the symbolic variables  $x_0, \dots, x_{n-1}$  for some positive integer `n`, and each of them can be accessed by typing `x[i]`, for some  $i \in \{0, \dots, n-1\}$ . As an example, type

```
x=SR.var("x"); a=SR.var("a", 4); a[0]+a[1]*x+a[2]*x**2+a[3]*x**3
```

Executing this cell we obtain  $a_3 * x^3 + a_2 * x^2 + a_1 * x + a_0$ , hence fixing the parameters  $a_3, a_2, a_1, a_0$  we can define a real polynomial of degree three. For such substitutions one may apply the following code:

```
x=SR.var("x"); a=SR.var("a", 4)
a[0]+a[1]*x+a[2]*x**2+a[3]*x**3
f=a[0]+a[1]*x+a[2]*x**2+a[3]*x**3
f.subs(a[0]==6, a[1]==4, a[2]==2, a[3]==1/8)
```

This prints out the polynomial  $\frac{1}{8} * x^3 + 2 * x^2 + 4 * x + 6$ , which we may plot by typing (produce the figure in your editor)

```
plot(1/8*x^3 + 2*x^2 + 4*x + 6, (x, -50, 50))
```

Notice to factor a polynomial we may use the command `factor`:

```
p(x)=x^5 + x^4 - 8*x^3 + 11*x^2 - 15*x + 2; show(factor(p(x)))
```

In this case Sage prints out the expression  $(x^4 + 3x^3 - 2x^2 + 7x - 1)(x - 2)$ . We will meet further option manipulating polynomials in Sage in the sequel. We will encounter more options for manipulating polynomials in SageMath later in this text.

**1.G.6.** Suppose that  $P(x)$  is a polynomial (with constant coefficients) satisfying the following: divided by  $x + 2$  leaves remainder  $-1$ , divided by  $x + 3$  leaves remainder  $1$ , while divided by  $x - 3$  leaves remainder  $4$ . Find the remainder  $v(x)$  of the division of  $P(x)$  by the polynomial  $(x + 2)(x + 3)(x - 3)$ .

**Solution.** Let us write  $P(x) = q(x) \cdot \pi(x) + v(x)$ , where  $q(x) = (x + 2)(x + 3)(x - 3)$  is the divisor,  $\pi(x)$  is the quotient and  $v(x)$  the remainder. Since the divisor is of degree  $3$ , the remainder  $v(x)$  is a polynomial at most of degree  $2$ , say  $v(x) = ax^2 + bx + c$ . By assumption we have  $P(-2) = -1$ ,  $P(-3) = 1$  and  $P(3) = 4$ . Since  $P(x) = (x_2)(x + 3)(x - 3) \cdot \pi(x) + ax^2 + bx + c$ , we get the following system of equations:

$$\{4a - 2b + c = -1, \quad 9a - 3b + c = 1, \quad 9a + 3b + c = 4\}.$$

Solving this system we obtain  $a = 1/2 = b$  and  $c = -2$ . For verifying this, use for example Sage via the block

```
var("a, b, c"); f1=4*a-2*b+c+1; f2=9*a-3*b+c-1; f3=9*a+3*b+c-4
solve((f1==0, f2==0, f3==0), a,b,c)
```

□

**1.G.7.** Find a polynomial  $P(x)$  of fourth degree satisfying  $P(1) = 1$ , such that  $P(x+1)$  is divided by  $(x-1)^2$ , and  $P(x-1)$  is divided by  $(x+1)^2$ .

**Solution.** By assumption, we have

$$P(x+1) = (x-1)^2 \cdot \pi_1(x), \quad \text{and} \quad P(x-1) = (x+1)^2 \cdot \pi_2(x),$$

where  $\pi_1(x), \pi_2(x)$  are the corresponding quotients. Using these equations, one can obtain the relations

$$P(x) = (x-2)^2 \cdot \pi_1(x-1), \quad \text{and} \quad P(x) = (x+2)^2 \cdot \pi_2(x+1),$$

respectively. This means that  $P(x)$  is divided by  $(x-2)^2$  and also by  $(x+2)^2$ . But then  $P(x)$  will be divided also by the product  $(x-2)^2(x+2)^2 = (x^2-4)^2$ .<sup>13</sup> Now,  $P(x)$  is of degree  $4$ , hence the previous conclusion implies that  $P(x) = c \cdot (x^2-4)^2$ , for some constant  $c \in \mathbb{R} \setminus \{0\}$ . Based on the condition  $P(1) = 1$  we compute  $c = 1/9$ , and hence  $P(x) = \frac{1}{9}(x^2-4)^2$ . □

**1.G.8.** Given the polynomial  $P(x) = x^2 + x + 2$ , show that the polynomial  $Q(x) := P(P(x)) - P(x) - 3$  is divided by  $P(x) - 1$ . Which is the quotient? ○

**1.G.9.** Prove that the polynomial  $P(x)$  of degree  $4$  satisfying  $P(0) = 0$  and  $P(x+1) - P(x) = 4x^3$ , admits  $x_0 = 1$  as a double root. ○

**1.G.10.** (a) Factor the polynomial  $p(x) = 4x^4 - 8x^3 - 3x^2 + 7x - 2$  using Horner's scheme and indicate the multiplicities of its roots. Verify your answer via Sage and present the graph of  $p(x)$  for  $x \in [-2, 2]$ .

(b) Consider the polynomials  $p_1(x) = x^4 + 2x^3 + x^2 + x + 12$ ,  $p_2(x) = 2x^5 + x^4 - 53x^3 - 7x + 3$ ,  $q_1(x) = x + 2$  and  $q_2(x) = x^2 - 5x + 1$ . Show that the Euclidean divisions of  $p_i(x)$  by  $q_i(x)$  for  $i = 1, 2$ , satisfy  $v_2(x) = -62x + v_1(x)$  and moreover  $\pi_2(x) = 2\pi_1(x) + 11x^2 - 2x - 9$ , where we write  $p_i(x) = q_i(x)\pi_i(x) + v_i(x)$  with  $i = 1, 2$ .

**Solution.** (a) Dividing the factors of  $2$  by all factors of  $4$  ones gets a list of all possible rational roots. In particular, we see that  $\rho_1 = -1$  is a root,  $p(\rho_1) = 4 + 8 - 3 - 7 - 2 = 0$ . Thus, using the Horner's table we get

$$\begin{array}{r|rrrrr} \rho_1 = -1 & 4 & -8 & -3 & 7 & -2 \\ & & -4 & 12 & -9 & 2 \\ \hline & 4 & -12 & 9 & -2 & 0 \end{array}$$

Hence  $p(x) = (x - \rho_1)(4x^3 - 12x^2 + 9x - 2) = (x + 1)(4x^3 - 12x^2 + 9x - 2)$ . Next we see that  $\rho_2 = 2$  is a root of  $4x^3 - 12x^2 + 9x - 2$ , thus using the Horner's method for this polynomial we get

$$\begin{array}{r|rrrr} \rho_2 = 2 & 4 & -12 & 9 & -2 \\ & & 8 & -8 & 2 \\ \hline & 4 & -4 & 1 & 0 \end{array}$$

<sup>13</sup>Here we are based on the general fact that if a polynomial  $P(x)$  (with constant coefficients) is divided by the monomials  $(x - \rho_1), (x - \rho_2), \dots, (x - \rho_k)$ , where  $\rho_i \neq \rho_j$  for  $1 \leq i \neq j \leq k$ , then  $P(x)$  is also divided by the product  $(x - \rho_1) \cdot (x - \rho_2) \cdot \dots \cdot (x - \rho_k)$ . The converse is also true.

Thus  $p(x) = (x - \rho_1)(x - \rho_2)(4x^2 - 4x + 1) = (x + 1)(x - 2)(2x - 1)^2$ , or equivalently  $p(x) = 4(x - \rho_1)(x - \rho_2)(x - \rho_3)^2$  where  $\rho_1 = -1$ ,  $\rho_2 = 2$  and  $\rho_3 = \frac{1}{2}$ . Note that  $\rho_3$  is a double root. In Sage we simply type

```
p(x)=4*x^4-8*x^3-3*x^2+7*x-2; factor(p(x))
```

which returns  $(2 * x - 1)^2 * (x + 1) * (x - 2)$ . In this block one can specify the ring over which the factorization is implemented by typing  $x = \mathbb{QQ}[x]$  at the beginning of the code. This defines  $x$  as a polynomial over the rational numbers. However, in our case, this approach will yield the same factorization result as the default setting. Additionally, by typing  $p.roots()$  SageMath will return the roots of the polynomial  $p$ , along with their multiplicities:

```
[(2, 1), (-1, 1), (1/2, 2)] # in the pair (a, b), a denotes a root, b denotes its multiplicity
```

As for the graph of  $p(x)$  for  $x \in [-2, 2]$ , one may add the syntax

```
plot(4*x^4-8*x^3-3*x^2+7*x-2, x, -2, 2)
```

(b) The first division gives

$$\begin{array}{r} x^3 + x - 1 \\ x + 2 \overline{) x^4 + 2x^3 + x^2 + x + 12} \\ \underline{-x^4 - 2x^3} \phantom{+ x^2 +} \\ x^2 + x \phantom{+ 12} \\ \underline{-x^2 - 2x} \phantom{+ 12} \\ -x + 12 \\ \phantom{-x +} \underline{x + 2} \\ 14 \end{array}$$

Thus  $p_1(x) = q_1(x)\pi_1(x) + v_1(x)$ , where  $\pi_1(x) = x^3 + x + 1$  and  $v_1(x) = 14$  (constant). For the second division one gets

$$\begin{array}{r} 2x^3 + 11x^2 - 11 \\ x^2 - 5x + 1 \overline{) 2x^5 + x^4 - 53x^3 - 7x + 3} \\ \underline{-2x^5 + 10x^4 - 2x^3} \phantom{- 7x + 3} \\ 11x^4 - 55x^3 \phantom{- 7x + 3} \\ \underline{-11x^4 + 55x^3 - 11x^2} \phantom{- 7x + 3} \\ -11x^2 - 7x + 3 \\ \phantom{-11x^2 -} \underline{11x^2 - 55x + 11} \\ -62x + 14 \end{array}$$

hence  $q_2(x) = q_2(x)\pi_2(x) + v_2(x)$  with  $\pi_2(x) = 2x^3 + 11x^2 - 11$  and  $v_2(x) = -62x + 14$ , respectively. Thus  $v_2(x) = -62x + v_1(x)$  and the second relation follows since

$$\begin{array}{r} 2 \\ x^3 + x - 1 \overline{) 2x^3 + 11x^2 - 11} \\ \underline{-2x^3} \phantom{- 11} \\ 11x^2 - 2x - 9 \end{array}$$

□

**1.G.11. (Polynomial division via SageMath)** Given a polynomial  $p(x) = a_n x^n + a_{n-1} x^{n-1} + \dots + a_1 x + a_0$  and a number  $x_0$ , use Sage to implement the division of  $p(x)$  by  $(x - x_0)$ , resulting in a quotient polynomial  $q(x)$  and a remainder  $r$ . Next use your program to confirm that dividing  $p(x) = 4 - 3x + 5x^2 - 2x^3 + x^4$  by  $(x - 3)$  results in the quotient  $q(x) = 21 + 8x + x^2 + x^3$  and the remainder  $r = 67$ . ○

*The omission of basic features of integers, such as their divisibility and the theory of prime numbers, up to this point, has been intentional. It is more practical to explore these topics in detail in Chapter 11, which is entirely dedicated to number theory. For this reason, we will delay discussing additional tasks related to the beautiful theory of integers and prime numbers, and instead, focus on problems involving complex numbers and their geometry for now.*

**1.G.12. (True or False?)** Answer the following True or False questions, providing a proof to support your statements.

(1) “The expression of the complex number  $z = \frac{1 + 2i}{4 + 5i}$  in the form  $z = x + iy$  is given by  $-\frac{6}{41} + i\frac{13}{41}$ ”.

- (2) “The ratio  $\frac{(1+i)^{2023}}{(1-i)^{2020}}$  equals  $2i - 2$ ”.
- (3) “The product  $zw$  of two elements  $z, w \in S^1$  on the unit circle  $S^1 = \{z \in \mathbb{C} : |z| = 1\}$  belongs also to  $S^1$ ”.
- (4) “Any element  $z \in S^1$  has an inverse which also belongs to  $S^1$ ”.
- (5) “The cubic equation  $z^3 + i = 0$  has three solutions over  $\mathbb{C}$ , given by  $z_1 = i, z_2 = \frac{\sqrt{3}}{2} - i\frac{1}{2}, z_3 = -\frac{\sqrt{3}}{2} - i\frac{1}{2}$ .”

○

**I.G.13.** Consider the complex numbers  $z_1 = 2 + 6i$  and  $z_2 = -4 - 2i$ . Suppose that there is another complex number  $w = x + iy$  which is at a distance of  $2\sqrt{2}$  from  $z_2$ . Determine the positions of  $w$  on the plane  $\mathbb{R}^2$ , such that the triangle formed by the the points  $P_1 = [2, 6], P_2 = [-4, -2]$  and  $P_3 = [x, y]$  (representing  $z_1, z_2$  and  $w$ , respectively) is a right triangle. In particular, show that there are two possible solutions for  $w$ , and illustrate both of them using SageMath. ○

**1.G.14.** Let  $a, b, c, d \in \mathbb{R}$  with  $ac > 0$  and  $ad = bc$ . Show that the polynomial  $P(x) = ax^3 + bx^2 + cx + d$  has a unique real solution and two purely imaginary solutions.

**Solution.** The condition  $ac > 0$  implies that  $a \neq 0$ , and so  $d = \frac{bc}{a}$ . Therefore we see that

$$P(x) = ax^3 + bx^2 + cx + \frac{bc}{a} = \frac{1}{a}(a^2x^3 + abx^2 + acx + bc) = \frac{1}{a}(ax^2(ax + b) + c(ax + b)) = \frac{1}{a}(ax + b)(ax^2 + c).$$

As a consequence, the equation  $P(x) = 0$  is equivalent to  $(ax + b)(ax^2 + c) = 0$ , that is,  $x = -\frac{b}{a}$  or  $x^2 = -\frac{c}{a} < 0$ . So we have a real solution  $x_0 = -\frac{b}{a}$  and two purely imaginary given by  $x_{1,2} = \pm i\sqrt{\frac{c}{a}}$ . □

*Euler's identity for complex numbers states that any complex number  $z = r(\cos(\varphi) + i \sin(\varphi))$ , where  $r = |z|$  and  $\varphi$  is the argument of  $z$ , can be expressed as  $z = r e^{i\varphi}$ . Euler's identity thus provides an alternative to the polar form of  $z$ . For example, given  $z \in S^1$  we get  $z = \cos(\varphi) + i \sin(\varphi) = e^{i\varphi}$ , such that  $|z| = 1$ . It is worth noting that the exponential  $e^{iy}$  of an imaginary number  $iy$  is given by the power series  $\sum_{n=0}^{\infty} \frac{(iy)^n}{n!}$ . We will present a proof of this claim later, in Section 5.4.12, which discusses the relationship between exponentials and trigonometric functions. However, it is useful to get an initial understanding of this concept at this point.*

**1.G.15.** Based on the Euler's identity, provide an answer to the following tasks:

- (a) Express  $e^{i\pi/2}, e^{i\pi}$ , and  $e^{i2\pi}$  in algebraic form.
- (b) Show that  $\cos(\varphi) = \frac{e^{i\varphi} + e^{-i\varphi}}{2}$  and  $\sin(\varphi) = \frac{e^{i\varphi} - e^{-i\varphi}}{2i}$ , respectively. Deduce that  $\tan(\varphi) = -i \frac{e^{i\varphi} - e^{-i\varphi}}{e^{i\varphi} + e^{-i\varphi}}$ .
- (c) Show that  $|e^{i\varphi}| = 1$ .
- (d) Using the formula  $e^{i(\alpha+\beta)} = e^{i\alpha}e^{i\beta}$ , prove the following classical trigonometric identities:

$$\cos(\alpha + \beta) = \cos(\alpha)\cos(\beta) - \sin(\alpha)\sin(\beta), \quad \sin(\alpha + \beta) = \sin(\alpha)\cos(\beta) + \cos(\alpha)\sin(\beta).$$

**Solution.** (a) Using Euler's identity we obtain

$$e^{i\pi/2} = \cos(\pi/2) + i \sin(\pi/2) = i = \sqrt{-1}, \quad e^{i\pi} = \cos(\pi) + i \sin(\pi) = -1, \quad e^{i2\pi} = \cos(2\pi) + i \sin(2\pi) = 1.$$

(b) We have  $e^{i\varphi} = \cos(\varphi) + i \sin(\varphi)$  and  $\cos(\varphi) - i \sin(\varphi) = e^{-i\varphi} = \overline{e^{i\varphi}}$  (see also 5.4.12). By adding these two equations and solving for  $\cos(\varphi)$ , we derive the formula for  $\cos(\varphi)$ . In a similar way we obtain the formula for  $\sin(\varphi)$ , and the final claim follows in combination with the usual definition of the trigonometric function  $\tan$ , that is,  $\tan(\varphi) := \frac{\sin(\varphi)}{\cos(\varphi)}$ .

(c) Indeed,  $|e^{i\varphi}| = |\cos(\varphi) + i \sin(\varphi)| = \sqrt{\cos^2(\varphi) + \sin^2(\varphi)} = \sqrt{1} = 1$ .

(d) We see that

$$e^{i(\alpha+\beta)} = e^{i\alpha}e^{i\beta} = (\cos(\alpha) + i \sin(\alpha)) \cdot (\cos(\beta) + i \sin(\beta)) = (\cos(\alpha)\cos(\beta) - \sin(\alpha)\sin(\beta)) + i(\sin(\alpha)\cos(\beta) + \cos(\alpha)\sin(\beta)).$$

On the other hand  $e^{i(\alpha+\beta)} = \cos(\alpha + \beta) + i \sin(\alpha + \beta)$ . By comparing the real/imaginary parts of these two equations we obtain the given formulas. □

**1.G.16.** (a) Show that the following equation does not admit a real solution:

$$(1 + iz)^{2025} = \frac{2025 + i}{1 + i2025}, \quad z \in \mathbb{C}. \quad (*)$$

(b) Consider the complex number  $w = \frac{1}{2} \left( z + \frac{1}{z} \right)$  with  $z \in \mathbb{C}$  such that  $\arg(z) = \varphi \neq k\pi$  for all  $k \in \mathbb{Z}$  and  $\text{Im}(w) = 0$ . Show that the  $|z| = 1$ , i.e.,  $z$  lies on the unit circle.

**Solution.** (a) Suppose in the opposite that the equation (\*) has a real solution  $z = x \in \mathbb{R}$ , that is,  $(1 + ix)^{2025} = \frac{2025 + i}{1 + 2025i}$ .

Taking absolute values in both sides we have the following equivalent relations:

$$\begin{aligned} |(1 + ix)^{2025}| = \left| \frac{2025 + i}{1 + i2025} \right| &\iff |(1 + ix)|^{2025} = \frac{|2025 + i|}{|1 + i2025|} \iff (\sqrt{1 + x^2})^{2025} = \frac{\sqrt{2025^2 + 1}}{\sqrt{1 + 2025^2}} \iff \\ (\sqrt{1 + x^2})^{2025} = 1 &\iff \sqrt{1 + x^2} = 1 \iff 1 + x^2 = 1 \iff x = 0. \end{aligned}$$

However,  $x = 0$  cannot be a solution of the equation (\*) as it follows from the computation below:

$$1^{2025} = \frac{2025 + i}{1 + i2025} \iff 1 + i2025 = 2025 + i,$$

a contradiction. Hence the given equation does not admit a real solution.

(b) By assumption,  $\varphi$  is the (principle) argument of  $z$  and we may use the polar form  $z = |z|(\cos \varphi + i \sin \varphi)$ . Thus we can write

$$\begin{aligned} w &= \frac{1}{2} \left( |z|(\cos \varphi + i \sin \varphi) + \frac{1}{|z|(\cos \varphi + i \sin \varphi)} \right) = \frac{1}{2} \left( |z|(\cos \varphi + i \sin \varphi) + \frac{1}{|z|}(\cos(-\varphi) + i \sin(-\varphi)) \right) \\ &= \frac{1}{2} \left( |z|(\cos \varphi + i \sin \varphi) + \frac{1}{|z|}(\cos(\varphi) - i \sin(\varphi)) \right) = \frac{1}{2} \left( \left|z| + \frac{1}{|z|} \right) \cos \varphi + i \frac{1}{2} \left( |z| - \frac{1}{|z|} \right) \sin \varphi. \end{aligned}$$

Here we have used that the complex number  $e^{i\varphi} = \cos \varphi + i \sin \varphi$  satisfies (see also the previous problem)

$$\frac{1}{e^{i\varphi}} = e^{-i\varphi} = \cos(-\varphi) + i \sin(-\varphi) = \cos(\varphi) - i \sin(\varphi).$$

Thus now the requirement  $\text{Im}(w) = 0$  (in combination with the condition  $\varphi \neq k\pi$ ) gives

$$\frac{1}{2} \left( |z| - \frac{1}{|z|} \right) \sin \varphi = 0 \iff |z| - \frac{1}{|z|} = 0 \iff |z|^2 = 1 \iff |z| = 1.$$

□

**1.G.17. Roots of unity and regular  $n$ -polygons.** (a) Prove that the cube roots of 1 are the vertices of an equilateral triangle inscribed in the unit circle  $S^1$  (on the plane), with side length given by  $\sqrt{3}$ . Verify your computation via Sage.

(b) As a generalization, deduce that for any positive integer  $n$  the equation  $z^n = 1$ , where  $z \in \mathbb{C}$ , has  $n$ -roots  $z_1, z_2, \dots, z_n$  called the  $n$ th roots of unity. Prove that these solutions form the vertices of the regular  $n$ -polygon in the plane.

**Solution.** (a) We are interested in solutions of the equation  $z^3 = 1$ , where  $z \in \mathbb{C}$ . By the fundamental theorem of algebra we expect three solutions over  $\mathbb{C}$ . To find them explicitly, we can use de Moivre's formula which provides an easy way for solving equations of the form  $z^n = z_0$ . Indeed, in polar form the equation  $z^3 = 1$  is expressed as  $r^3(\cos(3\varphi) + i \sin(3\varphi)) = 1(\cos 0 + i \sin 0)$ . Verify by simple computations that this equation is satisfied if and only if  $r = 1$  and  $3\varphi = 0 \pmod{2\pi}$ . This means that the three solutions are of the form  $z_0 = \cos 0 + i \sin 0$ ,  $z_1 = \cos \frac{2\pi}{3} + i \frac{2\pi}{3}$ , and  $z_2 = \cos \frac{4\pi}{3} + i \sin \frac{4\pi}{3}$ , or in algebraic form

$$z_0 = 1, \quad z_1 = -\frac{1}{2} + i \frac{\sqrt{3}}{2}, \quad z_2 = -\frac{1}{2} - i \frac{\sqrt{3}}{2}.$$

An appropriate Sage cell that gives directly all three solutions in algebraic form reads as

```
z=var (" z "); solve ( z**3-1==0 , z )
```

It is easy to verify that  $|z_i| = 1$  for any  $i = 0, 1, 2$ , so each of them lies on the unit circle  $S^1$ , see the figure below. In addition, we see that  $z_1^2 = \bar{z}_1 = z_2$ . It follows that the coordinate points of  $z_0, z_1, z_2 = \bar{z}_1$  form an equilateral triangle with sides of length  $\sqrt{3}$  as we can see in the figure (for instance the points  $z_1, z_2$  are conjugate each other, so their distance is  $2\sqrt{3}/2 = \sqrt{3}$ ).

(b) The first claim follows by the fundamental theorem. Now, as for the case  $n = 3$ , de Moivre's formula provides the argument of the roots. In particular, we see that the argument multiplied by  $n$  has to be a multiple of  $2\pi$ . Moreover, the absolute value has to be one, so the roots are of the form

$$z_k = \cos\left(\frac{2k\pi}{n}\right) + i \sin\left(\frac{2k\pi}{n}\right), \quad k = 0, \dots, n-1.$$

Recall now that polygons are geometric objects in the plane composed of points and line segments connected together to close and form a single shape. A regular polygon is a polygon having equal angles and sides of equal length. For the roots derived above we see that the argument of any two consecutive of them, differs by  $2\pi/n$ . Moreover, the absolute value of any root equals to 1. Together these claims prove that the points under question are vertexes of a regular  $n$ -polygon.  $\square$

**1.G.18. Polygons via Sage.** In Sage on can apply the following cell to produce the second figure given above (this already includes the code producing the first simpler figure).

```
n=3;
A=[exp(2*pi*I*k/n) for k in range(n)]
a = plot([],xmin=-1, xmax=1, ymin=-1, ymax=1, figsize=(4,4), rgbcolor=(1/4,1/8,3/4))
a+=list_plot(A, color="black", size=70, xmin=-1,xmax=1)
a+= circle ((0.0 ,0.0) ,1, color="black")
a+=line([(-1/2, (sqrt(3)/2)), (-1/2,-(sqrt(3)/2))], color="black", linestyle="--")
a+=line([(-1/2, (sqrt(3)/2)), (1, 0)], color="black", linestyle="--")
a+=line([(1, 0), (-1/2,-(sqrt(3)/2))], color="black", linestyle="--")
a+= text ("z_2", (-0.65, (sqrt(3)/2)+0.05), color="black", fontsize="16")
a+= text ("z_3", (-0.65, -(sqrt(3)/2) -0.05), color="black", fontsize="16")
a+= text ("z_1", (1.10, 0.07), color="black", fontsize="16")
show(a)
```

In fact, the commands of the first five lines in the previous code, with only difference the initial  $n$ , can produce similar plots for our favourite  $n$  (though for large  $n$  Sage needs time to answer). Below we present the figures for  $n = 5, 15, 25, 50$ .

Finally it is also possible to produce directly the regular polygons, using the command `polygon2d`. Let us present a Sage cell adapted to the case  $n = 6$ .

```
n=6; A=[exp(2*pi*I*k/n) for k in range(n)]
a = plot([],xmin=-1, xmax=1, ymin=-1, ymax=1, figsize=(4,4))
a+=list_plot(A, color="black", size=10, xmin=-1,xmax=1)
a+=circle((0.0,0.0),1,color="black")
L = [[cos(pi*i/3), sin(pi*i/3)] for i in range(6)]
b=polygon2d(L, color="lightgrey")
show(a+b)
```

This produces the hexagon:

**1.G.19.** Enumerate all ordered pairs  $(x, y) \in \mathbb{R} \times \mathbb{R}$  satisfying the relation  $(x + iy)^{2024} = x - iy$ .

**Solution.** Setting  $z = x + iy$  the given relation becomes  $z^{2024} = \bar{z}$ . Recall that  $|z^2| = |z|^2$  and by mathematical induction (or by de Moivre's formula) one can prove that  $|z^n| = |z|^n$  for any  $n \in \mathbb{Z}$ . Thus, having in mind the relation  $z^{2024} = \bar{z}$  we compute

$$|z|^{2024} = |z^{2024}| = |\bar{z}| = |z| \iff |z|(|z|^{2023} - 1) = 0.$$

From this equation we see that either  $|z| = 0$  or  $|z| = 1$ . The first condition implies that  $(x, y) = (0, 0)$ . If  $|z| = 1$ , then using the relation  $z^{2024} = \bar{z}$  we see that  $z^{2025} = z\bar{z} = |z|^2 = 1$ . However the equation  $z^{2025} = 1$  has 2025 distinct roots. Hence, all together we can enumerate  $2025 + 1$  ordered pairs  $(x, y) \in \mathbb{R} \times \mathbb{R}$  satisfying the given condition.  $\square$

B) MATERIAL ON DIFFERENCE EQUATIONS

**1.G.20. Tilings.** For the Problem 1.B.4 on 2-compositions of natural numbers and for the given solution provide a visual interpretation.

**Solution.** To provide a visual presentation of  $C_n$  (and so also of the Fibonacci numbers) one may think the 1s as squares, and the 2s as dominoes. Then  $C_n$  counts the distinct ways to tile a board of length  $n$  with squares and dominoes, and the result proved in 1.B.4 means that we have  $F_{n+1}$  ways to do so. Below we illustrate the idea for  $n = 4$  and  $n = 5$ . For  $n = 4$  one has the 2-compositions  $1 + 1 + 1 + 1, 1 + 1 + 2, 1 + 2 + 1, 2 + 1 + 1, 2 + 2$ , that is,  $C_4 = 5 = F_5$ . Notice that  $C_4 = C_3 + C_2 = 3 + 2$ .

For  $n = 5$  we can define 8 such decompositions, i.e.,  $C_5 = 8 = F_6$ , as we can see also in the figure below (notice that  $C_5 = C_4 + C_3 = 5 + 3$ ).

$\square$

**1.G.21. Basic properties of Fibonacci numbers.** Show that the Fibonacci numbers  $F_n$  satisfying the following:

- (a) The sum of the first  $n$  Fibonacci numbers equals to  $F_{n+2} - 1$ ;
- (b)  $F_1^2 + F_2^2 + \dots + F_n^2 = F_n F_{n+1}$ ;
- (c)  $F_{m+n} = F_{n-1} F_m + F_n F_{m+1}$ ;
- (d)  $F_{n-1} F_{n+1} - F_n^2 = (-1)^n$ .

**Solution.** (a) We have  $F_1 = F_3 - F_2, F_2 = F_4 - F_3, \dots, F_{n-1} = F_{n+1} - F_n$  and  $F_n = F_{n+2} - F_{n+1}$ . Adding these relations (side by side), we get  $F_1 + F_2 + \dots + F_n = F_{n+2} - F_2$  and the claim follows.

(b) First notice that using the recurrence relation of Fibonacci numbers one may extend these numbers to zero and negative indices, and here we need to know that  $F_0 = F_2 - F_1 = 0$ . Now, since we have

$$F_k F_{k+1} - F_{k-1} F_k = F_k (F_{k+1} - F_{k-1}) = F_k^2,$$

we obtain the relations

$$F_1^2 = F_1 F_2, \quad F_2^2 = F_2 F_3 - F_1 F_2, \quad \dots, \quad F_n^2 = F_n F_{n+1} - F_{n-1} F_n.$$

Adding these relations (side by side) we arrive to the desired formula.

(c)+(d) The last two cases can be proved by induction over  $n$  and we shall prove (d) only, which is known as the *Cassini identity*. For  $n = 1$  it becomes  $F_0 F_2 - F_1^2 = 0 \cdot 1 - 1^2 = -1 = (-1)^1$ , which is true. The induction hypothesis says that the result is true for some arbitrary positive integer  $k$ , which mean that

$$F_{k-1}F_{k+1} - F_k^2 = (-1)^k. \quad (*)$$

Then, for  $n = k + 1$  we compute

$$\begin{aligned} F_k F_{k+2} - F_{k+1}^2 &= (F_{k+1} - F_{k-1})(F_k + F_{k+1}) - F_{k+1}^2 = F_{k+1}F_k + F_{k+1}^2 - F_{k-1}F_k - F_{k-1}F_{k+1} - F_{k+1}^2 \\ &\stackrel{(*)}{=} F_{k+1}F_k - F_{k-1}F_k - (F_k^2 + (-1)^k) = F_{k+1}F_k - F_k(F_{k-1} + F_k) + (-1)^{k+1} \\ &= F_{k+1}F_k - F_k F_{k+1} + (-1)^{k+1} = (-1)^{k+1}, \end{aligned}$$

where we have applied repeatedly the definition of Fibonacci numbers. This means that the claim is true for  $n = k + 1$ , and hence is valid for all  $n \geq 1$ .  $\square$

Recurrence relations have a wide range of applications across various fields, often in surprising ways. For example, linear recurrences naturally arise in simple geometric problems, requiring creative problem-solving skills. For your convenience, we have included some examples of these problems below. In Chapter 3 we will cover difference equations again, this time with more advanced applications to expand upon the introduction given in this chapter.

**1.G.22.** Consider  $n$  lines dividing a plane into regions. Find the maximum number of regions that are formed.

**Solution.** Let us denote the number of regions by  $p_n$ . If there is no line in the plane, then the whole plane is one region and  $p_0 = 1$ . If there are  $n$  lines, then adding an additional line will increase the number of regions, exactly by the number of regions that the new line intersects. If no lines are parallel and no three lines intersect at the same point, then the number of regions intersected by the  $(n + 1)$ th line is one more than the number of intersections it has with the existing  $n$  lines. Each intersection divides an existing region into two, resulting in an increase of one region for each intersection. The new line can have at most  $n$  intersections with the existing  $n$  lines. Each segment of the line between two intersections crosses exactly one region, so the new line can cross at most  $n + 1$  regions. Thus we obtain the recurrence relation  $p_{n+1} = p_n + (n + 1)$ , with  $p_0 = 1$ . We can derive an explicit formula for  $p_n$  via Corollary 1.2.3, which we leave to the reader. A more straightforward approach relies on the observation that  $p_n = p_{n-1} + n$ . This gives

$$\begin{aligned} p_n &= p_{n-1} + n = p_{n-2} + (n - 1) + n \\ &= p_{n-3} + (n - 2) + (n - 1) + n = \dots \\ &= p_0 + \sum_{i=1}^n i = 1 + \frac{n(n + 1)}{2} = \frac{n^2 + n + 2}{2}. \end{aligned}$$

Or we can use Sage as we did in 1.B.3:

```
from sympy import Function, rsolve
from sympy.abc import n
p = Function("p")
eq = p(n) - p(n+1) + n + 1
initial = {p(0):1, p(1):2}
rsolve(eq, p(n), initial)
```

$\square$

**1.G.23.** What is the maximum number of areas that a 3-dimensional space can be divided into by  $n$  planes?

**Solution.** Let  $r_n$  be the desired number. Obviously,  $r_0 = 1$ . As in 1.G.22, let us consider  $n$  planes in the space. Now, add an additional plane and determine the maximum number of new regions it can create. The maximum number of new regions is precisely the number of regions that the new plane intersects. What is the maximum number of new regions that can be created?

The number of areas intersected by the  $(n + 1)$ th plane equals the number of regions created by the intersections of this new plane with the  $n$  existing planes. According to the exercise in plane, there can be at most  $1/2 \cdot (n^2 + n + 2)$  such regions. Therefore, we obtain the recurrent formula

$$r_{n+1} = r_n + \frac{n^2 + n + 2}{2}.$$

This equation can be solved directly as follows:

$$\begin{aligned}
 r_n &= r_{n-1} + \frac{(n-1)^2 + (n-1) + 2}{2} = r_{n-1} + \frac{n^2 - n + 2}{2} = r_{n-2} + \frac{(n-1)^2 - (n-1) + 2}{2} + \frac{n^2 - n + 2}{2} \\
 &= r_{n-2} + \frac{n^2}{2} + \frac{(n-1)^2}{2} - \frac{n}{2} - \frac{(n-1)}{2} + 1 + 1 = r_{n-3} + \frac{n^2}{2} + \frac{(n-1)^2}{2} + \frac{(n-3)^2}{2} - \frac{n}{2} - \frac{(n-1)}{2} - \frac{(n-2)}{2} \\
 &\quad + 1 + 1 + 1 \\
 &= \dots = r_0 + \frac{1}{2} \sum_{i=1}^n i^2 - \frac{1}{2} \sum_{i=1}^n i + \sum_{i=1}^n 1 = 1 + \frac{n(n+1)(2n+1)}{12} - \frac{n(n+1)}{4} + n = \frac{n^3 + 6n + 5}{6}.
 \end{aligned}$$

Above we used the formula

$$\sum_{i=1}^n i^2 = \frac{n(n+1)(2n+1)}{6},$$

which you may want to prove using mathematical induction. □

**1.G.24.** Find the maximum number of areas that the plane can be divided into by  $n$  circles.

**Solution.** A solution to this geometric problem again relies on a recurrence which can be described as follows:

First observe that the  $(n+1)$ th circle intersects the  $n$  existing circles in at most  $2n$  points. For example, see the figure presented at the right-hand side for the case of  $2 + 1$  circles; the third circle intersects the previous two into 4 points (hence  $4 = 2n$  for  $n = 2$ ). Thus, for the maximum number  $p_n$  of areas one can derive the recurrent formula

$$p_{n+1} = p_n + 2n.$$

Clearly  $p_1 = 2$ . Thus for  $p_n$  we obtain

$$\begin{aligned}
 p_n &= p_{n-1} + 2(n-1) = \\
 p_{n-2} + 2(n-2) + 2(n-1) &= \dots = p_1 + \sum_{i=1}^{n-1} 2i = n^2 - n + 2.
 \end{aligned}$$

ADDING THE THIRD CIRCLE

Or we may directly solve the recurrence in Sage, as before:

```

from sympy import Function, rsolve
from sympy.abc import n
p = Function("p")
eq = p(n)-p(n+1)+2*n
initial = {p(1):2, p(2):4}
rsolve(eq, p(n), initial)
    
```

□

**1.G.25.** Determine the maximum number of regions that a 3-dimensional space can be divided into by  $n$  balls. ○

**1.G.26.** Find the number of regions formed when  $n$  distinct planes intersect at a single point in a 3-dimensional space. ○

C) MATERIAL ON COMBINATORICS

**1.G.27. Pascal's triangle via Sage.** Recall that Pascal's triangle is formed by the binomial coefficients, as discussed in the section at the end of the paragraph 1.3.2. In particular, the entry in the  $n$ th row and  $k$ th column of Pascal's triangle is given by the binomial coefficient  $\binom{n}{k}$ . For example for  $n = 6$  we get the following illustration:

Note that in the second figure, the colored "diagonals" represent the natural numbers and triangular numbers, respectively, the latter as illustrated in the first exercise of this section. Present the Pascal's triangle via Sage for  $n = 9$ .

**Solution.** It is sufficient to use the command `binomial(n, i)` and type the cell:

```
[[binomial(n, i) for i in range(n+1)] for n in range(9)]
```

Alternatively, we can give the cell

```
n=8
[[binomial(i, j) for j in range(i + 1)] for i in range(n + 1)]
```

Sage prints out the following:

```
[[1],
 [1, 1],
 [1, 2, 1],
 [1, 3, 3, 1],
 [1, 4, 6, 4, 1],
 [1, 5, 10, 10, 5, 1],
 [1, 6, 15, 20, 15, 6, 1],
 [1, 7, 21, 35, 35, 21, 7, 1],
 [1, 8, 28, 56, 70, 56, 28, 8, 1]]
```

□

**1.G.28.** For any fixed  $n \in \mathbb{N}$ , determine the number of all solutions of the equation  $x_1 + x_2 + \cdots + x_k = n$  for the following two cases:

- (a) over the set  $\mathbb{Z}_{\geq} := \{a \in \mathbb{Z} : a \geq 0\}$  of non-negative integers;  
 (b) over the set  $\mathbb{Z}_{+} := \{a \in \mathbb{Z} : a > 0\}$  of strictly positive integers.

**Solution.** (a) Every solution  $(r_1, \dots, r_k)$  to the equation  $\sum_{i=1}^k x_i = n$  can be uniquely encoded as a sequence of 1s and separators. In particular, the sequence is constructed by writing  $r_1$  1s, followed by a separator, then  $r_2$  1s, followed by another separator, and so on. Consequently, this sequence contains exactly  $n$  1s, and  $k - 1$  separators. Each such sequence uniquely corresponds to a solution of the given equation. Therefore, the number of solutions is equal to the number of such sequences, and the latter is given by  $\binom{n+k-1}{n}$ .

(b) We now look for a solution in the domain of positive integers. We see that the natural numbers  $x_1, \dots, x_k$  provide a solution of the given equation if and only if the non-negative integers  $y_i = x_i - 1, i = 1, \dots, k$  form a solution of the equation

$$y_1 + y_2 + \cdots + y_k = n - k.$$

Using the result obtained in (a), we deduce that there are  $\binom{n-1}{k-1}$  of them. □

**1.G.29. (Trolleybus)** (a) In how many ways can five people seat in a car for five people, under the assumption that only two of them have a driving licence?

(b) In how many ways can 20 passengers and two drivers be seated in a trolleybus for 25 people? ○

**1.G.30. (Flipping coins – I)** We flip a coin six times.

(a) How many distinct sequences of heads and tails are there?

(b) How many sequences with exactly four heads are there?

(c) How many sequences with at least two heads are there? ○

**1.G.31. (Playing with divisions)** Determine the number of all possible ways that the following can happen:

(a) divide 40 identical balls among 4 boys?

(b) divide among three people  $A, B$  and  $C$ , 33 distinct coins such that  $A$  and  $B$  together have twice as many coins as  $C$ .

(c) divide 9 girls and 6 boys into two group such that each group contains at least two boys. ○

**1.G.32.** According to quality, we divide food products into groups  $I, II, III, IV$ . Determine the number of all possible divisions of 9 food products into these groups, such that the numbers of products in groups are all distinct.

**Solution.** If we directly write the considered groups from the elements of  $I, II, III, IV$ , we create combinations of repetitions of the ninth-order from four elements. The number of such combinations is  $\binom{12}{9} = 220$ . □

**1.G.33. (Handshakes)** New players meet in a volleyball team (6 people). How many handshakes are there when everybody shakes once with everybody else? How many handshakes are there if everybody shakes hands once with each opponent after playing a match? ○

**1.G.34.** We need to accommodate 9 people in one four-bed room, one three-bed room and one two-bed room. In how many ways can this be done?

**Solution.** We may assign to the people in the four-bed room the number 1, in the three-bed room number 2 and in the two-bed room number 3. In this way we create permutations with repetitions from the elements 1, 2, 3, where 1 occurs four times, 2 three times and 3 two times. The number of such permutations is  $\frac{9!}{4! \cdot 3! \cdot 2!} = 1260$ .  $\square$

**1.G.35.** In a long-distance race, where the racers start one after another in given time intervals, there were  $k$  racers, among them 3 friends. Determine the number of starting schedules in which no two of the 3 friends start next to each other. For simplicity assume  $k \geq 5$ .

**Solution.** Remaining  $k - 3$  racers can be ordered in  $(k - 3)!$  ways. For the three friends there are then  $k - 2$  places (the start, the end and the  $k - 4$  spaces) where we can put them in  $v(k - 2, 3)$  ways. Using the rule of (combinatorial) product, we obtain

$$(k - 3)! \cdot (k - 2) \cdot (k - 3) \cdot (k - 4) = (k - 2)! \cdot (k - 3) \cdot (k - 4).$$

$\square$

**1.G.36.** There are 32 participants of a tournament. The organisers have stated that the participants must divide arbitrarily into four groups, such that the first one has size 10, the second and the third 8, and the fourth 6. In how many ways can this be done?

**Solution.** We can imagine that from 32 participants we create a row, where first 10 are the first group, next 8 are the second group and so on. On the other hand, there are  $32!$  orderings of all participants. Note that the division into groups is not influenced if we change the order of the people in the same group. Therefore the number of distinct divisions equals to  $\frac{32!}{10! \cdot 8! \cdot 8! \cdot 6!}$ .  $\square$

#### D) MATERIAL ON PROBABILITIES

*Next we will provide supplementary material on basic and conditional probability. Probability theory will be explored in depth in Chapter 10, where we will build on this foundational material by introducing additional key results, such as Bayes' theorem, and discussing its significance in statistics. Additionally, the rich interplay between combinatorics and probability will be examined in Chapter 13, which concludes the book.*

**1.G.37.** For the final exams in the 6th class of all the high-schools in a European country, it is known that:

- 25% of the students fails in the exams of mathematics;
- 18% of the students fails in the exams of physics;
- 10% of the students fails both in the exams of mathematics and physics.

Choose randomly a student belonging to this class.

- (a) Find the probability the student has failed at least in one of these two subjects;
- (b) Find the probability the student has failed in the exams of mathematics, but not in the exams of physics.
- (c) If the student has failed in the exams of physics, find the probability he also failed in the exams of mathematics.
- (d) If the student has failed in the exams of mathematics, find the probability he also failed in the exams of physics.

**Solution.** We define two events: the event M, described by “The candidate has failed in the exams of mathematics”, and the event P, described by “The candidate has failed in the exams of physics”.

- (a) We should compute  $P(M \cup P) = P(M) + P(P) - P(M \cap P)$  which gives  $0.25 + 0.18 - 0.1 = 0.33$ .
- (b) In this case we should compute  $P(M \cap P^c)$ , which equals to  $P(M) - P(M \cap P) = 0.25 - 0.1 = 0.15$ .
- (c) We are looking for the probability  $P(M|P)$ . By definition, we have

$$P(M|P) = \frac{P(M \cap P)}{P(P)} = \frac{0.1}{0.18} \approx 0.55.$$

- (d) In this final case we are looking for the probability  $P(P|M)$ , which is given by

$$P(P|M) = \frac{P(P \cap M)}{P(M)} = \frac{0.1}{0.25} = 0.4.$$

$\square$

**1.G.38.** From ten cards, where exactly one is an ace, we randomly draw a card and put it back. How many times must we do this, so that the probability that the ace is drawn at least once, is greater than 0.9?

**Solution.** Let  $A_i$  be the following event: “at  $i$ th drawing the ace was drawn”. The individual events  $A_i$  are independent, so we know that

$$P\left(\bigcup_{i=1}^n A_i\right) = 1 - (1 - P(A_1)) \cdot (1 - P(A_2)) \cdots (1 - P(A_n)), \quad n \in \mathbb{N}.$$

We are looking for some  $n \in \mathbb{N}$  satisfying

$$P\left(\bigcup_{i=1}^n A_i\right) = 1 - (1 - P(A_1)) \cdot (1 - P(A_2)) \cdots (1 - P(A_n)) > 0.9.$$

Clearly,  $P(A_i) = 1/10$  for all  $i \in \mathbb{N}$ . Therefore, it is sufficient to solve the inequality

$$1 - \left(\frac{9}{10}\right)^n > 0.9,$$

from which one gets

$$n > \frac{\log_a 0.1}{\log_a 0.9}, \quad \text{where } a > 1.$$

Evaluating, we deduce that one must do the drawing at least twenty two times. In particular, a Sage cell verifying this has the following form:

```
x = var("x")
ineq = 1 - 0.9**x > 0.9
sol = solve(ineq, x, algorithm="sympy")
print(sol)
```

Sage prints out  $x > 21.8543453267828$ . □

**1.G.39. (Playing with a dice)**

- (a) Throwing a dice eleven times in a row the result was 4. Determine the probability that the twelfth roll results in 4.
- (b) Throwing  $n$  dice, compute the probability that among the numbers that appeared the values 1, 3 and 6 are not present.
- (c) Throwing a dice determine the conditional probability, that the first die resulted in five under the condition that the sum is 9. Based on this result, decide whether the events “first dice results in five” and “the sum is 9”, are independent. ○

**1.G.40.** We flip a coin five times. For every head, we put a white ball in a hat, for every tail we put in the same hat a black ball. Compute the probability that in the hat there are more black balls than white balls, if there is at least one black ball in the hat.

**Solution.** We can introduce the following two events:

- A – “There are more black than white balls in the hat”;
- H – “There is at least one black ball in the hat”.

Notice the event A has H as a consequence. Denote by  $A^c, H^c$  the complementary events of A and H, respectively. The goal is to compute the conditional probability  $P(A|H)$ . The probability  $P(H^c)$  is  $2^{-5}$ , and the probability of H is the same as the probability  $P(A^c)$  of the complementary event of A. Thus  $P(H) = 1 - 2^{-5}$  and moreover  $P(A) = 1/2$ . Furthermore  $P(A \cap H) = P(A)$ , since the event H contains the event A, as it was mentioned above. This finally gives

$$P(A|H) = \frac{P(A \cap H)}{P(H)} = \frac{\frac{1}{2}}{1 - \left(\frac{1}{2}\right)^5} = \frac{16}{31}.$$
□

**1.G.41.** In a painting exhibition there are 15 paintings and between them 12 are authentic and 3 are copies. A visitor chooses randomly a painting and asks the opinion of an art expert about the authentication of the artwork. The expert can give a correct opinion both about an original painting as much as for a copy, on average 9 out of 10 times. If the expert decides that the painting is authentic, find the probability the expert is right.

**Solution.** (a) Let us consider the events:

- A – “The painting is authentic”;
- B – “The expert considers that the painting is authentic”.

We are looking for the conditional probability  $P(A|B)$ . By the statement we have  $P(A) = \frac{12}{15} = \frac{4}{5}$  and  $P(A^c) = \frac{3}{15} = \frac{1}{5} = 1 - P(A)$ . We also see that the probability of the event B occurring, given that A is true, equals to 9/10, i.e.,  $P(B|A) = \frac{9}{10}$ .

Similarly  $P(B^c|A^c) = \frac{9}{10}$  and moreover  $P(B^c|A) = \frac{1}{10} = P(B|A^c)$ . Thus, by the definition of the conditional probability and the product rule we get

$$P(A|B) = \frac{P(A \cap B)}{P(B)} = \frac{P(A) \cdot P(B|A)}{P(B)}. \quad (*)$$

However, by Bayes' formula, see 10.2.7 we have

$$P(B) = P(A) \cdot P(B|A) + P(A^c) \cdot P(B|A^c) = \frac{4}{5} \cdot \frac{9}{10} + \frac{1}{5} \cdot \frac{1}{10} = \frac{37}{50}.$$

Thus, in combination with (\*) we arrive to  $P(A|B) = \frac{36}{37}$ . □

**1.G.42.** A rod of length two meters is randomly divided into three parts. Determine the probability that at least one part is at most 20 cm long.

**Solution.** Random division of a rod into three parts is given by two points of the cut,  $x$  and  $y$  (we first cut the rod in the distance  $x$  from the origin, we do not move it and again cut it in the distance  $y$  from the origin). The sample space is a square  $C$  with side 2 meters, see also the figure below.

If we place the square  $C$  so that its two sides lie on axes in the plane, then the condition that at least one part is at most 20 cm determines in the square a subregion  $O$ , defined by

$$O = \{(x, y) \in C : x \leq 20 \vee x \geq 180 \vee y \leq 20 \vee y \geq 180 \vee |x - y| \leq 20\}.$$

A straightforward computation shows that this subregion has area  $\frac{51}{100}$  times the area of the square. Let us now explain how one can treat this task via Sage. We first use the a cell to generate some random points.

```
num_points = 100_000
#Generate num_points points
x=[RealField().random_element(min=0, max=2) for _ in range(num_points)]
y=[RealField().random_element(min=0, max=2) for _ in range(num_points)]
```

Next we divide the points into two groups corresponding to the case where one piece of rod is less than 20 cm.

```
favourable_events = []
other_events = []
for i, j in zip(x, y):
    if abs(i-j) <= 5:
        favourable_events.append((i, j))
    else:
        other_events.append((i, j))
```

Finally we plot these two sets using red and blue colour (as we see in the figure posed above) via the cell

```
scatter1 = scatter_plot(short_rod_cases, facecolor="blue",
                        marker="o", markersize=10, edgecolor="blue")
scatter2 = scatter_plot(other_cases, facecolor="red",
                        marker="o", markersize=10, edgecolor="red")
show(scatter1+scatter2, axes=true, aspect_ratio=1, ticks=[0.2,0.2])
```

This returns the figure posed above. Recall that we are interested in the ratio of the blue area to the total area of the square. To this end, we can compute its approximate value by typing

```
len(short_rod_cases) / (len(short_rod_cases) + len(other_cases))
```

Sage prints out the estimation 0.51018. □

**1.G.43.** Michael and Alex have a lunch at the school canteen, which operates from 11 to 14. Each of them takes a lunch for 30 minutes, and the arrival time is random. What is the probability that they meet at a given day, if they always sit at the same table? ○

E) MATERIAL ON PLANE GEOMETRY

**1.G.44.** Compute the area  $S$  of a quadrilateral with vertices  $A = [0, -2]$ ,  $B = [1, -1]$ ,  $C = [1, 5]$ , and  $D = [-1, 1]$ . ○

**1.G.45.** Determine the relative position of the lines  $p, q$  in the plane for  $p : 2x - y - 5 = 0$ ,  $q : x + 2y - 5 = 0$ . If they are not parallel, determine the intersection point. ○

**1.G.46.** Determine the sum of the three angles, which are between the vectors  $(1, 1)$ ,  $(2, 1)$  and  $(3, 1)$  respectively and the  $x$ -axis in the plane  $\mathbb{R}^2$ . ○

**1.G.47.** Compute the area of parallelogram with vertices at  $[5, 5]$ ,  $[6, 8]$  at  $[6, 9]$ .

**Solution.** Although such parallelogram is not uniquely determined (the fourth vertex is not given), the triangle with vertices at  $[5, 5]$ ,  $[6, 8]$  and  $[6, 9]$  must be necessarily a half of every parallelogram with these three vertices (one of the sides of the triangle becomes the diagonal of the parallelogram). Therefore the area equals the determinant

$$\begin{vmatrix} 6-5 & 6-5 \\ 8-5 & 9-5 \end{vmatrix} = \begin{vmatrix} 1 & 1 \\ 3 & 4 \end{vmatrix} = 1 \cdot 4 - 1 \cdot 3 = 1. \quad \square$$

**1.G.48.** Determine the angle  $\varphi$  between the two diagonals  $A_3A_7$  and  $A_5A_{10}$  of a regular dodecagon  $A_0A_1A_2 \dots A_{11}$ .

**Solution.** The angle does not depend neither on the size, nor on the position of the given dodecagon. Consider a dodecagon inscribed in a circle with a diameter of 1, and let  $A_0$  be the point  $[1, 0]$ . The vertices of the dodecagon can be then represented by the twelfth roots of unity in the complex plane. Thus we can write  $A_k = \cos(2k\pi/12) + i \sin(2k\pi/12)$  and hence

$$\begin{aligned} A_3 &= \cos(\pi/2) + i \sin(\pi/2) = i \sim [0, 1], & A_5 &= \cos(5\pi/6) + i \sin(5\pi/6) = -\frac{\sqrt{3}}{2} + \frac{1}{2}i \sim \left[-\frac{\sqrt{3}}{2}, \frac{1}{2}\right], \\ A_7 &= \cos(7\pi/6) + i \sin(7\pi/6) = -\frac{\sqrt{3}}{2} - \frac{1}{2}i \sim \left[-\frac{\sqrt{3}}{2}, -\frac{1}{2}\right], & A_{10} &= \cos(5\pi/3) + i \sin(5\pi/3) = 1/2 - i\frac{\sqrt{3}}{2} \sim \\ & & & \left[1/2, -\frac{\sqrt{3}}{2}\right]. \end{aligned}$$

Combining now the description given in 1.5.7, we deduce that  $\cos \varphi = \frac{1}{2\sqrt{2+\sqrt{3}}}$ . This gives  $\varphi = 75^\circ$ . □

**1.G.49.** Consider the matrices

$$A = \begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix}, \quad B = \begin{pmatrix} 1 & 2 \\ -2 & 1 \end{pmatrix}, \quad X = \begin{pmatrix} a & b \\ c & d \end{pmatrix}, \quad D = \begin{pmatrix} 5 & -b \\ 4 & -4d \end{pmatrix}, \quad E = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}$$

with  $a, b, c, d \in \mathbb{R}$ . Solve the matrix equation  $X(E - A^2) + BB^T = D$ . ○

**1.G.50.** Illustrate the expression of a rotation as a composition of shears on an interactive plot, using Sage (use the method from 1.E.18).

**Solution.** A solution goes as follows:

```
# import the the right objects and define the shear functions
from sage.plot.point import point
from sage.plot.line import line
def shear_transformation(x, y, shear_factor):
    new_x = x + shear_factor * y
    new_y = y
    return new_x, new_y
def shear_vert_transformation(x, y, shear_factor):
    new_x = x
    new_y = y + shear_factor * x
    return new_x, new_y
# create an illustrative interactive plot
@interact
def plot_shear(b=(0.0, 1.0, 0.02)):
    # choose points and lines to show
    points1 = [(0, 0), (1, 1), (1, 2), (2, 3)]
    points2 = [(1, 1), (2, 2), (2, 3), (3, 4)]
```

```

# get the shear parameters a and apply shears
a = (sqrt(-b^2 + 1) - 1)/b
sheared_points11 = [shear_transformation(x, y, a) for x, y in points1]
sheared_points12 = [shear_transformation(x, y, a) for x, y in points2]
sheared_points21 = [shear_vert_transformation(x, y, b) for x, y in sheared_points11]
sheared_points22 = [shear_vert_transformation(x, y, b) for x, y in sheared_points12]
sheared_points31 = [shear_transformation(x, y, a) for x, y in sheared_points21]
sheared_points32 = [shear_transformation(x, y, a) for x, y in sheared_points22]
# prepare the objects for the final plot
p1 = point(points1, color='blue', size=50)
p2 = point(points2, color='blue', size=50)
p_sheared11 = point(sheared_points11, color='red', size=25)
p_sheared12 = point(sheared_points12, color='red', size=25)
p_sheared21 = point(sheared_points21, color='green', size=25)
p_sheared22 = point(sheared_points22, color='red', size=25)
p_sheared31 = point(sheared_points31, color='red', size=50)
p_sheared32 = point(sheared_points32, color='red', size=50)
l1 = line(points1, thickness=2)
l2 = line(points2, thickness=2)
l1_sheared1 = line(sheared_points11, thickness=1, color='black')
l2_sheared1 = line(sheared_points12, thickness=1, color='black')
l1_sheared2 = line(sheared_points21, thickness=1, color='green')
l2_sheared2 = line(sheared_points22, thickness=1, color='green')
l1_sheared3 = line(sheared_points31, thickness=2, color='red')
l2_sheared3 = line(sheared_points32, thickness=2, color='red')
# Combine the plots and show the result (choose options)
combined_plot = p1 + p_sheared11 + p_sheared21 + p_sheared31
combined_plot += p2 + p_sheared12 + p_sheared22 + p_sheared32
combined_plot += l1 + l1_sheared1 + l1_sheared2 + l1_sheared3
combined_plot += l2 + l2_sheared1 + l2_sheared2 + l2_sheared3
combined_plot.show(axes_labels=['x', 'y'], gridlines=True, aspect_ratio=1, figsize=8)

```

Executing this code (for one chosen value of  $b = \sin \theta$ , e.g.,  $b = 3$ ) we obtain the following picture:

□

**1.G.51.** (a) Let  $ABC$  be the triangle on the plane with vertices the points  $A = [1, 0]$ ,  $B = [4, -2]$  and  $C = [2, -3]$ , respectively. Reflect  $ABC$  with respect to the  $x$ -axis and illustrate the initial triangle and the result of the reflection via Sage.

**Solution.** On  $\mathbb{R}^2$  the reflection with respect to the  $x$ -axis is the linear mapping  $f : \mathbb{R}^2 \rightarrow \mathbb{R}^2$  with  $u = (x, y)^T \mapsto f(u) := (x, -y)^T$ . Obviously, the  $x$ -axis is the fixed points set of  $f$ , which means that  $f$  preserves  $A = [1, 0]$ . However, it transforms  $B$  and  $C$  to  $B' = [4, 2]$  and  $C' = [2, 3]$ , respectively, see the figure given below. Alternatively, recall that matrix of  $f$  with respect to the standard basis on  $\mathbb{R}^2$  is given  $\begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}$ , such that

$$f(u) = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix} u = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix} \begin{pmatrix} x \\ y \end{pmatrix} = \begin{pmatrix} x \\ -y \end{pmatrix}.$$

Viewing  $A, B, C$  as vectors we obtain

$$f(A) = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix} \begin{pmatrix} 1 \\ 0 \end{pmatrix} = \begin{pmatrix} 1 \\ 0 \end{pmatrix}, \quad f(B) = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix} \begin{pmatrix} 4 \\ -2 \end{pmatrix} = \begin{pmatrix} 4 \\ 2 \end{pmatrix}, \quad f(C) = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix} \begin{pmatrix} 2 \\ -3 \end{pmatrix} = \begin{pmatrix} 2 \\ 3 \end{pmatrix}.$$

Thus indeed, reflecting the triangle  $ABC$  via  $f$ , we arrive to the triangle  $AB'C'$ , where  $B' = [4, 2]$  and  $C' = [2, 3]$ , respectively. An illustration in Sage can be seen below. Can you reproduce it in your editor? For help, see the cell given in 1.E.26.

□

**1.G.52.** Let  $ABCD$  be the trapezoid on the plane with vertices the points  $A = [0, 0]$ ,  $B = [4, 0]$ ,  $C = [3, 3/2]$  and  $D = [3/2, 3/2]$ . Let  $\{e_1 = (1, 0), e_2 = (0, 1)\}$  be the standard basis, identifying the plane with  $\mathbb{R}^2$ .

- Transform  $ABCD$  via the homothety  $h_{1/2}$ ;
- Stretch  $ABCD$  in the direction of  $e_1$  with stretching parameter  $c = 3/4$ .
- Stretch  $ABCD$  in the direction of  $e_2$  with stretching parameter  $c = 4/3$ .
- Apply to  $ABCD$  a horizontal shear with parameter  $a = 2$
- Apply to  $ABCD$  a vertical shear with parameter  $a = 1/2$
- Transform  $ABCD$  via the axial symmetry.

Illustrate all the cases.

**Solution.** (a) The matrix of  $h_{1/2}$  is  $\begin{pmatrix} \frac{1}{2} & 0 \\ 0 & \frac{1}{2} \end{pmatrix}$ , and we have  $h_{1/2}((x, y)^T) = (x/2, y/2)^T$ . Viewing  $A, B, C, D$  as vectors on the plane, one computes

$$h_{1/2}(A) = [0, 0] = A, \quad h_{1/2}(B) = [2, 0], \quad h_{1/2}(C) = [3/2, 3/4], \quad h_{1/2}(D) = [3/4, 3/4].$$

Thus, the new coordinates of the points  $B, C, D$  are  $B' = [2, 0]$ ,  $C' = [3/2, 3/4]$  and  $D' = [3/4, 3/4]$ , respectively, and so  $h_{1/2}$  has shrunk the trapezium (because  $0 < c = 1/2 < 1$ ), as you can see here:

(b) The matrix of stretching in the direction of  $e_1$  only, with stretching parameter  $c = 3/4$  is again diagonal, given by  $\begin{pmatrix} 3/4 & 0 \\ 0 & 1 \end{pmatrix}$ . This means that the corresponding transformation is given by  $(x, y)^T \mapsto (\frac{3x}{4}, y)^T$ , so it preserves the  $y$ -coordinates. Therefore

$$A = [0, 0] \mapsto A, \quad B = [4, 0] \mapsto [3, 0], \quad C = [3, 3/2] \mapsto [9/4, 3/2], \quad D = [3/2, 3/2] \mapsto [9/8, 3/2],$$

and the initial trapezium  $ABCD$  has been transformed to  $AB'C'D'$ , with  $B' = [3, 0]$ ,  $C' = [9/4, 3/2]$ , and  $D' = [9/8, 3/2]$ , respectively. Hence in this case an illustration looks like as follows:

(c) The stretching here preserves  $x$  and transforms  $y$  by  $\frac{4}{3}$ , i.e., it has the form  $(x, y)^T \mapsto (x, \frac{4y}{3})^T$ . We compute

$$A = [0, 0] \mapsto A, \quad B = [4, 0] \mapsto B, \quad C = [3, 3/2] \mapsto [3, 2], \quad D = [3/2, 3/2] \mapsto [3/2, 2],$$

thus the initial trapezium  $ABCD$  has been transformed to  $ABC'D'$ , with  $C' = [3, 2]$ , and  $D' = [3/2, 2]$ , respectively. As for the illustration we get

(d) As a transformation, the horizontal shear on the plane with parameter  $a = 2$  has matrix  $\begin{pmatrix} 1 & 2 \\ 0 & 1 \end{pmatrix}$ , and thus we get the assignment  $(x, y)^T \mapsto (x + 2y, y)^T$ . We compute

$$A = [0, 0] \mapsto A, \quad B = [4, 0] \mapsto B, \quad C = [3, 3/2] \mapsto [6, 3/2], \quad D = [3/2, 3/2] \mapsto [9/2, 3/2].$$

This means that the new coordinates of initial trapezium are now  $ABC'D'$  with  $C' = [6, 3/2]$  and  $D' = [9/2, 3/2]$ , respectively. Let us for a few postpone its illustration, and present it below together with the illustration of the vertical shear.

(e) The vertical shear on the plane with parameter  $a = 1/2$  has matrix  $\begin{pmatrix} 1 & 0 \\ 1/2 & 1 \end{pmatrix}$ , so it corresponds to the mapping  $(x, y)^T \mapsto (x, \frac{x}{2} + y)^T$ . We compute

$$A = [0, 0] \mapsto A, \quad B = [4, 0] \mapsto [4, 2], \quad C = [3, 3/2] \mapsto [3, 3], \quad D = [3/2, 3/2] \mapsto [3/2, 9/4],$$

hence in this case the new coordinates of  $ABCD$  are  $AB'C'D'$  with  $B' = [4, 2]$ ,  $C' = [3, 3]$  and  $D' = [3/2, 9/4]$ , respectively. Below, at the l.h.s is presented an illustration of the horizontal shear, while the vertical shear corresponds to the figure at the r.h.s.

(f) Recall that the axial symmetry is the linear transformation  $(x, y)^T \mapsto (y, x)^T$ . Let us present only the illustration of its action on  $ABCD$ , and leave to the reader the mathematical explanation of the figure. Can you predict the vertices which remain fixed (without an illustration or computation).

□

**1.G.53.** Let  $ABCD$  be the rhombus on the plane with vertices the points  $A = [0, 0]$ ,  $B = [5, 0]$ ,  $C = [8.4]$ , and  $D = [3, 4]$ , respectively.

- Rotate  $ABCD$  counter-clockwise around the origin for  $\theta_1 = \pi/3$ .
- Then rotate the rhombus obtained in (a), counter-clockwise around the origin for  $\theta_2 = \pi/3$ .
- Finally rotate the rhombus obtained in (b), counter-clockwise around the origin for another  $\theta_3 = \pi/3$ .
- Determine directly the final position of  $ABCD$ , after imposing the rotations described in (a), (b) and (c).

**Solution.** First observe that the given polygon  $ABCD$  is indeed a rhombus. This is because the vectors  $u_1 = \overrightarrow{AB}$  and  $u_2 = \overrightarrow{AD}$  are of the same length (with respect to the dot product on  $\mathbb{R}^2$ ),  $\|u_1\| = \|u_2\| = 5$ , and moreover the opposite sides are parallel each other. The angle between  $u_1, u_2$  equals to  $\arccos(3/5) \approx 53.13^\circ$ .

For a moment think why after applying a rotation on  $ABCD$ , the new polygon will be again a rhombus. This is because rotations preserves lengths and angles (we will essentially prove this in Chapter 2, studying orthogonal transformations). Thus, rotating  $ABCD$  around the origin, for any possible angle, we will obtain a rhombus with the same characteristics (same lengths and angles as those described for  $ABCD$ ).

The rotation matrix for  $\theta = \pi/3$  is given by  $\begin{pmatrix} 1/2 & -\sqrt{3}/2 \\ \sqrt{3}/2 & 1/2 \end{pmatrix}$ , and hence as a linear transformation on  $\mathbb{R}^2$ , the rotation  $R_{\pi/3}$  has the form

$$(x, y)^T \mapsto \left( \frac{x - \sqrt{3}y}{2}, \frac{\sqrt{3}x + y}{2} \right)^T.$$

Based on direct computations, one can now verify the following:

- (a) Under the action of  $R_{\pi/3}$  the points  $A, B, C, D$  (seen as vectors on  $\mathbb{R}^2$ ) are mapped to:

$$A \mapsto A, \quad B \mapsto [5/2, 5\sqrt{3}2], \quad C \mapsto [4 - 2\sqrt{3}, 4\sqrt{3} + 2], \quad D \mapsto \left[ \frac{3}{2} - 2\sqrt{3}, \frac{3\sqrt{3}}{2} + 2 \right].$$

Hence, a counter-clockwise rotation around the origin for  $\theta = \pi/3$  transforms the rhombus  $ABCD$  to  $AB_1C_1D_1$ , where  $B_1 = [5/2, 5\sqrt{3}2]$ ,  $C_1 = [4 - 2\sqrt{3}, 4\sqrt{3} + 2]$  and  $D_1 = \left[ \frac{3}{2} - 2\sqrt{3}, \frac{3\sqrt{3}}{2} + 2 \right]$ , respectively (see the figure below, where we have included all the rotations together).

- (b) Next we need to apply  $R_{\pi/3}$  to  $AB_1C_1D_1$ . We compute

$$A \mapsto A, \quad B_1 \mapsto [-5/2, 5\sqrt{3}2], \quad C_1 \mapsto [-4 - 2\sqrt{3}, 4\sqrt{3} - 2], \quad D_1 \mapsto \left[ -\frac{3}{2} - 2\sqrt{3}, \frac{3\sqrt{3}}{2} - 2 \right].$$

This means that  $AB_1C_1D_1$  has been transformed to the rhombus  $AB_2C_2D_2$ , where  $B_2 = [-5/2, 5\sqrt{3}2]$ ,  $C_2 = [-4 - 2\sqrt{3}, 4\sqrt{3} - 2]$  and  $D_2 = \left[ -\frac{3}{2} - 2\sqrt{3}, \frac{3\sqrt{3}}{2} - 2 \right]$ , respectively.

- (c) Let us finally apply the third rotation, using this time the rhombus  $AB_2C_2D_2$  obtained in (b). We compute

$$A \mapsto A, \quad B_2 \mapsto [-5, 0], \quad C_2 \mapsto [-8, -4], \quad D_2 \mapsto [-3, -4],$$

Thus a counter-clockwise rotation around the origin by  $\pi/3$  transforms the rhombus  $AB_2C_2D_2$  to  $AB_3C_3D_3$ , where  $B_3 = [-5, 0] = -B$ ,  $C_3 = [-8, -4] = -C$  and  $D_3 = [-3, -4] = -D$ , respectively. Let us illustrate all these rotations together in one figure (via Sage), as follows:

The code behind this figure is based on a bit more advanced options from 2D-graphics in Sage, comparing with what we have seen so far (as assigning automatically names to given points in a list). For the interested reader we pose it here:

```
pts = [(0, 0), (5, 0), (8, 4), (3, 4), (5/2, 5*sqrt(3)/2),
       (4-2*sqrt(3), 2+4*sqrt(3)), (3/2-2*sqrt(3), (3/2)*sqrt(3)+2),
       (-5/2, 5*sqrt(3)/2), (-4-2*sqrt(3), 4*sqrt(3)-2), (-3/2-2*sqrt(3), (3/2)*sqrt(3)-2),
       (-5, 0), (-8, -4), (-3, -4)]
pt_names = ['$A$', '$B$', '$C$', '$D$', '$B_1$', '$C_1$', '$D_1$', '$B_2$', '$C_2$',
            '$D_2$', '$B_3$', '$C_3$', '$D_3$']
pt_opt = {'color': 'black', 'horizontal_alignment': 'left', 'vertical_alignment': 'top'}
plt=point2d(pts, color='blue', size=20)
plt += sum(text(name, vector(pt), **pt_opt) for name, pt in zip(pt_names, pts))

              rgbcolor=(1/8,1/4,1/2), linestyle="--")#the rhombus AB_3C_3D_3
plt.show(aspect_ratio=1, figsize=8)
```

(d) This task relies on the principle that composing two rotations results in another rotation, which can be easily determined. In other words, applying a rotation by an angle  $\theta_1$  followed by a rotation by an angle  $\theta_2$  is equivalent to a single rotation by the angle  $\theta_1 + \theta_2$ . In terms of matrices, this implies that

$$\begin{pmatrix} \cos \theta_1 & -\sin \theta_1 \\ \sin \theta_1 & \cos \theta_1 \end{pmatrix} \begin{pmatrix} \cos \theta_2 & -\sin \theta_2 \\ \sin \theta_2 & \cos \theta_2 \end{pmatrix} = \begin{pmatrix} \cos(\theta_1 + \theta_2) & -\sin(\theta_1 + \theta_2) \\ \sin(\theta_1 + \theta_2) & \cos(\theta_1 + \theta_2) \end{pmatrix},$$

that is,  $R_{\theta_1}R_{\theta_2} = R_{\theta_1+\theta_2}$ . To prove this identity, you can use the trigonometric identities provided in part (d) of Problem 1.G.15. For our case we compute

$$R_{\theta_1}R_{\theta_2} = R_{2\pi/3}, \quad \text{and} \quad (R_{\theta_1}R_{\theta_2})R_{\theta_3} = R_{2\pi/3}R_{\theta_3} = R_{2\pi/3}R_{\pi/3} = R_{\pi}.$$

To determine the final position of the initial rhombus  $ABCD$  it is now sufficient to apply a rotation by  $\pi$ . This results in the linear transformation

$$\begin{pmatrix} x \\ y \end{pmatrix} \mapsto \begin{pmatrix} \cos \pi & -\sin \pi \\ \sin \pi & \cos \pi \end{pmatrix} \begin{pmatrix} x \\ y \end{pmatrix} = \begin{pmatrix} -1 & 0 \\ 0 & -1 \end{pmatrix} \begin{pmatrix} x \\ y \end{pmatrix} = \begin{pmatrix} -x \\ -y \end{pmatrix} = - \begin{pmatrix} x \\ y \end{pmatrix}.$$

Hence  $ABCD$  will be finally transformed to  $AB'C'D'$ , where  $B' = -B$ ,  $C' = -C$  and  $D' = -D$ , respectively. As a verification, we see that these are the points obtained in step (c), that is  $B' = B_3$ ,  $C' = C_3$  and  $D' = D_3$ , respectively.  $\square$

F) MATERIAL ON RELATIONS AND MAPPINGS

**1.G.54.** Consider a relation  $R$  on the set  $\{1, 2, 3, 4\}$  where  $(a, b) \in R$  if and only if  $a - b$  is divisible by 2. Show that  $R$  is an equivalence relation.

**Solution.** To verify reflexivity we need to show that  $(a, a) \in R$  for all  $a \in \{1, 2, 3, 4\}$ . This is obvious since 0 is divisible by 2. Therefore,  $R$  is reflexive. To verify symmetry we need to show that if  $(a, b) \in R$  then  $(b, a) \in R$ . If  $(a, b) \in R$  the  $a - b$  is divisible by 2, and hence also  $b - a = -(a - b)$  is divisible by 2. Thus  $(b, a) \in R$  and  $R$  is symmetric. To verify transitivity we need to show that if  $(a, b) \in R$  and  $(b, c) \in R$  then  $(a, c) \in R$ . If  $(a, b) \in R$  and  $(b, c) \in R$  then both  $a - b$  and  $b - c$  are divisible by 2 and their sum  $(a - b) + (b - c) = a - c$  is also divisible by 2. Thus  $(a, c) \in R$  and  $R$  is transitive. For example  $(1, 3) \in R$  since  $1 - 3 = -2$  is divisible by 2, and since  $R$  is symmetric we have also  $(3, 1) \in R$ . Then we see that  $(1, 1) \in R$ , as well. Since  $R$  is reflexive, symmetric, and transitive, it is an equivalence relation.  $\square$

**1.G.55.** Determine the number of mappings from the set  $\{1, 2\}$  to the set  $\{a, b, c\}$ . How many of them are surjective and how many are injective?

**Solution.** The element 1 can be mapped to any of  $a, b, c$  and the same for 2. Thus there are exactly  $3^2$  mappings of the set  $\{1, 2\}$  to the set  $\{a, b, c\}$ . None of them can be surjective, because the set  $\{a, b, c\}$  has more elements than the set  $\{1, 2\}$ .

Injectivity requires that the images of 1 and 2 are different. There are three possibilities for the image of 1, and once the image of 1 is given, there remain two possibilities for the image of 2. Thus, the number of injective mappings of the set  $\{1, 2\}$  to the set  $\{a, b, c\}$  is 6.  $\square$

**1.G.56.** Let  $\{a, b, c, d\}$  be a set with a relation  $\{(a, a), (b, b), (a, b), (b, c), (c, b)\}$ . What is the minimal number of elements we have to add to the relation in order to make it an equivalence?

**Solution.** Let us successively ensure the three properties that define an equivalence. First it is the reflexivity. We must add the tuples  $\{(c, c), (d, d)\}$ . Second is the symmetry – we must add  $(b, a)$  and for the third step we must do the so-called transitive closure. Since  $a$  is in relation with  $b$  and  $b$  is in relation with  $c$ , we must add  $(a, c)$  and  $(c, a)$ .  $\square$

**1.G.57.** Determine how many distinct binary relations can be defined between a set  $X$  and the set of all subsets of  $X$ , if the set  $X$  has exactly 3 elements.

**Solution.** First, notice that the set of all subsets of  $X$  has exactly  $2^3 = 8$  elements, and thus the Cartesian product with  $X$  has  $8 \cdot 3 = 24$  elements. Possible binary relations correspond to subsets of this Cartesian product, and hence the total numbers of such relations is  $2^{24} = 16777216$ .  $\square$

**1.G.58.** Find the number of surjective mappings  $f$  from the set  $\{1, 2, 3, 4, 5\}$  to the set  $\{1, 2, 3\}$  such that  $f(1) = f(2)$ .

**Solution.** Every such mappings is uniquely given by the images of the elements  $\{1, 3, 4, 5\}$ , there are exactly that many mappings as there are surjective mappings of the set  $\{1, 3, 4, 5\}$  to the set  $\{1, 2, 3\}$ , that is, 36.  $\square$

**1.G.59.** Determine the number of surjective mappings of the set  $\{1, 2, 3, 4\}$  to the set  $\{1, 2, 3\}$ .  $\circ$

**1.G.60.** List all the relations on the two-element set  $\{1, 2\}$  that are symmetric, but neither reflexive nor transitive.

**Solution.** The reflexive relations are exactly those which contain both pairs  $(1, 1)$ ,  $(2, 2)$ . Hence this excludes the following relations

$$\{(1, 1), (2, 2)\}, \quad \{(1, 1), (2, 2), (1, 2)\}, \quad \{(1, 1), (2, 2), (2, 1)\}, \quad \{(1, 1), (2, 2), (1, 2), (2, 1)\}.$$

We claim that the remaining relations, which are symmetric but not transitive, must contain  $(1, 2)$ ,  $(2, 1)$ . If such a relation contains one of these two (ordered) pairs, by symmetry it must contain also the other. If it contains neither of these pairs, then it is clearly transitive. Thus, from the total number of 16 relations over a two-element set we select

$$\{(1, 2), (2, 1)\}, \quad \{(1, 2), (2, 1), (1, 1)\}, \quad \{(1, 2), (2, 1), (2, 2)\}.$$

It is now clear that each of these 3 relations is symmetric, but neither reflexive nor transitive.  $\square$

**1.G.61.** Determine the number of relations over the set  $\{1, 2, 3, 4\}$ , which are both symmetric and transitive.

**Solution.** Relations of the given properties is an equivalence over some subset of the set  $\{1, 2, 3, 4\}$ . In total,

$$1 + 4 \cdot 1 + \binom{4}{2} \cdot 2 + \binom{4}{3} \cdot 5 + 15 = 52,$$

Thus, there are 52 relations on the set  $\{1, 2, 3, 4\}$  that satisfy the required properties. □

**1.G.62.** Determine all the elements in  $S \circ R$ , if

$$R = \{(2, 4), (4, 4), (4, 5)\} \subset \mathbb{N} \times \mathbb{N}, \quad \text{and} \quad S = \{(3, 1), (3, 2), (3, 5), (4, 1), (4, 4)\} \subset \mathbb{N} \times \mathbb{N}.$$

**Solution.** Consider all choices of two ordered tuples

$$(2, 4), (4, 1), \quad (2, 4), (4, 4), \quad (4, 4), (4, 1), \quad (4, 4), (4, 4)$$

such that the second element of the first ordered tuple (which is a member of  $R$ ) is equal to the first element of the second ordered tuple (which is a member of  $S$ ). Then we obtain  $S \circ R = \{(2, 1), (2, 4), (4, 1), (4, 4)\}$ . This task can also be solved using Sage. First, define a function to compose two given relations as follows

```
def RelCompose(Rel1, Rel2):
    RS = set()
    for (a,b) in Rel1:
        for (c,d) in Rel2:
            if b == c:
                RS.add( (a,d) )
    return RS
```

Now we should introduce  $R, S$ , as follows:

```
R = { (2, 4), (4, 4), (4, 5) }; S = { (3, 1), (3, 2), (3, 5), (4, 1), (4, 4) }
print(RelCompose(R, S))
```

Executing the whole block Sage returns  $\{(4, 4), (2, 4), (4, 1), (2, 1)\}$ . □

**1.G.63.** Let  $R$  be the binary relation between the sets  $A = \mathbb{Z}$  and  $B = \mathbb{R}$ , defined by  $R = \{(0, 4), (-3, 0), (5, \pi), (5, 2), (0, 2)\}$ . Express explicitly  $R^{-1}$  and  $R \circ R^{-1}$ . ○

**1.G.64.** Is there an equivalence relation on the set of all lines in the plane that also serves as an ordering?

**Solution.** An equivalence relation (or ordering relation) must be reflexive, therefore every line must be in relation with itself. Furthermore we require that the relation is both symmetric (equivalence) and antisymmetric (ordering). This implies that each line can only be related to itself. If we define the relation such that two lines are in relation if and only if they are identical, we obtain a very natural relation, which is both an equivalence relation and an ordering. We just need to check that it is transitive, which is easy. Therefore, the only relation that meets the criteria is the identity relation over the set of all lines in the plane. □

**1.G.65.** We have a set  $\{3, 4, 5, 6, 7\}$ . Write explicitly the following relations and explore their properties:

- i)  $a$  divides  $b$ ,
- ii) Either  $a$  divides  $b$  or  $b$  divides  $a$ ,
- iii)  $a$  and  $b$  have a common divisor greater than one,

○

Solutions to the problems

**1.A.3.** Already the ancient Greeks knew that if we prescribe the area of square as  $a^2 = 2$ , then we cannot find a rational  $a$  to satisfy it. Why? Suppose that we know that  $(p/q)^2 = 2$  for some natural numbers  $p$  and  $q$ , which have no common divisor greater than 1 (otherwise we can further reduce the fraction  $p/q$ ). Then  $p^2 = 2q^2$  is an even number and on the l.h.s  $p^2$  must be even. Therefore so is  $p$ . Now  $p$  is even, thus  $p^2$  must be divisible by 4. But then  $q^2$  is even and so  $q$  must be even too. This certifies that  $p$  and  $q$  both have 2 as a common factor, a contradiction.

**1.A.4.** Let  $p, q$  be two arbitrary rational numbers with  $p \neq q$ . We may assume that  $p < q$ , and similarly is treated the other case. Set

$$\beta := p - \frac{p-q}{\sqrt{2}}.$$

We will show that  $\beta$  is an irrational, that is,  $\beta \in \mathbb{R} \setminus \mathbb{Q}$ , and in addition that  $p < \beta < q$ . The first claim follows because  $1/\sqrt{2}$  is an irrational, in combination with the following two facts:

- The product of a rational with an irrational is an irrational number.
- Adding a rational and an irrational number we obtain an irrational number.

Let us prove the first statement and in a very similar way occurs also the second one. Let  $p = \frac{a}{b} \in \mathbb{Q}$  be a rational number, and let  $x \in \mathbb{R} \setminus \mathbb{Q}$  be an irrational. Then  $xp = px = \frac{xa}{b}$ . Assume that  $xp$  is a rational, that is,

$$xp = \frac{xa}{b} = \frac{r}{s},$$

for some integers  $r, s$ . Multiplying both sides with  $\frac{b}{a}$  we obtain  $x = \frac{rb}{sa}$ . Being the product of the rationals  $\frac{r}{s}$  and  $\frac{b}{a}$ , the number  $x$  should be a rational, a contradiction. Now it remains to prove that  $p < \beta < q$ . We begin with  $0 < \frac{1}{\sqrt{2}} < 1$  and multiply both sides by  $q - p > 0$ . This gives  $0 < \frac{q-p}{\sqrt{2}} < q - p$  and by adding to both sides the number  $p$  we get  $p < p - \frac{p-q}{\sqrt{2}} < q$ . This proves the assertion.

**1.A.7.** By assumption,  $p(x) = 5x^4 + x^2 - 2x + 2$  so the Horner's table has the form

$\rho = 4$	5	0	1	-2	2
		20	80	324	1288
	5	20	81	322	1290

This means that  $p(x) = (x - 4)(5x^3 + 20x^2 + 81x + 322) + 1290$ . In terms of the long division method we have

	$5x^3 + 20x^2 + 81x + 322$				
$x - 4$ )	$5x^4$		$+ x^2$	$- 2x$	$+ 2$
	$- 5x^4 + 20x^3$				
	$20x^3 + x^2$				
	$- 20x^3 + 80x^2$				
	$81x^2 - 2x$				
	$- 81x^2 + 324x$				
	$322x + 2$				
	$- 322x + 1288$				
					1290

**1.A.9.** The horizontal distance between  $z, w$  is the absolute value of the difference of their real parts, that is,  $\text{hor} = |x - u|$ . For an illustration, see the figure below. Note that here one uses the absolute value of  $x - u$ , since depending whether  $z$  lies to the left or to the right of  $w$ , the horizontal distance is given by  $\pm(x - u)$ .

Similarly, the vertical distance between  $z, w$  is the absolute value of the difference of their imaginary parts, that is,  $\text{ver} = |y - v|$ . According to the Pythagorean theorem the distance  $d$  between  $z, w$  satisfies

$$d^2 = \text{hor}^2 + \text{ver}^2 = |x - u|^2 + |y - v|^2$$

and the assertion follows.

**1.A.11.** The distance under question equals to  $\sqrt{13}$ .

**1.A.12.** By assumption,  $i$  is a solution of the given equation. Hence we have that  $i^3 + (1 + i)i^2 + ai + 2 = 0$ . From this equation we compute  $a = 2 + i$ . Thus, we need to solve the equation

$$f(z) = 0, \quad \text{where} \quad f(z) = z^3 + (1 + i)z^2 + (2 + i)z + 2.$$

Since  $f(z)$  is of degree three, over  $\mathbb{C}$  we can specify three roots. In particular, we know that  $i$  is a solution of  $f(z) = 0$ , and we can use this to obtain the corresponding Horner table. Set  $\rho = i$ . We have

$$\begin{array}{r|rrrr} \rho = i & 1 & 1 + i & 2 + i & 2 \\ & & i & i - 2 & -2 \\ \hline & 1 & 1 + 2i & 2i & 0 \end{array}$$

The last entry of the bottom row is 0 since  $i$  is a root of  $f(z) = 0$ . Hence we can write

$$f(z) = z^3 + (1 + i)z^2 + (2 + i)z + 2 = (z - i)(z^2 + (1 + 2i)z + 2i) = (z - \rho)\pi(z)$$

with  $\pi(z) := z^2 + (1 + 2i)z + 2i$ . Now, the discriminant of  $\pi(z)$  is given by

$$\Delta = (1 + 2i)^2 - 4 \cdot 1 \cdot 2i = 1 + 4i - 4 - 8i = -3 - 4i = 1 - 4 - 4i = (1 - 2i)^2.$$

Thus, the rest two roots are given by

$$z_{2,3} = \frac{-(1 + 2i) \pm \sqrt{(1 - 2i)^2}}{2},$$

that is,  $z_2 = -2i$  and  $z_3 = -1$ .

**1.A.16.** (a) This is true, as we can see in figure below. In particular, the argument of a real number is  $k\pi$ , with  $k \in \mathbb{Z}$ .

(b) The principal argument of  $i$  equals to  $\varphi = \pi/2$  and is given correctly. However,  $-2i$  has the same principal argument as  $-i$ , i.e.,  $\vartheta = -\pi/2$ , see also the figure. Hence the last statement in (b) is false. One can show that a complex number will be imaginary, if and only if its argument is given by  $\pm\pi/2 + n\pi$ , with  $n \in \mathbb{Z}$ .

**1.A.17.** One can apply the method presented in Problem 1.A.14. This means that for the given  $z \in \mathbb{C}$  we need to compute its magnitude  $r = |z|$  and also its argument. Moreover, a direct calculation shows that

$$|z| = \sqrt{\left(1 + \cos \frac{\pi}{3}\right)^2 + \sin^2 \frac{\pi}{3}} = \sqrt{3}, \quad \cos(\varphi) = \frac{\text{Re}(z)}{|z|} = \frac{1 + \frac{1}{2}}{\sqrt{3}} = \frac{\sqrt{3}}{2}, \quad \sin(\varphi) = \frac{\text{Im}(z)}{|z|} = \frac{1}{2}.$$

Therefore we see that  $\varphi = \pi/6$ . All together, we obtain  $z = \sqrt{3} \left( \cos \frac{\pi}{6} + i \sin \frac{\pi}{6} \right)$ .

**1.A.19.** Recall that the de Moivre's formula states that  $z^n = |z|^n (\cos(n\varphi) + i \sin(n\varphi))$  for any  $n \in \mathbb{Z}$  and  $z \in \mathbb{C}$ , see 1.1.4. We are interested in  $z^{31}$ , where  $z = \cos \frac{\pi}{6} + i \sin \frac{\pi}{6}$  (note that  $z \in S^1 = \{z \in \mathbb{C} : |z| = 1\}$ ). In such tasks it is often useful to draw the diagram corresponding to  $z$ , which for the particular case takes the form

Therefore, we obtain

$$\left( \cos \frac{\pi}{6} + i \sin \frac{\pi}{6} \right)^{31} = \cos \frac{31\pi}{6} + i \sin \frac{31\pi}{6} = \cos \frac{7\pi}{6} + i \sin \frac{7\pi}{6} = -\frac{\sqrt{3}}{2} - i \frac{1}{2}.$$

**1.A.20.** This task highlights the different uses of de Moivre's theorem. Indeed, having in mind the result in 1.1.4, and the identities  $(a + b)^3 = a^3 + 3a^2b + 3ab^2 + b^3$ ,  $i^2 = -1$ ,  $i^3 = -i$ , we compute

$$\begin{aligned} \cos(3\varphi) + i \sin(3\varphi) &= (\cos(\varphi) + i \sin(\varphi))^3 = \cos^3(\varphi) + 3i \cos^2(\varphi) \sin(\varphi) + 3i^2 \cos(\varphi) \sin^2(\varphi) + i^3 \sin^3(\varphi) \\ &= (\cos^3(\varphi) - 3 \cos(\varphi) \sin^2(\varphi)) + i(3 \cos^2(\varphi) \sin(\varphi) - \sin^3(\varphi)). \end{aligned}$$

A comparison now of the real and the imaginary parts yields the result:

$$\cos(3\varphi) = \cos^3(\varphi) - 3 \cos(\varphi) \sin^2(\varphi) = \cos^3(\varphi) - 3 \cos(\varphi)(1 - \cos^2(\varphi)) = 4 \cos^3(\varphi) - 3 \cos(\varphi),$$

and

$$\sin(3\varphi) = 3 \cos^2(\varphi) \sin(\varphi) - \sin^3(\varphi) = 3(1 - \sin^2(\varphi)) \sin(\varphi) - \sin^3(\varphi) = 3 \sin(\varphi) - 4 \sin^3(\varphi).$$

**1.A.22.** Note that this equation has no rational roots. Substitution into formulas obtained in 1.A.21 yields  $p = b - a^2/3 = -7/3$ ,  $q = -7/27$ . It follows that

$$u = \frac{\sqrt[3]{28 \pm 12\sqrt{-147}}}{6}.$$

We can theoretically choose up to six possibilities for  $u$  (two for the choice of the sign and three independent choices of the cubic root). But we obtain only three distinct values for  $x$ . By substitution into the formulas, one of the roots is of the form

$$\frac{14}{\sqrt[3]{3(28 - 84i\sqrt{3})}} + \frac{\sqrt[3]{28 - 84i\sqrt{3}}}{6} - \frac{1}{3} \doteq 1.247,$$

and similarly for the other two (approximately  $-0.445$  and  $-1.802$ ). Finally observe that even if we have used complex numbers during the computation, all the solutions are real.

**1.B.2.** Set as before  $a = \left(1 + \frac{0.06}{12}\right) = 1.005$  and  $C = 30\,000$ . The condition  $d_k = 0$  gives the equation

$$a^k = \frac{\frac{P}{a-1}}{\frac{P}{a-1} - C} = \frac{200P}{200P - C}.$$

By taking logarithms of both sides, we see arrive to

$$k = \frac{\ln(200P) - \ln(200P - C)}{\ln a}$$

This, for  $P = 500$  gives approximately  $k = 71.5$ . Therefore, Michael will pay for 72 months, with the last repayment being less than €500.

**1.C.3.** (a) The pair of letters b and r can be assumed to be a single indivisible “double-letter”. In total we have six distinct letters and there are  $6!$  words of six indivisible letters. We have to multiply this by two, since the double-letter can be either br, or rb. So the solution is  $2 \cdot 6!$ .

(b) The events in this case form the complement to the part (i), in the set of all rearrangements of the seven-letters. The solution is therefore  $7! - 2 \cdot 6!$ .

**1.C.10.** First, we can place the white tower in any of  $8^2$  positions. Then we have to our disposal  $7^2$  positions (the remaining 7 rows and columns) in which we can place the black tower. Therefore, the total number of ways equals to  $8^2 \cdot 7^2 = 3136$ .

The “inclusion-exclusion” would of course, provide the same result:  $8^2(8^2 - 1) - 8^2 \cdot 7 \cdot 2 = 3136$  (the first terms are all possibilities, the second one the forbidden ones).

**1.D.3.** First divide the favourable cases according to the number of men in the chosen group: 2 or 1. Now, there are eight groups with five people of which one is a man (all women have to be present in such groups, thus it depends only on which man is chosen). Also, there are  $c(8, 2) \cdot c(4, 3) = \binom{8}{2} \cdot \binom{4}{3}$  of groups with two men. This is because we choose two men from eight and then independently three women from four. These two choices can be independently combined and thus using the rule of product we obtain the number of such groups. The total number of groups with five people is  $c(12, 5) = \binom{12}{5}$ . Therefore, the desired probability, being the quotient of the number of favourable outcomes to the total number of outcomes, equals to

$$\frac{8 + \binom{4}{3} \binom{8}{2}}{\binom{12}{5}} = \frac{5}{33}.$$

**1.D.8.** We solve this exercise using the theorem about multiplication of probabilities. This is explained in 1.4.8, based on the conditional probability concept. Here it seems to be obvious:

First we require a red ball, that happens with the probability  $9/16$ . If a red ball was drawn, then in the second round we draw a red ball with the probability  $8/15$  (there are 15 balls in the box, 8 of them are red). Finally, if two red balls were drawn, the probability that a white ball is drawn is  $7/14$  (there are 7 white balls and 7 red balls in the box). Thus we obtain

$$\frac{9}{16} \cdot \frac{8}{15} \cdot \frac{7}{14} = 0.15.$$

**1.E.5.** Eliminate  $t$  to obtain  $q : x - 2y = -5$ . Then solve for  $x$  and  $y$ . The intersection has coordinates  $x = 1, y = 3$ .

**1.E.7.** It is clear that

$$-2 \cdot (-x - \frac{3}{2}y + 2) = 2x + 3y - 4.$$

Thus  $p_1$  and  $p_4$  describe the same line. Moreover, note that  $p_2$  can be rewritten as  $-2x + 2y - 6 = 0$ , thus the lines  $p_2$  and  $p_3$  are parallel and distinct. Also, by eliminating  $t$ , the line  $p_5$  has an equation  $x + y = 0$ , which is not parallel to any other line.

**1.E.12.** We compute

$$A - B = \begin{pmatrix} -2 & 5 \\ -1 & 1 \end{pmatrix}, (A - B)^T = \begin{pmatrix} -2 & -1 \\ 5 & 1 \end{pmatrix}$$

and by matrix multiplication we obtain

$$v = 2 \begin{pmatrix} -2 & -1 \\ 5 & 1 \end{pmatrix} \begin{pmatrix} 2 & -2 \\ 4 & 5 \end{pmatrix} \begin{pmatrix} 3 \\ 2 \end{pmatrix} = \begin{pmatrix} -52 \\ 64 \end{pmatrix}.$$

**1.E.14.** Of course, all these results can be easily computed via Sage and the methods mentioned in the previous subsection. But it is all so easy with 2 by 2 matrices that we could count on fingers, too:

(a) We have  $A - B = \begin{pmatrix} -2 & 5 \\ -1 & 1 \end{pmatrix}$ , so we easily compute:

$$(A - B)^2 = \begin{pmatrix} -2 & 5 \\ -1 & 1 \end{pmatrix} \begin{pmatrix} -2 & 5 \\ -1 & 1 \end{pmatrix} = \begin{pmatrix} -1 & -5 \\ 1 & -4 \end{pmatrix}, A^2 = \begin{pmatrix} -10 & 10 \\ -4 & -6 \end{pmatrix}, B^2 = \begin{pmatrix} 4 & 0 \\ -3 & 1 \end{pmatrix}$$

and

$$AB = \begin{pmatrix} -5 & 5 \\ -6 & 2 \end{pmatrix} \neq BA = \begin{pmatrix} 0 & 10 \\ -2 & -3 \end{pmatrix}.$$

Thus, computing  $(A - B)^2$  we may use the formula  $A^2 - AB - BA + B^2$  (but we see that it is false to claim that  $(A - B)^2 = A^2 - 2AB + B^2$ ). Hence in matrix calculus the multiplication is not in general commutative.

(b) We compute  $ABC, BCA,$  and  $CAB$ , which yields:

$$D = 2 \begin{pmatrix} 10 & 35 \\ -4 & 22 \end{pmatrix} - \begin{pmatrix} 8 & 12 \\ -14 & 24 \end{pmatrix} - \begin{pmatrix} 2 & 6 \\ -50 & 30 \end{pmatrix} = \begin{pmatrix} 10 & 52 \\ 56 & -10 \end{pmatrix} \neq \begin{pmatrix} 0 & 0 \\ 0 & 0 \end{pmatrix}.$$

Therefore, in general given three arbitrary matrices  $A, B, C$ , we have  $ABC \neq BCA \neq CAB$ .

(c) We compute (in the result, we write  $E = \begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix}$ ):

$$\frac{c(AB) - (c(AB))^T}{\sqrt{2}} = \frac{c}{\sqrt{2}}(AB - (AB)^T) = \frac{\sqrt{2}c}{2} \left\{ \begin{pmatrix} -5 & 5 \\ -6 & 2 \end{pmatrix} - \begin{pmatrix} -5 & -6 \\ 5 & 2 \end{pmatrix} \right\} = \frac{11\sqrt{2}}{2}cE.$$

(d) This is a direct computational consequence of the formula for determinant. In Chapter 2, we will see that this holds true for square matrices of all sizes.

(f) Let us better handle this one by Sage, where it is convenient to use the cell presented in 1.E.12 and add the code

```
D=det(A)*B-det(B)*A-C.trace()*C; print(det(D)); print(divisors(det(D)))
```

This gives  $-38$ , which is the determinant of  $D$ , and  $[1, 2, 19, 38]$ , which are its divisors.

**1.E.15.** (a) For any two square matrices  $A$  and  $B$  we have

$$(A + B)(A - B) = A^2 - A \cdot B + B \cdot A - B^2.$$

Therefore, the identity  $(A + B) \cdot (A - B) = A^2 - B^2$  is valid if and only if  $AB = BA$ . Thus any pair of matrices which do not commute does the work. A choice is given for instance by

$$A = \begin{pmatrix} 1 & 2 \\ 3 & 4 \end{pmatrix}, \quad B = \begin{pmatrix} 4 & 3 \\ 2 & 1 \end{pmatrix}.$$

Indeed,  $AB = \begin{pmatrix} 8 & 5 \\ 20 & 13 \end{pmatrix} \neq BA = \begin{pmatrix} 13 & 20 \\ 5 & 8 \end{pmatrix}$ .

(b) Similarly, any two square matrices  $A, B$  satisfy

$$(A + B)(A + B) = A^2 + AB + BA + B^2$$

It follows that  $(A + B)(A + B) = A^2 + 2AB + B^2$  if and only if  $AB = BA$ , as in the first case. Hence the pair of matrices presented above provides an example also for this case.

**1.E.16.** The definition of the linear mappings shows, that knowing the values on  $u = (1, 0)$  and  $v = (0, 1)$  determines the values for all the other vectors:  $(x, y) \mapsto F(xu + yv) = xF(u) + yF(v)$ . This corresponds to placing the vectors  $F(u)$  and  $F(v)$  into the columns of the appropriate matrix  $A$ , and then express the value as  $\begin{pmatrix} x \\ y \end{pmatrix} \mapsto A \begin{pmatrix} x \\ y \end{pmatrix}$ . This answers the question about the role of the columns in the matrix  $A$ , once we have it. Moreover, the affine mappings differ from the linear ones only by having a constant vector added. Thus, an affine mapping is linear if and only if it keeps the origin fixed. In our case, clearly

$$\begin{aligned} F \left( \begin{pmatrix} x \\ y \end{pmatrix} \right) &= \begin{pmatrix} 7 & -3 \\ -2 & 5 \end{pmatrix} \begin{pmatrix} x \\ y \end{pmatrix} = A \begin{pmatrix} x \\ y \end{pmatrix}, \\ G \left( \begin{pmatrix} x \\ y \end{pmatrix} \right) &= \begin{pmatrix} 2 & 2 \\ 4 & -9 \end{pmatrix} \begin{pmatrix} x \\ y \end{pmatrix} + \begin{pmatrix} -4 \\ 3 \end{pmatrix} = B \begin{pmatrix} x \\ y \end{pmatrix} + w, \\ F \left( \begin{pmatrix} 0 \\ 0 \end{pmatrix} \right) &= \begin{pmatrix} 0 \\ 0 \end{pmatrix}, \quad G \left( \begin{pmatrix} 0 \\ 0 \end{pmatrix} \right) = \begin{pmatrix} -4 \\ 3 \end{pmatrix}, \end{aligned}$$

and we deduce that the mapping  $F$  is linear, but  $G$  is not.

The final claim is obvious from the associativity of matrix multiplication, i.e.,

$$B \left( A \begin{pmatrix} x \\ y \end{pmatrix} \right) + w = (BA) \begin{pmatrix} x \\ y \end{pmatrix} + w, \quad A \left( B \begin{pmatrix} x \\ y \end{pmatrix} + w \right) = (AB) \begin{pmatrix} x \\ y \end{pmatrix} + Aw.$$

Check these computations yourselves and see also the right column in 1.5.4.

**1.E.22.** This is a typical task to be discussed without any explicit coordinates in mind. Let us start with the linear mappings. In the plane, lines are parallel if and only if their directional vectors  $u$  in the parametric representations  $P(t) = P + tu$  are parallel. The images of the lines can be parametrized by  $F(P(t)) = F(P) + tF(u)$ . Now recall that on the plane, two non-zero vectors are parallel if and only if one is a scalar multiple of the other. Thus, the images of parallel lines are clearly parallel as well, except the case, where the image  $F(u) = 0$ . So, strictly speaking, the claim we should prove is false. But we have proved that invertible linear mappings transform parallel lines to parallel lines. Adding translations in order to deal with general affine mappings, does not spoil this property. On the other hand, for example, a shear transformation clearly changes both the angles and the distances, cf. 1.E.17.

**1.E.24.** An ‘‘admissible picture’’ that effectively illustrates the result of the task in 1.E.21, should resemble the figure shown below:

This figure allows you to visually verify the two requirements of the task: first, that the two lines are perpendicular, and second, that the line in question passes through the point  $P = [-6, 7]$ .

To create this plot, you can use a Sage cell with specific options to ensure the correct aspect ratio and figure size. For example, you can type:

```
x=var("x")
y2=-7*x/6; y1=(1/7)*(6*x+13)
fig = plot([], figsize=[4,4])
fig += plot(y1,x, (-7,7), aspect_ratio=1)
fig += plot(y2,x, (-7,7), aspect_ratio=1)
fig += point((-6, 7), size=70)
show(fig)
```

To verify the effect of the different options on the plot, try the following: Modify the Sage cell to use `aspect_ratio="automatic"`. You will observe that the two lines may appear non-perpendicular, which can be misleading. Additionally, changing the `figsize` to `[4, 8]` can produce a distorted or "ugly" figure, further complicating the visual interpretation. By experimenting with these settings in your editor, you can see firsthand how altering the aspect ratio and figure size impacts the clarity and accuracy of your plot.

**1.E.25.** We know that the area equals to the absolute value of the half of the determinant of the matrix, whose first column is given by the vector  $Q - P$  and the second column by the vector  $R - P$ , that is the determinant of the matrix

$$A = \begin{pmatrix} -2 - (-8) & 5 - (-8) \\ 0 - 1 & 9 - 1 \end{pmatrix} = \begin{pmatrix} 6 & 13 \\ -1 & 8 \end{pmatrix}.$$

A simple calculation yields  $\frac{1}{2} |\det(A)| = \frac{1}{2} |(6 \cdot 8 - (13 \cdot (-1)))| = \frac{61}{2}$ . Alternatively, in Sage we can type the cell

```
A=matrix([[6, 13], [-1, 8]]); A.det ( )
```

which returns the determinant of  $A$ . As we will prove in Chapter 2, changing the order of the vectors leads to the change of the sign of the determinant. But the absolute value remains unchanged. Similarly, the transposed matrix (writing the vectors rather in the rows) yields the same determinant. Finally, if the vertices  $P, Q, R$  are ordered in the anti-clockwise direction, the determinant formed by the vectors  $Q - P$  and  $R - P$  is always positive.

If the given coordinates were not in the standard Euclidean coordinate system, we would have to look at their defining frame  $e_1, e_2$ . If their norms are one and they are perpendicular (an orthonormal frame, see the end of 1.5.7), then we do not need to do anything. Otherwise, we should transform the coordinates first into the standard coordinate system, see the methods discussed in 1.E.22 (although area preserving transformation matrices are those with determinant one, e.g., all shears, so this might not be necessary at all – think about it!).

**1.E.26.** Let us denote the quadrilateral  $S$  by  $ABCD$ . Being a polygon, to sketch it in Sage we can apply the command `polygon` or `polygon2d`. Here we use the first command in the following cell:

```
P = polygon([(1,1), (6,1), (11,4), (2,4)], fill=False, color="black")
A =point([1, 1], size=40, color="black")
B =point([6, 1], size=40, color="black")
C =point([11, 4], size=40, color="black")
D =point([2, 4], size=40, color="black")
```

```

A1= text ("A", (0.8, 0.8), color="black", fontsize="12")
B1= text ("B", (6.2, 0.8), color="black", fontsize="12")
C1= text ("C", (11.2, 4.2), color="black", fontsize="12")
D1= text ("D", (1.8, 4.2), color="black", fontsize="12")
l=line([(1, 1), (11, 4)], color="black", linestyle="--")
show(P+A+B+C+D+A1+B1+C1+D1+l)

```

Executing this block we obtain the following illustration:

From this figure we observe that  $S$  is a trapezoid, with bases of length 5 and 9 and a height of 3. Thus, the area of  $S$  is calculated as

$$\text{Area}(S) = \frac{5+9}{2} \cdot 3 = 21.$$

This formula can be derived by noting that shearing transformations do not alter the area of a shape. By selecting an appropriate trapezoid that simplifies the calculations, you can verify this result. Can you identify a suitable trapezoid to use for this purpose?

Alternatively, we can divide  $S$  into two triangles,  $\triangle ABC$  and  $\triangle ACD$ , as shown in the figure. We can then find the area of  $S$  by summing the areas of these two triangles, which can be calculated using the determinants of the corresponding matrices:

$$d_1 = \begin{vmatrix} 6-1 & 11-1 \\ 1-1 & 4-1 \end{vmatrix} = \begin{vmatrix} 5 & 10 \\ 0 & 3 \end{vmatrix}, \quad d_2 = \begin{vmatrix} 11-1 & 2-1 \\ 4-1 & 4-1 \end{vmatrix} = \begin{vmatrix} 10 & 1 \\ 3 & 3 \end{vmatrix},$$

where in the columns are these vectors  $B-A$ ,  $C-A$  (for  $d_1$ ) and  $C-A$ ,  $D-A$  (for  $d_2$ ). In such terms we see that  $\text{Area}(S) = \frac{1}{2}(|d_1| + |d_2|)$ , and this gives 21 as well. Note that the second approach works for all polygonal objects in the plane.

**1.E.28.** The coordinates of the vertex  $C$  can be obtained by rotating the point  $A$  around the centre  $S$  through the angle  $2\pi/3$  in the positive direction. This gives  $C = [\frac{3}{2} - \sqrt{3}, -1 - \frac{\sqrt{3}}{2}]$ . As a verification in Sage you may type

```

a=2*pi/3;x1=0;y1=2;x2=1;y2=0}}
M=matrix([[cos(a), -sin(a)], [sin(a), cos(a)]])
A=vector([x1, y1]); S=vector([x2, y2])
rot=(M*(A-S)+S); show(rot)

```

**1.E.30.** For simplicity, set  $A = [-2, -2]$ ,  $B = [2, -11/6]$ ,  $C = [3, 1]$ ,  $D = [1, 4]$ , and  $E = [-2, 2]$ . The sides  $BC$  and  $CD$  are clearly visible from the position of the point  $[300, 1]$ . On the other hand,  $DE$  and  $EA$  cannot be seen. For the side  $AB$ , we compute

$$\begin{vmatrix} -2-300 & 2-300 \\ -2-1 & -\frac{11}{6}-1 \end{vmatrix} = -302 \cdot (-\frac{17}{6}) - (-298) \cdot (-3) < 0.$$

This implies that the side can be seen from the point  $[300, 1]$ .

**1.E.31.** Order the vertices in the positive direction, that is counter-clockwise:  $[5, 6]$ ,  $[7, 8]$ ,  $[5, 8]$ . Using the corresponding determinants we can determine whether the point  $[0, 1]$  lies to the “left” or to the “right” of the sides of the triangle when we view them as oriented line segments. We have

$$\begin{vmatrix} Q-X \\ R-X \end{vmatrix} = \begin{vmatrix} 7 & 7 \\ 5 & 7 \end{vmatrix} > 0, \quad \begin{vmatrix} R-X \\ P-X \end{vmatrix} = \begin{vmatrix} 5 & 7 \\ 5 & 5 \end{vmatrix} < 0, \quad \begin{vmatrix} P-X \\ Q-X \end{vmatrix} = \begin{vmatrix} 5 & 5 \\ 7 & 7 \end{vmatrix} = 0.$$

We see that the determinants are not all positive, so  $X$  is outside the triangle. In particular, if it is left of some oriented segment (a side of the triangle), the segment is not visible from  $P$ . Because the last determinant is zero, the points  $[0, 1]$ ,  $[5, 6]$  and  $[7, 8]$  lie on a line, and thus the side joining  $P$  and  $Q$  is not visible. The side joining  $Q$  and  $R$  is also not visible, unlike the side joining  $P$  and  $R$ , for which the determinant is negative.

**1.F.4.** we should determine first the three defining properties of an equivalence relation, as functions, and next examine if  $R$  satisfies them. We can do this as follows:

```
def is_reflexive(Rel, A=None):
    if not A:
        A = set(x[0] for x in Rel)
# in this way we define the domain
    return all({(a,a) in Rel for a in A})
def is_symmetric(Rel):
    return all({(b,a) in Rel for (a,b) in Rel})
def is_transitive(Rel):
    return all({(a,d) in Rel for (a,b) in Rel for (c,d) in Rel if b == c})
def relation_summary(Rel):
    A = set(x[0] for x in Rel)
    reflexive = is_reflexive(Rel, A)
    symmetric = is_symmetric(Rel)
    transitive = is_transitive(Rel)
    print(f'Reflexive: {reflexive}')
    print(f'Symmetric: {symmetric}')
    print(f'Transitive: {transitive}')
Rel1 = {('a', 'a'), ('b', 'b'), ('c', 'c'), ('d', 'd'), ('b', 'a'), ('b', 'c'), ('b', 'd')}
relation_summary(Rel1)
```

Sage returns the desired result:

```
Reflexive: True
Symmetric: False
Transitive: True
```

Notice the use of the so called “f-strings” in the print – we are allowed to use expressions whose values should be printed inside the string.

**1.F.5.** From the relationship  $((a, b), (a, b)) \in R$  for all  $a, b \in \mathbb{R}$  it follows that the relation is reflexive. It is also easy to see that the relation is symmetric, since in the equality of the second coordinates we can interchange the left and right side. If  $((a, b), (c, d)) \in R$  and  $((c, d), (e, f)) \in R$ , that is,  $b = d$  and  $d = f$ , then we get that  $((a, b), (e, f)) \in R$ , that is,  $b = f$ . Hence  $R$  is also transitive, and so an equivalence relation. Notice the points in the plane are related if and only if they have the same second coordinate (the line they determine is perpendicular to the  $y$  axis). Thus the corresponding partition divides the plane into the lines parallel with the  $x$  axis.

**1.F.6.** Directly from the definition of the domain and the codomain of a relation we obtain

$$D = \{a, b, c, d, f\} \subset A, \quad I = \{x, y, u, v\} \subset B.$$

To check if a relation is a mapping, we need to ensure that each element in the domain is assigned to exactly one element in the codomain. In our case we deduce that  $R$  is not a mapping since  $(c, x), (c, u) \in R$ , that is,  $c \in D$  has two images.

In Sage, the domain and codomain can be found like this:

```
A = set(["a", "b", "c", "d", "e", "f"])
B = set(["x", "y", "u", "v", "w"])
Rel = set( [ ("a", "v"), ("b", "x"), ("c", "x"), ("c", "u"), ("d", "v"), ("f", "y") ])
# to compute the domain we iterate over R taking the first element of each pair
domain = set(x[0] for x in Rel)
print(f"domain = {domain}")
# to compute the codomain, we take the second element
codomain = set(x[1] for x in Rel)
print(f"codomain = {codomain}")
```

**1.F.9.** In the first case, the map  $f$  is surjective (it is enough to set  $x = 0$ ) but not injective (it is enough to set  $(x, y) = (0, -9)$  and  $(x, y) = (1, 0)$ ). In the second case,  $f$  is an injective mapping (both its coordinates, that is functions  $y = 2x$  and  $y = x^2 + 10$  are clearly increasing over  $\mathbb{N}$ ). The mapping is not surjective (for instance the pair  $(1, 1)$  has no preimage).

**1.G.1.** An easy way is given by Sage, using the command `sum`. Typing in your editor the code

```
# Define symbolic variables
n, k = var("n k")
```

```
# Define the function to sum
f = k
# Compute the symbolic sum
sum1 = sum(f, k, 1, n)
# Show the symbolic sum
show(sum1)
```

Sage's output is  $\frac{1}{2}n^2 + \frac{1}{2}n$ , which represents the evaluated form of the sum  $\sum_{k=1}^n k$ .

However, since the task requires an illustration, we need to explore a different approach. The idea that we will present below likely dates back to the Pythagoreans (6th century BC), but is also closely associated with the German mathematician F. Gauss (1777-1855), one of the most influential scientists of his time. Let  $\Delta_n = 1 + 2 + \dots + (n - 1) + n$  be the sum that we want to compute, and rewrite this with the inverse ordering of the summands, that is,  $\Delta_n = n + (n - 1) + \dots + 2 + 1$ . Adding these two relations, we get

$$2\Delta_n = (n + 1) + (n - 1 + 2) + (n - 2 + 3) + \dots + (2 + (n - 1)) + (1 + n) = (n + 1) + (n + 1) + \dots + (n + 1),$$

where the sum in the r.h.s has  $n$ -factors. Thus  $2\Delta_n = n(n + 1)$ , which completes the proof.

Graphically, the triangular number  $\Delta_n = \frac{1}{2}n(n + 1)$  ( $n = 1, 2, \dots$ ), can be represented by the triangular grid of points (black dots) figured below, where the first row contains a single dot ( $\Delta_1 = 1$ ), and each subsequent row contains one more dot than the previous one (we always move the first dot upwards).

In the figure are presented the first five triangular numbers.<sup>14</sup> To illustrate the simplified proof given above, one converts the above triangle arrangements to half-square arrangements, as in the figure below.

Let us illustrate the case of  $\Delta_7$ . The shaded triangle is the triangle arrangement corresponding to  $\Delta_7$ , while the white triangle occurs after rotating the shaded diagram to obtain the rectangular of size  $7(7 + 1)$ . Hence  $2\Delta_7 = 56 = 7(7 + 1)$ , that is  $\Delta_7 = 28$ . Finally, as in 1.C.7 we see that the number of distinct handshakes or wine glass clinks that can be made among a group of  $n$  people is given by  $\binom{n}{2}$ , and this can be rephrased as  $\Delta_{n-1}$ .<sup>15</sup> This last claim is based on the relation

$$\Delta_n = \binom{n + 1}{2}.$$

As for the two given recurrence relations, they occur very easily and it worths to mention that if we add them, then we return back to the initial definition of  $\Delta_n$ .

**1.G.2.** Suppose that the length of the hill is  $\ell$  km. Then, the bicyclist needs  $\ell/25$  hours to goes up the hill, and  $\ell/75$  hours to goes down the same hill. For instance, if  $\ell = 25$  km, then the cyclist needs one hour to goes uphill and a bit more than half hour for downhill. Since the total distance is  $2\ell$  km, we deduce that the average speed is

$$\frac{2\ell}{\frac{\ell}{25} + \frac{\ell}{75}} = \frac{75 \cdot 2\ell}{4\ell} = \frac{75}{2} = 37.5 \text{ km}.$$

Often, the average speed is called the *harmonic mean* of the two given rates.

**1.G.8.** By assumption,  $P(x) = x^2 + x + 2$ , hence we have

<sup>14</sup>Many mathematicians include 0 as the very first element in the sequence of triangle numbers, but we do not adopt this here.

<sup>15</sup>Each person shakes hands with  $n - 1$  others, but each handshake involves two people, so we count each handshake twice.

$$Q(x) = P(P(x)) - P(x) - 3 = (P(x))^2 + P(x) + 2 - P(x) - 3 = (P(x))^2 - 1 = (P(x) - 1) \cdot (P(x) + 1).$$

This show that  $Q(x)$  is divided by  $P(x) - 1$ , with quotient  $\pi(x) = P(x) + 1 = x^2 + x + 3$ .

**1.G.9.** Suppose that  $P(x) = ax^4 + bx^3 + cx^2 + dx + e$ . Since  $P(0) = 0$  we get  $e = 0$  and so  $P(x) = ax^4 + bx^3 + cx^2 + dx$ . Now, we see that

$$\begin{aligned} P(x+1) - P(x) &= a(x+1)^4 + b(x+1)^3 + c(x+1)^2 + d(x+1) - (ax^4 + bx^3 + cx^2 + dx) \\ &= a(x^4 + 4x^3 + 6x^2 + 4x + 1) + b(x^3 + 3x^2 + 3x + 1) + c(x^2 + 2x + 1) + d(x+1) \\ &\quad - ax^4 - bx^3 - cx^2 - dx \\ &= 4ax^3 + 3(2a+b)x^2 + (4a+3b+2c)x + (a+b+c+d). \end{aligned}$$

Hence, by the relation  $P(x+1) - P(x) = 4x^3$  we get the following system of equations:

$$\{4a = 4, \quad 2a + b = 0, \quad 4a + 3b + 2c = 0, \quad a + b + c + d\}.$$

This has unique solution given by  $a = 1, b = -2, c = 1$  and  $d = 0$ , thus  $P(x) = x^4 - 2x^3 + x^2 = x^2(x^2 - 2x + 1) = x^2(x-1)^2$ , and the claim follows.

**1.G.11.** This task can be challenging, especially at this point. However, we will make every effort to explain the code thoroughly, including our comments within the block, to ensure a clear understanding of each step. We will use the `def` keyword to define a function (or routine), which we name `horner_division`. This function has two inputs: A list of coefficients starting from degree 0, which we may think as  $[a_0, \dots, a_n]$ . The number  $n$  represents the number of coefficients in the polynomial  $p$ . Sage encodes this number by the command `len`. The second entry is the real number  $x_0$ . To perform the division we will combine the `for` loop with the `range()` function. Such combinations are essential in SageMath for handling repetitive tasks, as demonstrated in our example. Recall that the `range()` function generates a sequence of numbers, commonly used in `for` loops. We can customize such sequences using different arguments:

- One argument: `range(stop)` generates numbers from 0 to `stop - 1`.
- Two arguments: `range(start, stop)` generates numbers from `start` to `stop`.
- Three arguments: `range(start, stop, step)` generates numbers from `start` to `stop` with increments of `step`.

With all the necessary tools in place, we can now construct our routine. The code is as follows:

```
def horner_division(p, x0):
    n = len(p) # The number of coefficients in the polynomial
    q = [0] * (n - 1) # Initialize a list to hold the coefficients of the quotient
    r = p[n - 1] # Start with the leading coefficient (highest degree term)
    for i in range(n - 2, -1, -1): # Loop from the second last coefficient to the first
        q[i] = r # Assign the current remainder as a coefficient in the quotient
        r = p[i] + x0 * r # Update the remainder using the current coefficient and x0
    return q, r # Return the list of quotient coefficients and the remainder
```

Our routine is now ready to be tested. Let us use it to prove the second claim.

```
# Example polynomial
# Define the polynomial p(x) = 4 - 3x + 5x^2 - 2x^3 + x^4
p = [4, -3, 5, -2, 1]; x0 = 3
q, r = horner_division(p, x0)
print("Quotient coefficients:", q)
print("Remainder:", r)
```

Sage's output has the form

```
Quotient coefficients: [21, 8, 1, 1]
Remainder: 67
```

Thus dividing  $p(x) = 4 - 3x + 5x^2 - 2x^3 + x^4$  by  $(x - 3)$  we have quotient  $q(x) = 21 + 8x + x^2 + x^3$  and remainder  $r = 67$ .

**1.G.12.** (1) Fractions of the form  $z := \frac{z_1}{z_2}$ , where  $z_1, z_2$  are complex numbers with  $z_2 \neq 0$ , can be written in the form  $z = x + iy$  with  $x, y \in \mathbb{R}$ , after multiplying  $z$  with  $\frac{\bar{z}_2}{z_2}$ . This is because  $z_2 \bar{z}_2 = |z_2|^2 \in \mathbb{R}$ . For the given  $z$  we compute

$$\frac{1 + 2i}{4 - 5i} = \frac{1 + 2i}{4 - 5i} \cdot \frac{4 + 5i}{4 + 5i} = \frac{4 + 5i + 8i + 10i^2}{|4 + 5i|^2} = \frac{-6 + 13i}{4^2 + 5^2} = -\frac{6}{41} + i\frac{13}{41}.$$

This can be quickly verified in Sage by executing the following cell:

```
real((1+2*I)/(4-5*I)) == -6/41; imag((1+2*I)/(4-5*I)) == 13/41
```

For both commands Sage prints out True. You can also obtain the result directly by typing the following command:

```
z=(1+2*I)/(4-5*I); simplify(z)
```

(2) Denote by  $\alpha$  the quantity that we want to compute. We have

$$\alpha := \frac{(1+i)^{2023}}{(1-i)^{2020}} = \left(\frac{1+i}{1-i}\right)^{2020} (1+i)^3$$

and moreover

$$\frac{1+i}{1-i} = \frac{1+i}{1-i} \cdot \frac{1+i}{1+i} = \frac{(1+i)^2}{2} = i.$$

Hence  $\alpha = i^{2020}(1+i)^3 = i^{2020}(2i-2)$ , and it suffices to compute  $i^{2020}$ . A direct computation shows that  $i^4 = 1$  and moreover  $i^8 = 1$ . By induction it follows that  $i^{4n} = 1$  for all  $n \in \mathbb{N}$ . Thus  $i^{2020} = i^{4 \cdot 505} = 1$  and so  $\alpha = 2i - 2$ . A verification by Sage occurs by the cell

```
a=((1+I)**(2023))/((1-I)**(2020)); simplify(a)
```

(3-4) Both claims are true and indicate that  $S^1$  has the structure of a commutative group under multiplication, as discussed in 1.1.1. Indeed, the first assertion is true because the absolute value function is multiplicative, which implies that  $S^1$  is closed under multiplication. Specifically, for any  $z \in S^1$  we have  $|z| = 1$ , and hence  $z\bar{z} = |z|^2 = 1$ . Moreover, since  $|\frac{1}{z}| = \frac{1}{|z|} = 1$ , we confirm that  $\frac{1}{z} \in S^1$  for any  $z \in S^1$ , ensuring that  $S^1$  is closed under taking reciprocals. Below, we will explore a slightly different but equivalent interpretation of the unit circle, which provides an alternative way to verify these properties.

(5) The statement is true. We will verify this using Sage, and encourage the reader to explore and present alternative methods.

```
z=var("z"); solve(z**3+I==0, z)
```

**1.G.13.** The complex numbers that satisfy the conditions of the task lie on a circle in  $\mathbb{R}^2$ , with centre at  $P_2 = [-4, -2]$  and radius  $\rho$ , where  $\rho$  is the distance between  $z_2$  and  $w$ , i.e.,  $\rho = 2\sqrt{2} = |z_2 - w|$ . Let us illustrate this circle along with the complex numbers  $z_1, z_2$  in a figure (see the figure in the left-hand side).

Now,  $|z_2 - w| = |w - z_2| = |(x+4) + i(y+2)|$ , and we obtain  $\rho^2 = (2\sqrt{2})^2 = 8 = (x+4)^2 + (y+2)^2 = (x^2 + y^2) + 4(2x+y) + 20$ , i.e.,

$$(x^2 + y^2) + 4(2x + y) + 12 = 0. \quad (\dagger)$$

Moreover, if  $b = |z_1 - w| = |(2-x) + i(6-y)|$  is the distance between  $z_1, w$ , then we compute

$$b^2 = (2-x)^2 + (6-y)^2 = (x^2 + y^2) - 4(x+3y) + 40. \quad (\ddagger)$$

Finally, the distance between  $z_1, z_2$  is given by  $d = |z_1 - z_2| = |6 + 8i| = \sqrt{36 + 100} = 10$ . Recall that in Sage this can be verified by the command `abs(6 + 8i)`. We can now proceed with the Pythagorean theorem, which yields the condition  $d^2 = \rho^2 + b^2$ . Due to  $(\ddagger)$  and the above observations, this translates as

$$100 = 8 + (x^2 + y^2) - 4(x+3y) + 40 \iff 52 = (x^2 + y^2) - 4(x+3y).$$

Hence together with  $(\dagger)$  we result to the following system of equations

$$\left\{ \begin{array}{l} (x^2 + y^2) + 4(2x + y) = -12, \\ (x^2 + y^2) - 4(x + 3y) = 52. \end{array} \right.$$

We may multiple the first equation by a minus and then add it to the second one. This gives the equation  $y = -\left(\frac{3}{4}x + 4\right)$ . Replacing now this expression of  $y$  into any of the two equations determining the system (or even in the equation  $(\ddagger)$ ), one arrives to the following quadratic relation that determines  $x$ , namely

$$\frac{25}{16}x^2 + 11x + 12 = 0,$$

with discriminant  $\Delta = 46 > 0$ . Thus, there are two solutions that result in valid triangles, which are illustrated in the figure on the right above. Let us present the explicit form of the solutions:

$$x_{1,2} = \frac{8(-11 \pm \sqrt{46})}{25}, \quad y_{1,2} = -\left(\frac{3}{4}\left(\frac{-88 \pm 8\sqrt{46}}{25}\right) + 4\right).$$

Using Sage one may verify this by typing

```
x, y=var("x, y")
solve([x**2+y**2+4*(2*x+y)+12==0, x**2+y**2-4*(x+3*y)-52==0], x, y)
```

**1.G.25.** Consider first the division of a plane by  $n$  circles. As we know by 1.G.24, the maximum number  $y_n$  of areas a plane can be divided into by  $n$  circles is  $y_n = y_{n-1} + 2(n-1)$ ,  $y_1 = 2$ , that is,  $y_n = n^2 - n + 2$ . For the maximum number  $p_n$  of areas a space can be divided into by  $n$  balls, we obtain the recurrent formula  $p_{n+1} = p_n + y_n$ ,  $p_1 = 2$ , that is,  $p_n = \frac{n}{3}(n^2 - 3n + 8)$ .

**1.G.26.** Let  $x_n$  denote the number of regions in question. When  $n = 1$ , a single plane divides the space into two regions. This means that  $x_1 = 2$ . Now, each new additional plane will intersect all the existing  $n$  planes along lines that divide the new plane into regions. In more details, a new plane will intersect the existing  $n$  planes along  $n$  lines, each of which divides the new plane into additional regions. Thus each new plane adds  $2(n-1)$  new regions. Therefore we derive the following recurrence relation:  $x_n = x_{n-1} + 2(n-1)$ , with the initial condition  $x_1 = 2$ . It is now straightforward to see that the solution has the form  $x_n = n(n-1) + 2$ .

**1.G.29.** (a) For the driver's place we have two choices and the other places are then arbitrary, that is, for the second seat we have four choices, for the third three choices, then two and then 1. That makes  $2 \cdot 4! = 48$  ways.

(b) Similarly in the bus we have two choices for the driver, and then the other driver plus the passengers can be seated among the 24 seats arbitrarily. First choose the seats to be occupied, that is,  $\binom{24}{1}$ . Among these seats the people can be seated in  $21!$  ways. The solution is  $2 \cdot \binom{24}{1} 21! = \frac{24!}{3}$  ways.

**1.G.30.** (a)  $2^6 = 64$ .

(b)  $\binom{6}{4} = 15$ .

(c) No head is one possibility  $\binom{6}{0} = 1$ , one head is  $\binom{6}{1} = 6$ . Thus there are 7 sequences with at most one head and the result is  $64 - 7 = 57$ .

**1.G.31.** (i) Let us add three matches to the 40 balls. If we order the balls and matches in a row, the matches divide the balls in 4 sections. We order the boys at random, give the first boy all the balls from the first section, give the second boy all the balls from the second section and so on. It is now evident that the result is  $\binom{43}{3} = 12\,341$ .

(ii) From the problem statement it is clear that  $C$  must receive 11 coins. That can be done in  $\binom{33}{11}$  ways. Each of the remaining 22 coins can be given either to  $A$  or to  $B$ , which gives  $2^{22}$  ways. Using the rule of product we obtain the result  $\binom{33}{11} \cdot 2^{22}$ . (iii) We divide the boys and the girls independently. Thus the answer is  $2^9(2^5 - 7) = 12800$ .

**1.G.33.** Each pair of players shakes hands at the introduction. As we know the number of handshakes is the combination  $c(6, 2) = \binom{6}{2} = 15$ . After a match each of the six players shakes hands six times (with each of six opponents). Hence the required number is  $6^2 = 36$ .

**1.G.39.** (a) The answer is  $1/6$ .

(b) One can reformulate this task, as we are throwing the dice  $n$  times. The probability that the first roll does not result into 1, 3 or 6 is  $1/2$ . The probability that neither the first nor the second roll is clearly  $1/4$ . This is because the result of the first roll does not influence the result of the second roll. Because the event determined by the result of a given roll and the event determined by the result of another roll are always (stochastically) independent, we deduce that the probability is  $1/2^n$ .

(c) If we denote the event "first dice resulted in five" by  $A$  and the event "the sum is 9" by  $H$ , then it holds

$$P(A|H) = \frac{P(A \cap H)}{P(H)} = \frac{\frac{1}{36}}{\frac{4}{36}} = \frac{1}{4}.$$

Note that the sum 9 occurs when the first die is 3 and the second 6, the first is 4 and the second 6, the first is 5 and the second is 4, or the first is 6 and the second is 3. Of those four results (that have the same probability) only one is favourable to the event  $A$ . Since the probability of  $A$  is clearly  $1/6 \neq 1/4$ , the events are not mutually independent.

**1.G.43.** The space of all possible events can be viewed as a square  $3 \times 3$ . Denote by  $x$  the arrival time of Michael and by  $y$  the arrival time of Alex. In such terms we can claim that these two persons will meet if and only if  $|x - y| \leq \frac{1}{2}$ . This inequality determines in the square of all possible events the area whose volume is  $11/36$  of the volume of the whole square. Thus, this is also the probability of the event.

**1.G.44.** Dividing the quadrilateral into two triangles  $ABC$  and  $ACD$  with areas  $S_1$  and  $S_2$  we obtain

$$S = S_1 + S_2 = \frac{1}{2} \begin{vmatrix} 1-0 & 1-0 \\ -1+2 & 5+2 \end{vmatrix} + \frac{1}{2} \begin{vmatrix} 1-0 & -1-0 \\ 5+2 & 1+2 \end{vmatrix} = \frac{1}{2} (7-1) + \frac{1}{2} (3+7) = 8.$$

**1.G.45.** Eliminating  $y$  yields  $(4x - 2y - 10) + (x + 2y - 5) = 0$ , from which  $x = 3$ , and hence  $y = 1$ . Hence the lines intersect at the point  $P = [3, 1]$ .

**1.G.46.** The given vectors correspond to complex numbers  $1 + i$ ,  $2 + i$  and  $3 + i$ . We are to find the sum of their arguments. According to de Moivre's formula this equals the argument of their product. Their product is  $(1 + i)(2 + i)(3 + i) = (1 + 3i)(3 + i) = 10i$ , which is a purely imaginary number with argument  $\pi/2$ . So the sum we are looking for is  $\pi/2$ .

**1.G.49.** Clearly,  $A^2 = A$  and hence  $E - A^2 = E - A = \begin{pmatrix} 0 & 0 \\ 0 & 1 \end{pmatrix}$ . Also,  $B$  is symmetric, i.e.,  $B = B^T$ , and hence

$BB^T = B^2 = \begin{pmatrix} 5 & 4 \\ 4 & 5 \end{pmatrix}$ . Thus, the equation  $X(E - A^2) + BB^T = D$  is equivalent to  $\begin{pmatrix} 5 & b+4 \\ 4 & d+5 \end{pmatrix} = \begin{pmatrix} 5 & -b \\ 4 & -4d \end{pmatrix} \iff \begin{pmatrix} 0 & 2b+4 \\ 0 & 5d+5 \end{pmatrix} = \begin{pmatrix} 0 & 0 \\ 0 & 0 \end{pmatrix}$ . Its solution is given by  $b = -2$ ,  $d = -1$ , and  $a, c \in \mathbb{R}$  free. In Sage we can directly compute the expression  $X(E - A^2) + BB^T - D$  as follows:

```
var("a, b, c, d")
X=matrix([[a, b], [c, d]]); D=matrix([[5, -b], [4, -4*d]])
A=matrix([[1, 0], [0, 0]]); B=matrix([[1, 2], [2, 1]])
E = identity_matrix(2)
show(X*E-X*A^2+B*(B.transpose())-D)
```

**1.G.59.** The number we need to determine is obtained by subtracting the number of non-surjective mappings from the number of all mappings. The number of all mappings is  $V(3, 4) = 3^4$ . Non-surjective mappings have either a one element, or a two element codomain. There are just three mappings with a one element codomain. The number of mappings with a two-element codomain is  $\binom{3}{2}(2^4 - 2)$  (there are  $\binom{3}{2}$  ways to choose the codomain and for a fixed two-element codomain there are  $2^4 - 2$  ways how to map four elements onto them). Therefore, the number of surjective mappings is  $3^4 - \binom{3}{2}(2^4 - 2) - 3 = 36$ .

**1.G.63.** We see that  $R^{-1} = \{(4, 0), (0, -3), (\pi, 5), (2, 5), (2, 0)\}$ . Moreover,

$$R \circ R^{-1} = \{(4, 4), (0, 0), (\pi, \pi), (2, 2), (4, 2), (\pi, 2), (2, \pi), (2, 4)\}.$$

**1.G.65.** Here are the solutions:

- i)  $(3, 3), (4, 4), (5, 5), (6, 6), (7, 7), (3, 6)$ , check that it is an ordering relation.
- ii) again  $(i, i)$  for  $i = 1, \dots, 7$  and additionally  $(3, 6), (6, 3)$ , check that it is an equivalence relation.
- iii)  $(i, i)$  for  $i = 1, \dots, 7$  and also  $(3, 6), (6, 3), (4, 6), (6, 4)$ . Check that it is not an equivalence, since transitivity does not hold.

## Elementary linear algebra

Can't you count with scalars yet?  
 – no worry, let us go straight to matrices...

### A. Vectors and matrices

 The vectors ( $n$ -tuples of scalars) and matrices (2-dimensional arrays of scalars) are the backbone of most of the computational power in practical tasks in all disciplines relying on any kind of data analytics or numerics (e.g., physics, biology, chemistry, engineering, or economics). In this chapter we shall focus on matrix calculus and illustrate some of its simple applications.

To start with, we display a few elementary tasks on matrices and vectors, extending the discussion in the first chapter (see, e.g., 1.E.12 and 1.E.14). Recall that the matrix multiplication works only if the matrix on the left has got the same

In the previous chapter we warmed up by considering relatively simple problems which did not require any sophisticated tools. It was enough to use addition and multiplication of scalars. In this and subsequent chapters we shall add more sophisticated thoughts and concepts.

First we restrict ourselves to concepts and operations consisting of a finite number of multiplications and additions to a finite number of scalars. This will take us three chapters and only then will we move on to infinitesimal concepts and tools. Typically we deal with finite collections of scalars of a given size. We speak about “linear objects” and “linear algebra”. Although it might seem to be a very special tool, we shall see later that even more complicated objects are studied mostly using their “linear approximations”.

 In this chapter we will work with finite sequences of scalars. Such sequences arise in real-world problems whenever we deal with objects described by several parameters, which we shall call coordinates. Do not try much to imagine the space with more than three coordinates. You have to live with the fact that we are able to depict only one, two or three dimensions. However, we will deal with an arbitrary number of dimensions. For example, observing any parameter in a group of 500 students (for instance, their study results), our data will have 500 elements and we would like to work with them. Our goal is to develop tools which will work well even if the number of elements is large.

Do not be afraid of terms like field or ring of scalars  $\mathbb{K}$ . Simply, imagine any specific domain of numbers. Rings of scalars are for instance integers  $\mathbb{Z}$  and all residue classes  $\mathbb{Z}_k$ . Among fields we have seen only  $\mathbb{R}$ ,  $\mathbb{Q}$ ,  $\mathbb{C}$  and residue classes  $\mathbb{Z}_k$  for  $k$  prime.  $\mathbb{Z}_2$  is very specific among them, because the equation  $x = -x$  does not imply  $x = 0$  here, whereas in nearly every other field it does.

### 1. Vectors and matrices

In the first two parts of this chapter, we will work with vectors and matrices in the simple context of finite sequences of scalars. We can imagine working with integers or residue classes as well as real or complex numbers. We hope to illustrate how easily a concise and formal reasoning can lead to strong results valid in a much broader context than just for real numbers.

number of columns as the number of rows of the matrix on the right. The number of rows in the result coincides with that of the left matrix, while its number of columns equals the number of columns of the right-hand matrix.

**2.A.1. Matrix multiplication.** Check the computations:

$$\begin{aligned} \text{(a)} \quad & \begin{pmatrix} 1 & 2 \\ -1 & 3 \end{pmatrix} \begin{pmatrix} 1 & -1 \\ 2 & 1 \end{pmatrix} = \begin{pmatrix} 5 & 1 \\ 5 & 4 \end{pmatrix}, \\ \text{(b)} \quad & \begin{pmatrix} 1 & -1 \\ 2 & 1 \end{pmatrix} \begin{pmatrix} 1 & 2 \\ -1 & 3 \end{pmatrix} = \begin{pmatrix} 2 & -1 \\ 1 & 7 \end{pmatrix}, \\ \text{(c)} \quad & \begin{pmatrix} 1 & 2 & 3 \\ 1 & -1 & 1 \end{pmatrix} \begin{pmatrix} 1 & -1 & 2 & 1 \\ 1 & 1 & -2 & -3 \\ 3 & 2 & 1 & 0 \end{pmatrix} \\ & = \begin{pmatrix} 12 & 7 & 1 & -5 \\ 3 & 0 & 5 & 4 \end{pmatrix}, \\ \text{(d)} \quad & (1 \ 3 \ -3) \begin{pmatrix} 1 & -2 & 3 \\ 3 & 2 & 1 \\ 1 & -1 & -4 \end{pmatrix} = (7 \ 7 \ 18), \\ \text{(e)} \quad & (1 \ 2 \ -2) \begin{pmatrix} 2 \\ 1 \\ 3 \end{pmatrix} = (-2) = -2. \end{aligned}$$

**Remark.** As we already mentioned in Chapter 1, the multiplication of matrices is not commutative in general. Parts (a) and (b) in 2.A.1 illustrate this fact for  $2 \times 2$  matrices. On the other hand, part (e) illustrates that multiplying rows and columns produces the so called *scalar products* of vectors (also called *dot products*), and our approach to distances and angles will rely on them. For two vectors like  $u = (2, 1, 3)^T$  and  $v = (1, 2, -2)^T$ , we write  $\langle u, v \rangle$  or  $u \cdot v$  for  $v^T u = -2$ .

As usual, we use the superscript  $T$  to indicate the transposition of the matrices (i.e., we write the rows of  $A$  as columns in  $A^T$ ), and  $E$  for the identity matrix and its dimension will be clear from the context.

**2.A.2.** For the following matrices and vectors

$$A = \begin{pmatrix} 1 & 1 \\ 0 & \sqrt{2} \end{pmatrix}, \quad B = \begin{pmatrix} 1 & 4 \\ 4 & 0 \end{pmatrix}, \quad u = \begin{pmatrix} 0 \\ \sqrt{2} \end{pmatrix}, \quad v = \begin{pmatrix} 1 \\ 4 \end{pmatrix}$$

compute the given expressions:

- 1)  $(A - E)(A + E)$ ,
- 2)  $A(Bu)$ ,
- 3)  $(A - B)(A + B)u$ ,
- 4)  $aA^2 + aB^2$  ( $a \in \mathbb{R}$ ),
- 5)  $u \cdot v - 4\sqrt{2}$ ,
- 6)  $4A^3 - B^2$ ,
- 7)  $\sqrt{2}u - \frac{1}{2}v$ ,
- 8)  $\frac{\sqrt{2}}{2}u - ABu + 2v$ ,
- 9)  $A^2u - B^2v$ ,
- 10)  $(B^2u) \cdot (4v)$ .

**2.A.3.** Compute all tasks in 2.A.2 in Sage.

**Solution.** A solution goes as follows:

Later, we follow the general terminology where the notion of vectors is related to fields of scalars only.

**2.1.1. Vectors over scalars.** For now, a *vector* is for us an ordered  $n$ -tuple of scalars from  $\mathbb{K}$ , where the fixed  $n \in \mathbb{N}$  is called *dimension*.

We can add and multiply scalars. We will be able to add vectors, but multiplying a vector will be possible only by a scalar. This corresponds to the idea we have already seen in the plane  $\mathbb{R}^2$ . There, addition is realized as vector composition (as composition of arrows having their direction and size and compared when emanating from the origin). Multiplication by scalar is realized as stretching the vectors.

A vector  $u = (a_1, \dots, a_n)$  is multiplied by a scalar  $c$  by multiplying every element of the  $n$ -tuple  $u$  by  $c$ . Addition is defined coordinate-wise.

BASIC VECTOR OPERATIONS

For all vectors  $u, v$  and scalars  $c$  we define

$$\begin{aligned} u + v &= (a_1, \dots, a_n) + (b_1, \dots, b_n) \\ &= (a_1 + b_1, \dots, a_n + b_n) \\ c \cdot u &= c \cdot (a_1, \dots, a_n) = (c \cdot a_1, \dots, c \cdot a_n). \end{aligned}$$

For vector addition and multiplication by scalars we shall use the same symbols as for scalars, that is, respectively, plus and either dot or juxtaposition, i.e.,  $cu = c(a_1, \dots, a_n) = (ca_1, \dots, ca_n)$ .

**The vector notation convention.** We shall not, unlike many other textbooks, use any special notations for vectors and leave it to the reader to pay attention to the context. For scalars, we shall mostly use letters from the beginning of the alphabet, for the vectors from the end of the alphabet. The middle part of the alphabet can be used for indices of variables or components and also for summation indices.

In the general theory in the end of this chapter and later, we will work exclusively with fields of scalars when talking about vectors. Now we will work with the more relaxed properties of scalars as listed in 1.1.1.

For vector addition in  $\mathbb{K}^n$ , the properties (CG1)–(CG4) (see 1.1.1) clearly hold with the zero element being (notice we define the addition coordinate-wise)  $0 = (0, \dots, 0) \in \mathbb{K}^n$ . We are purposely using the same symbol for both the zero vector element and the zero scalar element. Next, let us notice the following basic properties of vectors:

VECTOR PROPERTIES

For all vectors  $v, w \in \mathbb{K}^n$  and scalars  $a, b \in \mathbb{K}$  we have

- (V1)  $a \cdot (v + w) = a \cdot v + a \cdot w$
- (V2)  $(a + b) \cdot v = a \cdot v + b \cdot v$
- (V3)  $a \cdot (b \cdot v) = (a \cdot b) \cdot v$
- (V4)  $1 \cdot v = v$

```
E=matrix.identity(2)
A=matrix([[1, 1], [0, sqrt(2)]])
B=matrix([[1, 4], [4, 0]])
u=vector([0, sqrt(2)])
v=vector([1, 4])
show((A-E)*(A+E))
show(A*B*u)
show((A-B)*(A+B)*u)
show(A^2+B^2)
u.dot_product(v)
show(4*A^3-B^2)
show(sqrt(2)*u-(1/2)*v)
show((sqrt(2)/2)*u-A*B*u+2*v)
show(A^2*u-B^2*v)
(B^2*u).dot_product(4*v)
```

□

Doing computations with matrices, we always recommend to use Sage to verify your formal computations, especially for large size matrices.

**2.A.4.** Determine explicitly each of the following vectors (by hand), and next verify your answer in Sage:

- 1)  $u_1 := (A - E)^2(4B)u$ ,    3)  $u_3 := A(Bu)$ ,
- 2)  $u_2 := (A - E)^T(B^2u)$ ,    4)  $u_4 := B(Au)$ ,

where  $E$  is the identity  $3 \times 3$  matrix and  $A, B, u$  are respectively given by

$$A = \begin{pmatrix} 1 & \sqrt{2} & \pi \\ 0 & 1 & 1 \\ -\pi & 0 & 2 \end{pmatrix}, \quad B = \begin{pmatrix} 0 & 1 & 1 \\ -1 & 0 & \pi \\ -1 & 0 & 1 \end{pmatrix}, \quad u = \begin{pmatrix} \pi \\ 0 \\ \sqrt{2} \end{pmatrix}.$$

○

*While explicit computations in high dimensions (i.e., dealing with vectors with large number of components) can hardly be imagined without the use of computer aided mathematics software, like Sage, the understanding of structure and properties is often based on visual perception. Of course, we are then limited to dimensions two or three, but even then we can gain essential insight how the things may work in general (and this fact might be viewed as one of the strategies to build a mathematical mindset). Thus, we should enjoy the Sage tools designed to plot vectors and similar objects.<sup>1</sup>*

**2.A.5.** Use Sage for plotting: (a) The vectors  $u = (1, 2, 3)^T$ ,  $v = (2, -3, 4)^T$ ,  $u + v$ ,  $u - v$ , which are all vectors of the 3-dimensional Euclidean space  $\mathbb{R}^3$ .

(b) Repeat for the vectors  $x = (4, 0, 2)^T$ ,  $y = (-3, 0, 1)^T$ ,  $x + y$ , and  $x - y$ .

**Solution.** (a) The simplest method is to introduce the vectors, and then use the function `plot`, as follows:

```
u = vector([1, 2, 3])
```

<sup>1</sup>Notice that so far Sage allows us to introduce vectors and make operations between them, without a reference to the choice of scalars. Later in 2.C.12 we will see how to treat vectors in Sage, when they are viewed as elements of some specific vector space.

The properties (V1)–(V4) of our vectors are easily checked for any specific ring of scalars  $\mathbb{K}$ , since we need just the corresponding properties of scalars as listed in 1.1.1, applied to individual components of the vectors. In this way we shall work with, for instance,  $\mathbb{R}^n$ ,  $\mathbb{Q}^n$ ,  $\mathbb{C}^n$ , but also with  $\mathbb{Z}^n$ ,  $(\mathbb{Z}_k)^n$ ,  $n = 1, 2, 3, \dots$

**2.1.2. Matrices over scalars.** Matrices are slightly more complicated objects, useful when working with vectors.

#### MATRICES OF TYPE $m/n$

A matrix of the type  $m/n$  over scalars  $\mathbb{K}$  is a rectangular schema  $A$  with  $m$  rows and  $n$  columns

$$A = \begin{pmatrix} a_{11} & a_{12} & \dots & a_{1n} \\ a_{21} & a_{22} & \dots & a_{2n} \\ \vdots & & & \vdots \\ a_{m1} & a_{m2} & \dots & a_{mn} \end{pmatrix}$$

where  $a_{ij} \in \mathbb{K}$  for all  $1 \leq i \leq m$ ,  $1 \leq j \leq n$ . For a matrix  $A$  with elements  $a_{ij}$  we also use the notation  $A = (a_{ij})$ .

The vector  $(a_{i1}, a_{i2}, \dots, a_{in}) \in \mathbb{K}^n$  is called the ( $i$ -th) row of the matrix  $A$ ,  $i = 1, \dots, m$ . The vector  $(a_{1j}, a_{2j}, \dots, a_{mj}) \in \mathbb{K}^m$  is called the ( $j$ -th) column of the matrix  $A$ ,  $j = 1, \dots, n$ .

Matrices of the type  $1/n$  or  $n/1$  are actually just vectors in  $\mathbb{K}^n$ .

All general matrices can be understood as vectors in  $\mathbb{K}^{mn}$ , we just consider all the columns. In particular, matrix addition and matrix multiplication by scalars is defined:

$$A + B = (a_{ij} + b_{ij}), \quad a \cdot A = (a \cdot a_{ij})$$

where  $A = (a_{ij})$ ,  $B = (b_{ij})$ ,  $a \in \mathbb{K}$ .

The matrix  $-A = (-a_{ij})$  is called the additive inverse to the matrix  $A$  and the matrix

$$0 = \begin{pmatrix} 0 & \dots & 0 \\ \vdots & & \vdots \\ 0 & \dots & 0 \end{pmatrix}$$

is called the zero matrix. By considering matrices as  $mn$ -dimensional vectors, we obtain the following:

**Proposition.** The formulas for  $A+B$ ,  $a \cdot A$ ,  $-A$ ,  $0$  define the operations of addition and multiplication by scalars for the set of all matrices of the type  $m/n$ , which satisfy properties (V1)–(V4).

**2.1.3. Matrices and equations.** Many mathematical models are based on systems of linear equations. Matrices are useful for the description of such systems. In order to see this, let us introduce the notion of scalar product of two vectors, assigning to the vectors  $(a_1, \dots, a_n)$  and  $(x_1, \dots, x_n)$  their product

$$(a_1, \dots, a_n) \cdot (x_1, \dots, x_n) = a_1x_1 + \dots + a_nx_n.$$

This means, we multiply the corresponding coordinates of the vectors and sum the results.

```
v = vector([2, -3, 4])
u_plus_v = u + v
u_minus_v = u - v
uu=plot(u, color="blue")
vv=plot(v, color="green")
uplusv=plot(u_plus_v, color="green")
uminusv=plot(u_minus_v, color="purple")
show(uu+vv+uplusv+uminusv)
```

However, Sage offers an alternative method for plotting vectors in three dimensions, using the `arrow3d` function. For instance, to visualize the vectors in (a) you can use the following block:

```
u=vector([1, 2, 3])
v=vector([2, -3, 4])
u_plus_v=u + v
u_minus_v=u - v
u_ar=arrow3d([0, 0, 0], u, color="red")
v_ar=arrow3d([0, 0, 0], v, color="blue")
u_plus_v_ar=arrow3d([0, 0, 0],
u_plus_v, color="green")
u_minus_v_ar=arrow3d([0, 0, 0],
u_minus_v, color="purple")
p=u_ar+v_ar+u_plus_v_ar+u_minus_v_ar
p.show()
```

In this block we used red, blue, green and purple to represent the vectors  $u, v, u+v$  and  $u-v$ , respectively. Run the code in your Sage environment to generate and view the vector plot. Next apply the same method to analyze the second set of vectors. □

*As our first real task essentially involving matrices, we are going to develop a systematic approach for solving systems of linear equations. Our first aim is to introduce the beautiful Gauss elimination method (see 2.1.7 for details), treating a few examples. You might also look into 2.1.3. Later, in Section C, we shall relate the description given here with the important notions of “affine spaces” and “vector spaces”.*

**2.A.6. A colourful example.** A company of painters orders 810 litres of paint, to contain 270 litres each of red, green and blue coloured paint. The provider can satisfy this order by mixing the colours he usually sells, namely:

- reddish colour – it contains 50% of red, 25% of green and 25% of blue colour;
- greenish colour – it contains 12.5% of red, 75% of green and 12.5% of blue colour;
- bluish colour – it contains 20% of red, 20% of green and 60% of blue colour.

How many litres of each of the colours at the warehouse have to be mixed in order to satisfy the order?

**Solution.** Let us denote by

- $x$  – the number of litres of reddish colour to be used;
- $y$  – the number of litres of bluish colour to be used;

Every system of  $m$  linear equations in  $n$  variables

$$\begin{aligned} a_{11}x_1 + a_{12}x_2 + \cdots + a_{1n}x_n &= b_1 \\ a_{21}x_1 + a_{22}x_2 + \cdots + a_{2n}x_n &= b_2 \\ &\vdots \\ a_{m1}x_1 + a_{m2}x_2 + \cdots + a_{mn}x_n &= b_m \end{aligned}$$

can be seen as a constraint on values of  $m$  scalar products with one unknown vector  $(x_1, \dots, x_n)$  (called the *vector of variables*, or *vector variable*) and the known vectors of coordinates  $(a_{i1}, \dots, a_{in})$ .

The vector of variables can be also seen as a column in a matrix of the type  $n/1$ , and similarly the values  $b_1, \dots, b_m$  can be seen as a vector  $u$ , and that is again a single column of the matrix of the type  $m/1$ . Our system of equations can then be formally written as  $A \cdot x = u$  as follows:

$$\begin{pmatrix} a_{11} & \cdots & a_{1n} \\ \vdots & & \vdots \\ a_{m1} & \cdots & a_{mn} \end{pmatrix} \cdot \begin{pmatrix} x_1 \\ \vdots \\ x_n \end{pmatrix} = \begin{pmatrix} b_1 \\ \vdots \\ b_m \end{pmatrix}$$

where the left-hand side is interpreted as  $m$  scalar products of the individual rows of the matrix (giving rise to a column vector) with the vector variable  $x$ , whose values are prescribed by the equations. That means that the identity of the  $i$ -th coordinates corresponds to the original  $i$ -th equation

$$a_{i1}x_1 + \cdots + a_{in}x_n = b_i$$

and the notation  $A \cdot x = u$  gives the original system of equations.

**2.1.4. Matrix product.** In the plane, that is, for vectors of dimension two, we developed a matrix calculus. We noticed that it is effective to work with (see 1.5.4). Now we generalize such a calculus and we develop all the tools we know already from the plane case to deal with higher dimensions  $n$ .

It is possible to define matrix multiplication only when the dimensions of the rows and columns allow it, that is, when the scalar product is defined for them as before:

MATRIX PRODUCT

For any matrix  $A = (a_{ij})$  of the type  $m/n$  and any matrix  $B = (b_{jk})$  of the type  $n/q$  over the ring of scalars  $\mathbb{K}$  we define their product  $C = A \cdot B = (c_{ik})$  as a matrix of the type  $m/q$  with the elements

$$c_{ik} = \sum_{j=1}^n a_{ij}b_{jk}, \text{ for arbitrary } 1 \leq i \leq m, 1 \leq k \leq q.$$

That is, the element  $c_{ik}$  of the product is exactly the scalar product of the  $i$ -th row of the matrix on the left and of the  $k$ -th column of the matrix on the right. For instance we have

$$\begin{pmatrix} 2 & 1 \\ 1 & -1 \end{pmatrix} \cdot \begin{pmatrix} 2 & 1 & 1 \\ -1 & 0 & 1 \end{pmatrix} = \begin{pmatrix} 3 & 2 & 3 \\ 3 & 1 & 0 \end{pmatrix}.$$

- $z$  – the number of litres of greenish colour to be used;

By mixing the colours, we want the final colour to contain 270 litres of red. By assumption, the reddish contains 50% of red, the greenish contains 12.5% of red and the bluish 20% of red. Hence, we get the equation

$$0.5x + 0.125y + 0.2z = 270.$$

Similarly, for blue and green colour, respectively, we get

$$\begin{aligned} 0.25x + 0.75y + 0.2z &= 270, \\ 0.25x + 0.125y + 0.6z &= 270. \end{aligned}$$

From the first equation we have  $x = 540 - 0.25y - 0.4z$ , and then the second and third equations give  $2.75y + 0.4z = 540$  and  $0.25y + 2z = 540$ , respectively. Hence,  $z = 270 - 0.125y$  and after substituting into the first equation, we obtain  $2.7y = 432$ , that is,  $y = 160$ . Therefore  $z = 270 - 0.125 \cdot 160 = 250$  and  $x = 540 - 0.25 \cdot 160 + 0.4 \cdot 250 = 400$ . This means that it is necessary to mix 400 litres of reddish, 160 litres of bluish and 250 litres of greenish colour.

Once you have set up the system that describes the problem, you can quickly find the solution using Sage. For example, enter the following block

```
var("x, y, z")
eq1=0.5*x+0.125*y+0.2*z-270
eq2=0.25*x+0.75*y+0.2*z-270
eq3=0.25*x+0.125*y+0.6*z-270
solve([eq1==0,eq2==0, eq3==0], x, y, z)
```

Sage's output is the list

```
[[x == 400, y == 160, z == 250]] □
```

**2.A.7. Matrix notation.** Approach the previous problem using the matrix notation and solving the matrix equation in Sage.

**Solution.** A practical approach to solve linear systems of equations relies on matrix notation. The first step is to construct the corresponding *coefficient matrix*, where each row represents the coefficients of the variables in a specific equation. In particular, the first row contains the coefficients from the first equation, the second row from the second equation, and so forth.

In our case, the system in 2.A.6 leads to the  $3 \times 3$  matrix

$$A = \begin{pmatrix} 0.5 & 0.125 & 0.2 \\ 0.25 & 0.75 & 0.2 \\ 0.25 & 0.125 & 0.6 \end{pmatrix}.$$

Then we write the system of equations as  $Ax = b$ , where  $x = (x_1, x_2, x_3)^T$  and  $b = (270, 270, 270)^T$ , respectively. We call  $x$  the vector of unknowns, and  $b$  the vector of constants in the right hand side of the system.

Merging  $A$  and the vector  $b$ , we arrive at the so called *extended matrix*<sup>2</sup>, which in our example has got the form

$$(A \mid b) = \left( \begin{array}{ccc|c} 0.5 & 0.125 & 0.2 & 270 \\ 0.25 & 0.75 & 0.2 & 270 \\ 0.25 & 0.125 & 0.6 & 270 \end{array} \right). \quad (\#)$$

<sup>2</sup>The extended matrix is also referred to as the *augmented matrix*.

**2.1.5. Square matrices.** If there is the same number of rows and columns in the matrix, we speak of a *square matrix*. The number of rows or columns is then called the *dimension of the matrix*. The matrix

$$E = (\delta_{ij}) = \begin{pmatrix} 1 & \dots & 0 \\ \vdots & \ddots & \vdots \\ 0 & \dots & 1 \end{pmatrix}$$

is called the *unit matrix*, or alternatively, the *identity matrix*. The numbers  $\delta_{ij}$  defined in such a way are also called the *Kronecker delta*. When we restrict ourselves to square matrices over  $\mathbb{K}$  of fixed dimension  $n$ , the matrix product is defined for any two matrices. That is, there is the well defined multiplication operation there. Its properties are similar to that of scalars:

**Proposition.** *On the set of all square matrices of dimension  $n$  over an arbitrary ring of scalars  $\mathbb{K}$ , the multiplication operation is defined with the following properties of rings (see 1.1.1):*

- (R1) Multiplication is associative.
- (R3) The unit matrix  $E = (\delta_{ij})$  is the unit element for multiplication.
- (R4) Multiplication and addition is distributive.

*In general, neither the property (R2) nor (ID) are true. Therefore, the square matrices for  $n > 1$  do not form an integral domain, and consequently they cannot be a (commutative or non-commutative) field.*

**PROOF.** Associativity of multiplication – (R1): Since scalars are associative, distributive and commutative, we can compute for any three matrices  $A = (a_{ij})$  of type  $m/n$ ,  $B = (b_{jk})$  of type  $n/p$  and  $C = (c_{kl})$  of type  $p/q$ :

$$\begin{aligned} A \cdot B &= \left( \sum_j a_{ij} \cdot b_{jk} \right), & B \cdot C &= \left( \sum_k b_{jk} \cdot c_{kl} \right), \\ (A \cdot B) \cdot C &= \left( \sum_k \left( \sum_j a_{ij} b_{jk} \right) c_{kl} \right) = \left( \sum_{j,k} a_{ij} b_{jk} c_{kl} \right), \\ A \cdot (B \cdot C) &= \left( \sum_j a_{ij} \left( \sum_k b_{jk} c_{kl} \right) \right) = \left( \sum_{j,k} a_{ij} b_{jk} c_{kl} \right). \end{aligned}$$

Note that while computing, we relied on the fact that it does not matter in which order are we performing the sums and products, that is, we were relying on the properties of scalars.

We can easily see that multiplication by a unit matrix has the property of a unit element:

$$A \cdot E = \begin{pmatrix} a_{11} & \dots & a_{1m} \\ \vdots & & \\ a_{m1} & \dots & a_{mm} \end{pmatrix} \cdot \begin{pmatrix} 1 & 0 & \dots & 0 \\ 0 & 1 & \dots & 0 \\ \vdots & \vdots & & \\ 0 & 0 & \dots & 1 \end{pmatrix} = A$$

and similarly from the left,

$$E \cdot A = A.$$

It remains to prove the distributivity of multiplication and addition. Again using the distributivity of scalars we can

Observe that the extended matrix completely encodes the original linear system of equations (just leaving out the variable names). We shall come back to the extended matrix in the next task.

In order to find a solution of  $Ax = b$  in Sage, we can use the command `A.solve_right(b)`. For our case:

```
A=matrix(QQ, [[0.5, 0.125, 0.2], [0.25,
0.75, 0.2], [0.25, 0.125, 0.6]])
b=vector([270, 270, 270])
x = A.solve_right(b); print(x)
```

Or, instead of `A.solve_right(b)`, we could type `A\b`, i.e.,

```
A=matrix(QQ, [[0.5, 0.125, 0.2],
[0.25, 0.75, 0.2], [0.25, 0.125, 0.6]])
b=vector([270, 270, 270])
A \ b #this is a Matlab like command
```

In the sequel we will refer to `A\b` as the “backslash” operator in Sage. If we are interested in a system of the form  $xA = b$ , in order to solve for  $x$  we use the command `A.solve_left(b)`. Let us notice that if the matrix equation does not have a solution, Sage returns an error (see also 2.A.20 for a similar case), while if it does have solutions, Sage returns just one. We shall come back to this phenomenon later.

**2.A.8. Using the echelon form.** Solve the previous problem again, this time using the transformation to the echelon form of the extended matrix.

**Solution.** The mathematical approach suggests to look for “equivalent” systems of equations with the same solution sets, perhaps much nicer than the original one. The crucial observation is that *elementary row transformations* allow us to transform the extended matrix into a *row echelon form*, see 2.1.7. Recall, the elementary row operations correspond to interchanging of any two rows, multiplying each element of a row by a non-zero number, or adding (a multiple of) a row to another one.

Dealing with an extended matrix  $B = (A \mid b)$ , in Sage the elementary row operations are implemented via the following functions:<sup>3</sup>

- |                                      |   |
|--------------------------------------|---|
| <code>B.swap.rows()</code>           | interchange two rows,                                 |
| <code>B.rescale.row()</code>         | scale a row by a factor,                              |
| <code>B.add_multiple_of_row()</code> | add a multiple of one row to another row and replace. |

Recall, a matrix is in row echelon form if it meets the following requirements:

- The first non-zero number from the left in a non-zero row, known as the *leading coefficient* or *pivot*, is always to the right of the leading coefficient of the row above it.
- Rows containing only zeros are located at the bottom of the matrix.

<sup>3</sup>In Sage there are similar functions encoding the column operations.

easily calculate for matrices  $A = (a_{ij})$  of the type  $m/n$ ,  $B = (b_{jk})$  of the type  $n/p$ ,  $C = (c_{jk})$  of the type  $n/p$ ,  $D = (d_{kl})$  of the type  $p/q$

$$\begin{aligned}
 A \cdot (B + C) &= \left( \sum_j a_{ij}(b_{jk} + c_{jk}) \right) \\
 &= \left( \left( \sum_j a_{ij}b_{jk} \right) + \left( \sum_j a_{ij}c_{jk} \right) \right) = A \cdot B + A \cdot C \\
 (B + C) \cdot D &= \left( \sum_k (b_{jk} + c_{jk})d_{kl} \right) \\
 &= \left( \left( \sum_k b_{jk}d_{kl} \right) + \left( \sum_k c_{jk}d_{kl} \right) \right) = B \cdot D + C \cdot D.
 \end{aligned}$$

As we have seen in 1.5.4, two matrices of dimension two do not necessarily commute: for example

$$\begin{aligned}
 \begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix} \cdot \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix} &= \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix} \\
 \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix} \cdot \begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix} &= \begin{pmatrix} 0 & 0 \\ 0 & 0 \end{pmatrix}.
 \end{aligned}$$

This gives us immediately a counterexample to the validity of (R2) and (ID). For matrices of type  $1/1$  both axioms clearly hold, because the scalars itself have them. For matrices of greater dimension the counterexamples can be obtained similarly. Simply place the counterexamples for dimension 2 in their left upper corner, and select the rest to be zero. (Verify this on your own!) □

In the proof we have actually worked with matrices of more general types, thus we have proved the properties in greater generality:

ASSOCIATIVITY AND DISTRIBUTIVITY

Matrix multiplication is associative and distributive, that is,

$$\begin{aligned}
 A \cdot (B \cdot C) &= (A \cdot B) \cdot C \\
 A \cdot (B + C) &= A \cdot B + A \cdot C,
 \end{aligned}$$

whenever are all the given operations defined. The unit matrix is a unit element for multiplication (both from the right and from the left).

**2.1.6. Inverse matrices.** With scalars we can do the following: from the equation  $a \cdot x = b$  with a fixed invertible  $a$  we can express  $x = a^{-1} \cdot b$  for any  $b$ . We would like to be able to do this for matrices too. So we need to solve the problem – how to tell that such a matrix exists, and if so, how to compute it?

We say that  $B$  is the *inverse* of  $A$  if

$$A \cdot B = B \cdot A = E.$$

Then we write  $B = A^{-1}$ . From the definition it is clear that both matrices must be square and of the same dimension  $n$ . A matrix which has an inverse is called an *invertible matrix* or a *regular square matrix*.

These two conditions ensure that all entries in a column below a leading coefficient are zeros.

Paragraph 2.1.8 explains how to interpret the elementary row transformations as matrix multiplication. This presentation is often very convenient, and we shall come back to this later in Section E, see for example the task in 2.E.3.

We will now apply this method to solve the system posed in 2.A.6. Let  $R_1, R_2, R_3$  denote the rows of the matrix obtained at each step of the procedure. We begin by considering the extended matrix  $B = (A \mid b)$ , as outlined in relation (#) of 2.A.7, and apply the row operations  $R_1 \rightarrow 2R_1$ ,  $R_2 \rightarrow 4R_2$  and  $R_3 \rightarrow 4R_3$ . This yields

$$B = (A \mid b) \sim \left( \begin{array}{ccc|c} 1 & 0.25 & 0.4 & 540 \\ 1 & 3 & 0.8 & 1080 \\ 1 & 0.5 & 2.4 & 1080 \end{array} \right).$$

In Sage these operations are implemented by the block

```
B=matrix(QQ, [[0.5, 0.125, 0.2, 270], [0.25,
0.75, 0.2, 270], [0.25, 0.125, 0.6, 270]])
B.rescale_row(0,2) #multiply the 1st row
# by 2 (Sage labels rows as 0,1,...)
B.rescale_row(1,4) #the 2nd row by 4
B.rescale_row(2,4) #the 3rd row by 4
show(B)
```

where the last command is used to verify the matrix obtained along this first step. Notice, the first argument in these commands is the index of the row to be replaced, the second argument is the row to form a multiple of, and the final argument is the scale factor. Next, `B.add_multiple_of_row(k,l,c)` will replace then  $k$ th row  $R_k$  by  $R_k + cR_l$ , where  $R_l$  denotes the  $l$ th row and  $c$  is some (non-zero) constant.

Using the resulting matrix, we proceed with the row operations  $R_2 \rightarrow R_2 - R_1$  and  $R_3 \rightarrow R_3 - R_1$ , while keeping  $R_1$  untouched:

$$(A \mid b) \sim \left( \begin{array}{ccc|c} 1 & 0.25 & 0.4 & 540 \\ 0 & 2.75 & 0.4 & 540 \\ 0 & 0.25 & 2 & 540 \end{array} \right).$$

These row operations also admit an easy description in Sage, simply by adding in the previous cell the code

```
B.add_multiple_of_row(1,0,-1)
#replace the 2nd row R2 by R2-R1
B.add_multiple_of_row(2,0,-1)
#replace the 3rd row R3 by R3-R1
show(B)
```

Notice, in Sage we do *not* need to introduce new matrices when doing row operations successively. Next we multiply both  $R_2$  and  $R_3$  by 4 and then interchange them, i.e.,  $R_1 \rightarrow R_1$ ,  $R_2 \rightarrow 4R_2$ ,  $R_3 \rightarrow 4R_3$  and next  $R_2 \leftrightarrow R_3$ . This provides

$$B \sim \left( \begin{array}{ccc|c} 1 & 0.25 & 0.4 & 540 \\ 0 & 11 & 1.6 & 2160 \\ 0 & 1 & 8 & 2160 \end{array} \right) \sim \left( \begin{array}{ccc|c} 1 & 0.25 & 0.4 & 540 \\ 0 & 1 & 8 & 2160 \\ 0 & 11 & 1.6 & 2160 \end{array} \right).$$

In order to describe this step in Sage, we should continue typing in the previous cell the code given below:

In the subsequent paragraphs we derive (among other things) that  $B$  is actually the inverse of  $A$  whenever just one of the above required equations holds. The other is then a consequence.

We easily check that if  $A^{-1}$  and  $B^{-1}$  exist, then there also is the inverse of the product  $A \cdot B$

$$(1) \quad (A \cdot B)^{-1} = B^{-1} \cdot A^{-1}.$$

Indeed, because of the associativity of matrix multiplication proved a while ago, we have

$$(B^{-1} \cdot A^{-1}) \cdot (A \cdot B) = B^{-1} \cdot (A^{-1} \cdot A) \cdot B = E$$

$$(A \cdot B) \cdot (B^{-1} \cdot A^{-1}) = A \cdot (B \cdot B^{-1}) \cdot A^{-1} = E.$$

Because we can calculate with matrices similarly as with scalars (they are just a little more complicated), the existence of an inverse matrix can really help us with the solution of systems of linear equations: if we express a system of  $n$  equations for  $n$  unknowns as a matrix product

$$A \cdot x = \begin{pmatrix} a_{11} & \cdots & a_{1m} \\ \vdots & & \vdots \\ a_{m1} & \cdots & a_{mm} \end{pmatrix} \cdot \begin{pmatrix} x_1 \\ \vdots \\ x_m \end{pmatrix} = \begin{pmatrix} b_1 \\ \vdots \\ b_m \end{pmatrix} = u$$

and when the inverse of the matrix  $A$  exists, then we can multiply from the left by  $A^{-1}$  to obtain

$$A^{-1} \cdot u = A^{-1} \cdot A \cdot x = E \cdot x = x,$$

that is,  $A^{-1} \cdot u$  is the desired solution.

On the other hand, expanding the condition  $A \cdot A^{-1} = E$  for unknown scalars in the matrix  $A^{-1}$  gives us  $n$  systems of linear equations for the same matrix on the left and different vectors on the right. Thus we should think about methods for solutions of the systems of linear equations.

**2.1.7. Equivalent operations with matrices.** Let us gain some practical insight into the relation between systems of equations and their matrices. Clearly, searching for the inverse can be more complicated than finding the direct solution to the system of equations. But note that whenever we have to solve more systems of equations with the same matrix  $A$  but with different right sides  $u$ , then yielding  $A^{-1}$  can be really beneficial for us.

From the point of view of solving systems of equations  $A \cdot x = u$ , it is natural to consider the matrices  $A$  and vectors  $u$  equivalent whenever they give a system of equations with the same solution set. Let us think about possible operations which would simplify the matrix  $A$  such that obtaining the solution is easier.

We begin with simple manipulations of rows of equations which do not influence the solution, and similar modifications of the right-hand side vector. If we are able to change a square matrix into the unit matrix, then the right-hand side vector is a solution of the original system. If some of the rows of the system vanish during the course of manipulations (that is,

```
B.rescale_row(1,4)
#multiply the 2nd row R2 by 4
B.rescale_row(2,4)
#multiply the 3rd row R3 by 4
B.swap_rows(1,2)
#interchange the 2nd row by the 3rd row
show(B)
```

Observe now that in the matrix obtained in this step, the coefficient of  $y$  in the third row is not yet zero. Therefore, it remains to apply one more row operation, namely  $R_3 \rightarrow R_3 - 11R_2$ :

$$B \sim \left( \begin{array}{ccc|c} 1 & 0.25 & 0.4 & 540 \\ 0 & 1 & 8 & 2160 \\ 0 & 0 & -86.4 & -21600 \end{array} \right).$$

This matrix is in row echelon form, and in Sage for this last row operation we successively proceed with the code

```
B.add_multiple_of_row(2,1,-11)
#replace the 3rd row R3 by R3-11R2
show(B)
```

Finally, by the so called *backward substitution*, we can describe the solution of the initial system. In particular, from the last row we get  $z = \frac{-21600}{-86.4} = 250$ . Using this, from the second row we obtain  $y = 2160 - 8 \cdot 250 = 160$  and finally from the first row we have  $x = 540 - 0.4 \cdot 250 - 0.25 \cdot 160 = 400$ .  $\square$

**2.A.9.** Based on elementary row transformation solve the linear system posed below. Then use Sage to find an echelon form of the corresponding extended matrix, and verify your solution:

$$\begin{cases} x_1 + 2x_2 + 3x_3 = 2, \\ 2x_1 - 3x_2 - x_3 = -3, \\ -3x_1 + x_2 + 2x_3 = -3. \end{cases}$$

**Solution.** Let us express the system in the matrix form  $Ax = b$ :

$$\begin{pmatrix} 1 & 2 & 3 \\ 2 & -3 & -1 \\ -3 & 1 & 2 \end{pmatrix} \begin{pmatrix} x_1 \\ x_2 \\ x_3 \end{pmatrix} = \begin{pmatrix} 2 \\ -3 \\ -3 \end{pmatrix},$$

. The extended matrix is given by

$$B := (A | b) = \left( \begin{array}{ccc|c} 1 & 2 & 3 & 2 \\ 2 & -3 & -1 & -3 \\ -3 & 1 & 2 & -3 \end{array} \right).$$

Let us now perform elementary row operations to transform the extended matrix into row echelon form. We have:

$$\begin{aligned} (A | b) &\sim \left( \begin{array}{ccc|c} 1 & 2 & 3 & 2 \\ 0 & -7 & -7 & -7 \\ 0 & 7 & 11 & 3 \end{array} \right) \\ &\sim \left( \begin{array}{ccc|c} 1 & 2 & 3 & 2 \\ 0 & -7 & -7 & -7 \\ 0 & 0 & 4 & -4 \end{array} \right) \sim \left( \begin{array}{ccc|c} 1 & 2 & 3 & 2 \\ 0 & 1 & 1 & 1 \\ 0 & 0 & 1 & -1 \end{array} \right). \end{aligned}$$

Above, we first applied the operations  $R_2 \rightarrow R_2 - 2R_1$ ,  $R_3 \rightarrow R_3 + 3R_1$  on  $B$  to obtain the first mentioned matrix. Using this, we proceeded with  $R_3 \rightarrow R_3 + R_2$ , to get the

they become zero), then we get some direct information about the solution. Our simple operations are:

#### ELEMENTARY ROW TRANSFORMATIONS

- interchanging two rows,
- multiplication of any given row by a non-zero scalar,
- adding another row to any given row.

These operations are called *elementary row transformations*. It is clear that the corresponding operations at the level of the equations in the system do not change the set of the solutions whenever we deal with a field of scalars, they still look reasonable if our ring of coordinates is an integral domain (but multiplying by a divisor of zero might be a problem).

Analogically, *elementary column transformations* of matrices are

- interchanging two columns
- multiplication of any given column by a non-zero scalar,
- adding another column to any given column.

These do not preserve the solution set, since they change the variables themselves.

Systematically we can use elementary row transformations for subsequent elimination of variables. This gives an algorithm which is usually called the *Gaussian elimination method*. Henceforth, we shall assume that our scalars come from an integral domain (e.g. integers are allowed, but not say  $\mathbb{Z}_4$ ).

#### GAUSSIAN ELIMINATION OF VARIABLES

**Proposition.** Any non-zero matrix over an arbitrary integral domain of scalars  $\mathbb{K}$  can be transformed, using finitely many elementary row transformations, into row echelon form:

- For each  $j$ , if  $a_{ik} = 0$  for all columns  $k = 1, \dots, j$ , then  $a_{kj} = 0$  for all  $k \geq i$ ,
- if  $a_{(i-1)j}$  is the first non-zero element at the  $(i-1)$ -st row, then  $a_{ij} = 0$ .

**PROOF.** The matrix in row echelon form looks like

$$\begin{pmatrix} 0 & \dots & 0 & a_{1j} & \dots & \dots & \dots & a_{1m} \\ 0 & \dots & 0 & 0 & \dots & a_{2k} & \dots & a_{2m} \\ \vdots & & & & & & & \\ 0 & \dots & \dots & \dots & \dots & 0 & a_{lp} & \dots \\ \vdots & & & & & & & \end{pmatrix}.$$

The matrix can (but does not have to) end with some zero rows. In order to transform an arbitrary matrix, we can use a simple algorithm, which will bring us, row by row, to the resulting echelon form:

second matrix, and the final step consists of the operations  $R_2 \rightarrow -\frac{1}{7}R_2$  and  $R_3 \rightarrow \frac{1}{4}R_3$ , which give the third matrix. This one is in row echelon form and implies directly  $x_3 = -1$ , and moreover

$$\begin{cases} x_1 + 2x_2 + 3x_3 = 2, \\ x_2 + x_3 = 1, \end{cases}$$

from where we specify  $x_2 = 2$  and  $x_1 = 1$ .

Sage provides an easy way to compute a row echelon form corresponding to a matrix  $B$ , via the command `B.echelon_form()`. For our example we can type

```
A=matrix([[1, 2, 3], [2, -3, -1], [-3, 1, 2]])
b=vector([2, -3, -3])
B=A.augment(b) #the augmented matrix
show(B)
show(B.echelon_form())
```

This code returns the extended matrix  $B$  and a row echelon form associated to  $B$ :<sup>4</sup>

$$\begin{pmatrix} 1 & 2 & 3 & 2 \\ 0 & 7 & 3 & 11 \\ 0 & 0 & 4 & -4 \end{pmatrix}.$$

Note that Sage’s solution differs from ours. However, there is no need to worry, as there are various methods for performing row reduction, and thus the row echelon form of a matrix is *not* unique! From the last row of this matrix we obtain  $4x_3 = -4$ , that is,  $x_3 = -1$ , and so the second row which reads as  $7x_2 + 3x_3 = 11$ , becomes  $7x_2 = 14$ , so  $x_2 = 2$ . From the first row we have  $x_1 + 2x_2 + 3x_3 = 2$ , and by replacing the values found for  $x_2, x_3$  we get  $x_1 = 1$ , and so the same solution as above.  $\square$

*In summary, the most efficient method for solving large systems of linear equations involves applying elementary row transformations to achieve row echelon form. This technique, known as Gaussian elimination, can be optimized through various sophisticated schemes for selecting the best pivots in numerical contexts. Subsequent examples will illustrate that systems of linear equations may have infinitely many solutions, exactly one solution, or none at all. For a theoretical exploration of the classification of solutions using matrix invariants and other methods, see 2.1.13 and 2.3.5.*

**2.A.10.** Using the Gauss elimination method solve the following linear system:

$$\begin{cases} 2x_1 - x_2 + 3x_3 = 0, \\ 3x_1 + 16x_2 + 7x_3 = 0, \\ 3x_1 - 5x_2 + 4x_3 = 0, \\ -7x_1 + 7x_2 + -10x_3 = 0. \end{cases}$$

<sup>4</sup>If we want the vertical line in the presentation of the extended matrix, we can type `B = A.augment(b, subdivide = "True")`.

GAUSSIAN ELIMINATION ALGORITHM

- (1) By a possible interchange of rows we can obtain a matrix where the first row has a non-zero element in the first non-zero column. Let that column be column  $j$ . In other words,  $a_{1j} \neq 0$ , but  $a_{iq} = 0$  for all  $i$ , and all  $q$ ,  $1 \leq q < j$ .
- (2) For each  $i = 2, \dots$ , multiply the first row by the element  $a_{ij}$ , multiply  $i$ -th row by the element  $a_{1j}$  and subtract, to obtain  $a_{ij} = 0$  on the  $i$ -th row.
- (3) By repeated application of the steps (1) and (2), always for the not-yet-echelon part of rows and columns in the matrix we reach, after a finite number of steps, the final form of the matrix.

This algorithm clearly stops after a finite number of steps and provides the proof of the proposition.  $\square$

The given algorithm is really the usual elimination of variables used in the systems of linear equations.

In a completely analogous manner we define the column echelon form of matrices and considering column elementary transformations instead the row ones, we obtain an algorithm for transforming matrices into the column echelon form.

**Remark.** Although we could formulate the Gaussian elimination for general scalars from any ring, this does not make much sense in view of solving equations. Clearly having divisors of zero among the scalars, we might get zeros during the procedure and lose information this way. Think carefully about the differences between the choices  $\mathbb{K} = \mathbb{Z}$ ,  $\mathbb{K} = \mathbb{R}$  and possibly  $\mathbb{Z}_2$  or  $\mathbb{Z}_4$ .

On the other hand, if we are dealing with fields of scalars, we can always arrive at a row echelon form where the non-zero entries on the “diagonal” are ones. This is done by applying the appropriate scalar multiplication to each individual row. However, this is not possible in general – think for instance of the integers  $\mathbb{Z}$ .

**2.1.8. Matrices of elementary row transformations.** Let us now restrict ourselves to fields of scalars  $\mathbb{K}$ , that is, every non-zero scalar has an inverse.

Note that elementary row or column transformations correspond respectively to multiplication from the left or right by the following matrices (only the differences from the unit matrix are indicated):

- (1) Interchanging the  $i$ -th and  $j$ -th row (column)

$$\begin{pmatrix} \ddots & & & & \\ & 0 & \dots & 1 & \\ & \vdots & \ddots & \vdots & \\ & 1 & \dots & 0 & \\ & & & & \ddots \end{pmatrix} \begin{array}{l} \leftarrow i\text{-th row} \\ \leftarrow j\text{-th row} \end{array}$$

**Solution.** This is a so called *homogeneous linear system*, since the vector  $b$  is the zero vector. In matrix notation it reads as

$$\begin{pmatrix} 2 & -1 & 3 \\ 3 & 16 & 7 \\ 3 & -5 & 4 \\ -7 & 7 & -10 \end{pmatrix} \begin{pmatrix} x_1 \\ x_2 \\ x_3 \end{pmatrix} = \begin{pmatrix} 0 \\ 0 \\ 0 \\ 0 \end{pmatrix},$$

that is,  $Ax = 0$ , where  $0$  denotes the zero vector. A homogeneous system of linear equations has either exactly one solution, the zero one, or infinitely many solutions, see 2.3.5 for details. By transforming the matrix into a row echelon form via elementary row operations, we will prove that the given system has infinitely many solutions. Initially we obtain

$$A \sim \begin{pmatrix} 2 & -1 & 3 \\ 3 & 16 & 7 \\ 3 & -5 & 4 \\ -7 & 7 & -10 \end{pmatrix} \sim \begin{pmatrix} 2 & -1 & 3 \\ 0 & 35/2 & 5/2 \\ 0 & -7/2 & -1/2 \\ 0 & 7/2 & 1/2 \end{pmatrix}.$$

From there, we see that the second, third and fourth equations are multiples of the equation  $7x_2 + x_3 = 0$ . We continue as follows:

$$\begin{pmatrix} 2 & -1 & 3 \\ 0 & 35/2 & 5/2 \\ 0 & -7/2 & -1/2 \\ 0 & 7/2 & 1/2 \end{pmatrix} \sim \begin{pmatrix} 2 & -1 & 3 \\ 0 & 35/2 & 5/2 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix} \sim \begin{pmatrix} 2 & -1 & 3 \\ 0 & 7 & 1 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix}.$$

We can translate this literally as

$$\left\{ 2x_1 - x_2 + 3x_3 = 0, \quad 7x_2 + x_3 = 0 \right\},$$

where observe that the equations induced by the last two rows are redundant. In particular,  $x_3$  is a free variable to which we assign the real parameter  $t \in \mathbb{R}$ . This gives infinite many solutions of the form

$$x_2 = -\frac{1}{7}x_3 = -\frac{1}{7}t, \quad x_1 = \frac{1}{2}(x_2 - 3x_3) = -\frac{11}{7}t.$$

We may verify this result in Sage, as before:

```
var("x1, x2, x3"); eq1=2*x1-x2+3*x3
eq2=3*x1+16*x2+7*x3; eq3=3*x1-5*x2+4*x3
eq4=-7*x1+7*x2-10*x3
solve([eq1==0, eq2==0, eq3==0, eq4==0],
x1, x2, x3)
```

which answers

```
x1 == -11/7*r1, x2 == -1/7*r1, x3 == r1
```

Notice the substitution  $t = -7s$  brings our solution to the form  $(11s, s, -7s)$ , with  $s \in \mathbb{R}$ , that is,

$$(x_1, x_2, x_3)^T = s \cdot (11, 1, -7)^T, \quad s \in \mathbb{R},$$

where “ $\cdot$ ” is simply the scalar multiplication. This expression can be obtained very quickly in Sage, by the command `A.right_kernel()`, where  $A$  is the matrix of the linear homogeneous system, as discussed in the next task.  $\square$

(2) Multiplication of the  $i$ -th row (column) by the scalar  $a$ :

$$\begin{pmatrix} \ddots & & & & \\ & 1 & & & \\ & & a & & \\ & & & 1 & \\ & & & & \ddots \end{pmatrix} \leftarrow i\text{-th row}$$

(3) To row  $i$ , add row  $j$  (columns):

$$i\text{-th row and } j\text{-th column} \rightarrow \begin{pmatrix} \ddots & & & & \\ & 1 & & & \\ & & \ddots & & \\ & & & 1 & \\ & & & & \ddots \end{pmatrix}$$

This trivial observation is actually very important, since the product of invertible matrices is invertible (recall 2.1.6(1)) and all elementary transformations over a field of scalars are invertible (the definition of the elementary transformation itself ensures that inverse transformations are of the same type and it is easy to determine the corresponding matrix).

Thus, the Gaussian elimination algorithm tells us, that for an arbitrary matrix  $A$ , we can obtain its equivalent row echelon form  $A' = P \cdot A$  by multiplying with a suitable invertible matrix  $P = P_k \cdots P_1$  from the left (that is, sequential multiplication with  $k$  matrices of the elementary row transformations).

If we apply the same elimination procedure for the columns, we can transform any matrix  $B$  into its column echelon form  $B'$  by multiplying it from the right by a suitable invertible matrix  $Q = Q_1 \cdots Q_\ell$ . If we start with the matrix  $B = A'$  in row echelon form, this procedure eliminates only the still non-zero elements out of the “diagonal” of the matrix and in the end we can transform the remaining elements to be units. Thus we have verified a very important result which we will use many times in the future:

**2.1.9. Theorem.** *For every matrix  $A$  of the type  $m/n$  over a field of scalars  $\mathbb{K}$ , there exist square invertible matrices  $P$  and  $Q$  of dimensions  $m$  and  $n$ , respectively, such that the matrix  $P \cdot A$  is in row echelon form and*

$$P \cdot A \cdot Q = \begin{pmatrix} 1 & \dots & 0 & 0 & \dots & 0 \\ \vdots & \ddots & & & & \\ 0 & \dots & 1 & 0 & \dots & 0 \\ 0 & \dots & 0 & 0 & \dots & 0 \\ \vdots & & & & & \end{pmatrix}.$$

*The number of the ones in the diagonal is independent of the particular choice of  $P$  and  $Q$ .*

**PROOF.** We already have proved everything but the last sentence. We shall see this last claim below in 2.1.11.  $\square$

**2.A.11.** Analyze the space of solutions in the previous task in view of the vector addition and scalar multiplication.

**Solution.** Of course, knowing that  $Ax = 0$ ,  $Ay = 0$ , the sum must be a solution again:  $A(x + y) = Ax + Ay = 0$ . Similarly  $A(cx) = c(Ax)$  for all scalars  $c$ . Viewing matrices as linear mappings  $x \mapsto Ax$ , the *kernel* of a (real)  $m \times n$  matrix  $A$ , also known as the *null space* of  $A$ , is the set of vectors  $x \in \mathbb{R}^n$  satisfying  $Ax = 0$ , where  $0$  denotes the zero vector of degree  $m$ .

We saw in the previous task that the solution space, i.e., the kernel of  $A$ , was spanned by one vector  $(11, 1, -7)^T$ .

To compute the null space of  $A$  in Sage we can just type `A.right_kernel()`. However, be aware that Sage also provides the command `A.kernel()`, which refers to the left kernel of  $A$  and it is an alias of the command `A.left_kernel()`. In our text we will use only the left/right kernel commands to avoid confusions.

Now, to obtain a verification of the previous expression you can type

```
A=matrix([[2, -1, 3], [3, 16, 7],
          [3, -5, 4], [-7, 7, -10]])
sol=A.right_kernel()
show(sol)
```

The output has the form `RowSpan(11 1 -7)`, which essentially means that the corresponding solution is spanned by the vector  $(11, 1, -7)^T$ , as we described above. Alternatively, you can simply type `A.right_kernel()`, and then Sage returns a more complex information:

```
Free module of degree 3 and rank 1
over Integer Ring
Echelon basis matrix: [11 1 -7]
```

In the first line of this output, the “degree 3” part refers to the “dimension” of the vectors in the kernel, that is  $3 \times 1$  vectors. The “rank 1” part indicates the “dimension” of the right kernel of  $A$ , i.e., of the null space of  $A$ .

Notice, Sage automatically considered  $A$  over the ring  $\mathbb{Z}$ , and therefore it talks about *free modules* instead of *vector spaces*. The answer would be different if we enforced the field  $\mathbb{Q}$  (by adding `QQ` in the definition of  $A$ ).<sup>5</sup>

We will learn about vector spaces, subspaces and the notion of dimension of a vector space in Section C, where we will meet further examples on null spaces. □

**2.A.12.** Based on Gauss elimination method, solve the linear system below. Next present the solution in Sage.

$$\begin{cases} 3x_1 & & + & 3x_3 & - & 5x_4 & = & -8, \\ x_1 & - & x_2 & + & x_3 & - & x_4 & = & -2, \\ -2x_1 & - & x_2 & + & 4x_3 & - & 2x_4 & = & 0, \\ 2x_1 & + & x_2 & - & x_3 & - & x_4 & = & -3. \end{cases}$$

<sup>5</sup>Beware that declaring  $A$  to be over the field  $\mathbb{R}$ , we obtain a completely different result since the numerical errors in the 53 bit arithmetic prevent us to have the echelon form with two zero rows. Thus Sage would answer that there is only the zero solution there!

**2.1.10. Algorithm for computing inverse matrices.** In the previous paragraphs we almost obtained the complete algorithm for computing the inverse matrix. Using the simple modification below, we find either that the inverse does not exist, or we compute the inverse. Keep in mind that we are still working over a field of scalars.

Equivalent row transformations of a square matrix  $A$  of dimension  $n$  leads to an invertible matrix  $P'$  such that  $P' \cdot A$  is in row echelon form. If  $A$  has an inverse, then there exists also the inverse of  $P' \cdot A$ . But if the last row of  $P' \cdot A$  is zero, then the last row of  $P' \cdot A \cdot B$  is also zero for any matrix  $B$  of dimension  $n$ . Thus, the existence of a zero row in the result of (row) Gaussian elimination excludes the existence of  $A^{-1}$ .

Assume now that  $A^{-1}$  exists. As we have just seen, the row echelon form of  $A$  will have exclusively non-zero rows only. In particular, all diagonal elements of  $P' \cdot A$  are non-zero. But now, we can employ row elimination by the elementary row transformation from the bottom-right corner backwards and also transform the diagonal elements to be units. In this way, we obtain the unit matrix  $E$ . Summarizing, we find another invertible matrix  $P''$  such that for  $P = P'' \cdot P'$  we have  $P \cdot A = E$ .

Now observe that we could clearly work with columns instead of row transformation and thus, under the assumption of the existence of  $A^{-1}$ , we would find a matrix  $Q$  such that  $A \cdot Q = E$ . From this we see immediately that

$$P = P \cdot E = P \cdot (A \cdot Q) = (P \cdot A) \cdot Q = E \cdot Q = Q.$$

That is, we have found the inverse matrix

$$A^{-1} = P = Q$$

for the matrix  $A$ . Notice that at the point of finding the matrix  $P$  with the property  $P \cdot A = E$ , we do not have to do any further computation, since we have already obtained the inverse matrix.

In practice, we can work as follows:

COMPUTING THE INVERSE MATRIX

Write the unit matrix  $E$  to the right of the matrix  $A$ , producing an augmented matrix  $(A, E)$ . Transform the augmented matrix using the elementary row transformations to row echelon form. This produces an augmented matrix  $(PA, PE)$ , where  $P$  is invertible, and  $PA$  is in row echelon form. By the above, either we may achieve  $PA = E$ , in which case  $A$  is invertible and  $P = PE = A^{-1}$ , or  $PA$  has a row of zeros, in which case we conclude that the inverse matrix for  $A$  does not exist.

**2.1.11. Linear dependence and rank.** In the previous practical algorithms dealing with matrices we worked all the time with row and column additions and scalar multiplications, seeing them as vectors.

Such operations are called *linear combinations*. We shall return to such operations in an abstract sense later on in 2.3.1.

**Solution.** The corresponding extended matrix has the form

$$B := (A \mid b) = \left( \begin{array}{cccc|c} 3 & 0 & 3 & -5 & -8 \\ 1 & -1 & 1 & -1 & -2 \\ -2 & -1 & 4 & -2 & 0 \\ 2 & 1 & -1 & -1 & -3 \end{array} \right).$$

By changing the order of rows (equations) we obtain

$$B \sim \left( \begin{array}{cccc|c} 1 & -1 & 1 & -1 & -2 \\ 2 & 1 & -1 & -1 & -3 \\ -2 & -1 & 4 & -2 & 0 \\ 3 & 0 & 3 & -5 & -8 \end{array} \right)$$

which we transform into a row echelon form:

$$\begin{aligned} \left( \begin{array}{cccc|c} 1 & -1 & 1 & -1 & -2 \\ 2 & 1 & -1 & -1 & -3 \\ -2 & -1 & 4 & -2 & 0 \\ 3 & 0 & 3 & -5 & -8 \end{array} \right) &\sim \left( \begin{array}{cccc|c} 1 & -1 & 1 & -1 & -2 \\ 0 & 3 & -3 & 1 & 1 \\ 0 & -3 & 6 & -4 & -4 \\ 0 & 3 & 0 & -2 & -2 \end{array} \right) \\ &\sim \left( \begin{array}{cccc|c} 1 & -1 & 1 & -1 & -2 \\ 0 & 3 & -3 & 1 & 1 \\ 0 & 0 & 3 & -3 & -3 \\ 0 & 0 & 3 & -3 & -3 \end{array} \right) &\sim \left( \begin{array}{cccc|c} 1 & -1 & 1 & -1 & -2 \\ 0 & 3 & -3 & 1 & 1 \\ 0 & 0 & 3 & -3 & -3 \\ 0 & 0 & 0 & 0 & 0 \end{array} \right). \end{aligned}$$

Notice that via the command `B.echelon_form()`, Sage computes a different echelon form. In any case, we obtain three equations in four variables, and thus the initial linear system has infinitely many solutions (as in the previous example, although this is not a homogeneous system). These three equations have exactly one solution for any choice for the free variable  $x_4 \in \mathbb{R}$ . So we may set  $x_4 = t \in \mathbb{R}$ , and translate the final matrix of the Gauss elimination as

$$\begin{aligned} x_1 - x_2 + x_3 - t &= -2, \\ 3x_2 - 3x_3 + t &= 1, \\ 3x_3 - 3t &= -3. \end{aligned}$$

The solution now can be easily described by back substitution:

$$x_3 = t - 1, \quad x_2 = \frac{1}{3}(2t - 2), \quad x_1 = \frac{1}{3}(2t - 5).$$

Of course, the same solution occurs if we use the echelon form that Sage provides. Now, to have a Sage verification of the given solution, it sufficient to use the cell

```
Eq1=x1-x2+x3-x4+2
Eq2=3*x2-3*x3+x4-1
Eq3=3*x3-3*x4+3
show(solve([Eq1==0, Eq2==0, Eq3==0],
           x1, x2, x3))
```

Notice for  $t = 3s$  our solution  $(x_1, x_2, x_3, x_4)$  takes the form

$$\left( 2s - \frac{5}{3}, 2s - \frac{2}{3}, 3s - 1, 3s \right), \quad s \in \mathbb{R}. \quad \square$$

**2.A.13. Sage and general systems.** Analyze the solutions of the system of linear equations from the previous task in view of the vector operations and Sage tools.

**Solution.** We could approach the linear system of 2.A.12 by using the backslash operator in Sage:

But it will be useful to understand their core meaning right now. A linear combination of rows of a matrix  $A = (a_{ij})$  of type  $m/n$  is understood as an expression of the form

$$c_1 u_{i_1} + \dots + c_k u_{i_k},$$

where  $c_i$  are scalars,  $u_j = (a_{j1}, \dots, a_{jn})$  are rows of the matrix  $A$ . Similarly, we can consider linear combinations of columns by replacing the above rows  $u_j$  by the columns  $u_j = (a_{1j}, \dots, a_{mj})$ .

If the zero row can be written as a linear combination of some given rows with at least one non-zero scalar coefficient, we say that these rows are *linearly dependent*. In the alternative case, that is, when the only possibility of obtaining the zero row is to select all the scalars  $c_j$  equal to zero, the rows are called *linearly independent*.

Analogously, we define linearly dependent and linearly independent columns.

**Lemma.** *The number of non-zero “steps” in the row echelon form always equals to the number of linearly independent rows of the matrix. In particular, the elementary row transformations do not change the maximal number of linearly independent rows. Similarly for columns and the column echelon form, and the maximal number of linearly independent rows and columns coincides (and equals to the number of ones in Theorem 2.1.9)*

**PROOF.** Indeed, the claims all follow once we prove that the number  $h$  of ones in the matrix  $E_h$  from the theorem 2.1.9 does not depend on our choice of the row or column transformations in our procedure. Thus, assume that by two different row transformation procedures into the echelon form we obtain two different  $h' < h$ . But then according to our algorithm there are invertible matrices  $P', P'', Q',$  and  $Q''$  such that

$$E_h = P' \cdot A \cdot Q', \quad E_{h'} = P'' \cdot A \cdot Q''.$$

In particular,  $E_h = P' \cdot P''^{-1} \cdot E_{h'} \cdot Q''^{-1} \cdot Q'$  and so there are invertible matrices  $P$  and  $Q$  such that

$$E_{h'} \cdot Q = P \cdot E_h.$$

Now, on the left hand side, there are the first  $h'$  rows of  $Q$ , complemented by zero rows. At the same time, on the right hand side, there are  $h$  first columns of  $P$ , complemented by zero columns. Thus, the equality implies that taking the first  $h$  columns in  $P$ , only the first  $h'$  of the rows there are non-zero. But this shows, that our Gaussian elimination algorithm applied to  $P$  would show  $P$  is not invertible. Therefore  $h' = h$ , and we have proved that the number of ones in the matrix  $P \cdot A \cdot Q$  in theorem 2.1.9 is independent of the choice of our elimination procedure and it is always equal to the number of linearly independent rows in  $A$ , which must be the same as the number of linearly independent columns in  $A$ .  $\square$

**Definition.** The maximal number  $h(A)$  of linearly independent rows (or columns) in  $A$  is called the *rank of the matrix*.

We have the following theorem:

```
A=matrix([[3, 0, 3, -5], [1, -1, 1, -1],
          [-2, -1, 4, -2], [2, 1, -1, -1]])
b=vector([-8, -2, 0, -3])
x=A.solve_right(b); x
```

The output is the solution given above with  $t = 0$  only:

```
(-5/3, -2/3, -1, 0)
```

As we have seen before, this provides just one solution of the system. But the matrix form  $Ax = b$  of the equation reveals that having two such solutions  $x$  and  $y$ , ensures that  $A(x - y) = Ax - Ay = b - b = 0$  (notice we can compute with vectors and matrices just like if they were scalars). On the contrary, if  $y$  was a solution of the homogeneous system,  $Ay = 0$ , then  $A(x + y) = b + 0 = b$ .

Hence we should be grateful to Sage, picking one of the solutions to the original system and combining the backslash operator with the `right_kernel()` method, as follows:

```
A=matrix([[3, 0, 3, -5], [1, -1, 1, -1],
          [-2, -1, 4, -2], [2, 1, -1, -1]])
b=vector([-8, -2, 0, -3])
x=A.solve_right(b)
k=A.right_kernel().matrix()
# basis of solutions in rows
nrows = k.nrows()
# counts the kernel dimension
if nrows > 0: # non unique solution
    t=vector( var("t", n=nrows))
    # row of parameters t0, ...
    show(x + t*k)
else: # unique solution
    show(x)
```

Executing this block, Sage’s output is as in the end of the previous task. Actually, we add the vector subspace of the solutions to the homogeneous system, to one of the general solutions.  $\square$

*If we work over a field of scalars, e.g.,  $\mathbb{Q}$  or  $\mathbb{R}$ , the extended matrices  $B = (A \mid b)$  of the linear systems can be transformed further, aiming at having all the pivots equal to one, and all the other entries in the columns of the pivots equal to zero. This matrix is in a special row echelon form, known as the reduced row echelon form (often referred to as RREF).*

*It is not difficult to prove that this reduced row echelon form of any matrix is unique, once the pivot columns are fixed.*

**2.A.14.** Come back to the task in 2.A.12 and solve it using the RREF method. Then check with Sage.

**Solution.** A few elementary row transformations of the augmented matrix lead to

$$\left( \begin{array}{cccc|c} 1 & -1 & 1 & -1 & -2 \\ 0 & 3 & -3 & 1 & 1 \\ 0 & 0 & 3 & -3 & -3 \\ 0 & 0 & 0 & 0 & 0 \end{array} \right) \sim \left( \begin{array}{cccc|c} 1 & -1 & 1 & -1 & -2 \\ 0 & 1 & -1 & 1/3 & 1/3 \\ 0 & 0 & 1 & -1 & -1 \\ 0 & 0 & 0 & 0 & 0 \end{array} \right)$$

**Theorem.** Let  $A$  be a matrix of type  $m/n$  over a field of scalars  $\mathbb{K}$ . The matrix  $A$  has the same maximal number  $h(A)$  of linearly independent rows as linearly independent columns. In particular, the rank is always at most the minimum of the dimensions of the matrix  $A$ .

The algorithm for computing the inverse matrix also says that a square matrix  $A$  of dimension  $m$  has an inverse if and only if its rank equals  $m$ .

**2.1.12. Matrices as mappings.** Similarly to the way we worked with matrices in the geometry of the plane (see 1.5.7), we can interpret every matrix  $A$  of the type  $m/n$  as a mapping

$$A : \mathbb{K}^n \rightarrow \mathbb{K}^m, \quad x \mapsto A \cdot x.$$

By the distributivity of matrix multiplication, it is clear how the linear combinations of vectors are mapped using such mappings:

$$A \cdot (ax + by) = a(A \cdot x) + b(A \cdot y).$$

Straight from the definition we see, by the associativity of multiplication, that composition of mappings corresponds to matrix multiplication in given order. Thus invertible matrices of dimension  $n$  correspond to bijective mappings

$$A : \mathbb{K}^n \rightarrow \mathbb{K}^n.$$

**Remark.** From this point of view, the theorem 2.1.9 is very interesting. We can see it as follows: the rank of the matrix determines how large is the image of the whole  $\mathbb{K}^n$  under this mapping. In fact, if  $A = P \cdot E_k \cdot Q$  where the matrix  $E_k$  has  $k$  ones as in 2.1.9, then the invertible  $Q$  first bijectively “shuffles” the  $n$ -dimensional vectors in  $\mathbb{K}^n$ , the matrix  $E_k$  then “copies” the first  $k$  coordinates and completes them with the remaining  $m - k$  zeros.

This “ $k$ -dimensional” image then cannot be enlarged by multiplying with  $P$ . Multiplying by  $P$  can only bijectively reshuffle the coordinates in the image.

**2.1.13. Back to linear equations.** We shall return to the notions of dimension, linear independence and so on in the third part of this chapter. But we should notice now what our results say about the solutions of the systems of linear equations.

If we consider the matrix of the system of equations and add to it the column of the required results, we speak about the *extended matrix of the system*. The above Gaussian elimination approach corresponds to the sequential variable elimination in the equations and the deletion of the linearly dependent equations (these are simply consequences of other equations).

Thus we have derived complete information about the size of the set of solutions of the system of linear equations, based on the rank of the matrix of the system. If we are left with more non-zero rows in the row echelon form of the extended matrix than in the original matrix of the system, then there cannot be a solution (simply, we cannot obtain the given vector value with the corresponding linear mapping). If the

$$\sim \left( \begin{array}{cccc|c} 1 & -1 & 0 & 0 & -1 \\ 0 & 1 & 0 & -2/3 & -2/3 \\ 0 & 0 & 1 & -1 & -1 \\ 0 & 0 & 0 & 0 & 0 \end{array} \right) \sim \left( \begin{array}{cccc|c} 1 & 0 & 0 & -2/3 & -5/3 \\ 0 & 1 & 0 & -2/3 & -2/3 \\ 0 & 0 & 1 & -1 & -1 \\ 0 & 0 & 0 & 0 & 0 \end{array} \right).$$

The final matrix is in reduced row echelon form, which evidently directly provides the solution

$$\begin{pmatrix} x_1 \\ x_2 \\ x_3 \\ x_4 \end{pmatrix} = \begin{pmatrix} -5/3 \\ -2/3 \\ -1 \\ 0 \end{pmatrix} + t \cdot \begin{pmatrix} 2/3 \\ 2/3 \\ 1 \\ 1 \end{pmatrix}, \quad t \in \mathbb{R},$$

as above. Notice again, that this solution is the sum of a particular solution of our initial system and the general solution of the corresponding homogeneous system  $Ax = 0$ , cf. the Kronecker-Capelli Theorem in 2.3.5. We also mention that in the Gauss elimination method, free variables are the variables whose column in the reduced row echelon form does not contain any pivot (e.g.,  $x_4$  is the free variable of this specific example, and indeed, the fourth column in REEF is the unique column which does not contain any pivot).

The reduced echelon form of a given matrix  $B$  can be quickly described in Sage, by the command `B.rref()`. Thus, the following cell verifies the (necessarily unique) expression presented above.

```
A=matrix([[3, 0, 3, -5], [1, -1, 1, -1],
[-2, -1, 4, -2], [2, 1, -1, -1]])
b=vector([-8, -2, 0, -3])
B=A.augment(b)
show(B.rref())
```

□

**2.A.15. Remarks on Sage methods.** Although we noticed the importance of `B.echelon_form()` in 2.A.10 and 2.A.12 (mimicking our handling of matrices by hand), the Sage method `B.rref()` seems to be much more efficient. We should also mention that Sage provides methods for directly identifying the pivots of the augmented matrix. The relevant command is `B.pivots()` (or we can use the command `B.pivot_rows()`).

For example, adding in the previous cell `B.pivots()`, Sage answers  $(0, 1, 2)$ , which means that the pivots are in the first, second and third columns.

Recall now that a linear system of equations is *inconsistent* (does not have a solution), if there is a pivot in the last column of an echelon form of the augmented matrix. Therefore, we can combine this with the previous commands in Sage to derive quickly if a linear system of equations is consistent or not.

**2.A.16.** Use Sage to find the reduced echelon form and the pivot entries of the following matrices:

$$B_{\pm} = \begin{pmatrix} 1 & 1 & -2 \\ 3 & 2 & 0 \\ 2 & \pm 1 & 2 \end{pmatrix}, \quad C = \begin{pmatrix} 2 & 1 & 7 & 0 \\ -1 & 4 & 10 & 5 \\ 3 & 2 & 12 & 10 \\ 0 & 0 & 0 & 10 \end{pmatrix}.$$

Next, deduce about the consistency of

- (a) the linear systems having as extended matrix one of  $B_{\pm}$ ;
- (b) the homogeneous linear system  $Cx = 0$ . ○

rank of both matrices is the same, then the backwards elimination provides exactly as many free parameters as the difference between the number of variables  $n$  and the rank  $h(A)$ . In particular, there will be exactly one solution if and only if the matrix is invertible.

All this will be stated explicitly in terms of abstract vector spaces in the important Kronecker-Capelli theorem, see 2.3.5.

## 2. Determinants

In the fifth part of the first chapter, we introduced the scalar function  $\det$  on square matrices of dimension 2 over the real numbers, called determinant, see 1.5.5. We saw that the determinant assigned a non-zero number to a matrix if and only if the matrix was invertible. We did not say it in exactly this way, but you can check for yourself in previous paragraphs starting with 1.5.4 and formula 1.5.5(1).

We saw also that determinants were useful in another way, see the paragraphs 1.5.10 and 1.5.11. There we showed that the area of the parallelepiped should be linearly dependent on every two of the vectors defining it. It was useful to require the change of the sign when changing the order of these vectors. Because determinants (and only determinants) have these properties, up to a constant scalar multiple, we concluded that it was determining the area. Now we will see that we can proceed similarly for every finite dimension.

We work again with arbitrary scalars  $\mathbb{K}$  and matrices over these scalars. Our results about determinants will thus hold for all commutative rings, notably also for integer matrices or matrices over any residue classes.

**2.2.1. Definition of the determinant.** Each bijective mapping from a set  $X$  to itself is called a *permutation of the set*  $X$ , cf. 1.3.1. If  $X = \{1, 2, \dots, n\}$ , the permutation can be written by putting the resulting ordering into a table:

$$\begin{pmatrix} 1 & 2 & \dots & n \\ \sigma(1) & \sigma(2) & \dots & \sigma(n) \end{pmatrix}.$$

In this way, we shall view a permutation as a bijection or an ordering.

The element  $x \in X$  is called a fixed point of the permutation  $\sigma$  if  $\sigma(x) = x$ . If there exist exactly two distinct elements  $x, y \in X$  such that  $\sigma(x) = y$  while all other elements  $z \in X$  are fixed points, then the permutation  $\sigma$  is called a *transposition*, and we denote it by  $(x, y)$ . Of course, then  $\sigma(y) = x$  holds for such a transformation.

For dimension 2, the formula for a determinant was simple – take all possible products of two elements, one from every column and every row of the matrix, give them a sign such that interchanging two columns leads to the change of the sign of the whole result, and sum all of them (that is, both):

$$A = \begin{pmatrix} a & b \\ c & d \end{pmatrix}, \quad \det A = ad - bc.$$

 Our next focus is on computing inverses  $A^{-1}$  of matrices  $A \in \text{Mat}_n(\mathbb{K})$  for fields  $\mathbb{K}$ . Viewing  $X = A^{-1}$  as an unknown matrix, we aim at  $AX = E$  (the identity matrix). This provides  $n$  systems of linear equations with the same coefficient matrix  $A$  (we view the matrix equation column-wise).

We already touched this in the case  $n = 2$ . We realize that the general case is equivalent to finding RREF for the augmented matrix  $(A \mid E)$ .

**2.A.17.** Solve the following matrix equations:

$$\begin{pmatrix} 1 & 3 \\ 3 & 8 \end{pmatrix} X_1 = \begin{pmatrix} 1 & 2 \\ 3 & 4 \end{pmatrix}, \quad X_2 \begin{pmatrix} 1 & 3 \\ 3 & 8 \end{pmatrix} = \begin{pmatrix} 1 & 2 \\ 3 & 4 \end{pmatrix}.$$

**2.A.18.** Compute the inverse of the matrices

$$A = \begin{pmatrix} 4 & 3 & 2 \\ 5 & 6 & 3 \\ 3 & 5 & 2 \end{pmatrix}, \quad B = \begin{pmatrix} 1 & 0 & 1 \\ 3 & 3 & 4 \\ 2 & 2 & 3 \end{pmatrix}.$$

Then determine the matrix  $(A^T \cdot B)^{-1}$ .

**Solution.** As just explained, an  $n \times n$  matrix  $A$  is invertible if and only if  $A$  is row-equivalent to the  $n \times n$  identity matrix  $E$ . Hence, to find the inverse we first form the augmented matrix  $(A \mid E)$ , which in our case reads as

$$(A \mid E) = \left( \begin{array}{ccc|ccc} 4 & 3 & 2 & 1 & 0 & 0 \\ 5 & 6 & 3 & 0 & 1 & 0 \\ 3 & 5 & 2 & 0 & 0 & 1 \end{array} \right).$$

The goal now is to transform the submatrix  $A$  of the augmented matrix into the identity matrix using elementary row operations on  $(A \mid E)$ . This process illustrates how Gaussian elimination is applied to compute the inverse of a matrix

Note that this transformation may not always be possible, depending on the rank of  $A$ . (Later we shall see that having the maximal rank is equivalent to having the determinant non-zero). However, whenever we can achieve the unit matrix in the place of  $A$ , the original unit submatrix gets transformed into the desired  $A^{-1}$ . Notice, this is exactly solving all the given  $n$  systems simultaneously, using the RREF method with the shared coefficient matrix  $A$ . In this case the final (augmented) matrix will be  $(E \mid A^{-1})$ .

Consider now square matrices  $A = (a_{ij})$  of dimension  $n$  over  $\mathbb{K}$ . The formula for the determinant of the matrix  $A$  is also composed of all possible products from elements from individual rows and columns, with properly chosen signs.

In dimension 3 we can guess the correct signs easily. The product of the elements on the diagonal should be with positive sign and we want anti-symmetry when interchanging two columns or rows. This gives the so called *Sarrus rule*:

SARRUS RULE

$$\begin{vmatrix} a_{11} & a_{12} & a_{13} \\ a_{21} & a_{22} & a_{23} \\ a_{31} & a_{32} & a_{33} \end{vmatrix} = a_{11}a_{22}a_{33} + a_{13}a_{21}a_{32} + a_{12}a_{23}a_{31} - a_{13}a_{22}a_{31} - a_{11}a_{23}a_{32} - a_{12}a_{21}a_{33}$$

The general definition can be formulated via a sum over all permutations:

DEFINITION OF DETERMINANT

The determinant of the matrix  $A$  is a scalar  $\det A = |A|$  defined by the relation

$$|A| = \sum_{\sigma \in \Sigma_n} \text{sgn}(\sigma) a_{1\sigma(1)} \cdot a_{2\sigma(2)} \cdots a_{n\sigma(n)}$$

where  $\Sigma_n$  is the set of all possible permutations over  $\{1, \dots, n\}$  and the symbol  $\text{sgn}$  for a permutation  $\sigma$ , called the parity of  $\sigma$ , will be described below. Each of the expressions

$$\text{sgn}(\sigma) a_{1\sigma(1)} \cdot a_{2\sigma(2)} \cdots a_{n\sigma(n)}$$

is called a *term in the determinant*  $|A|$ .

**2.2.2. Parity of permutation.** How should we define the sign of a permutation? We say that a pair of elements  $a, b \in X = \{1, \dots, n\}$  forms an *inversion in the permutation*  $\sigma$ , if  $a < b$  and  $\sigma(a) > \sigma(b)$ . A permutation  $\sigma$  is called *even* or *odd*, if it contains an even or odd number of inversions, respectively.

Thus, the *parity*  $\text{sgn} \sigma$  of the permutation  $\sigma$  is  $(-1)^{\text{number of inversions}}$  and we denote it by  $\text{sgn}(\sigma)$ . This amounts to our definition of sign for computing determinant. But we should like to know how to calculate the parity. The following theorem reveals that the Sarrus rule really defines the determinant in dimension 3.

**Theorem.** Over the set  $X = \{1, 2, \dots, n\}$  there are exactly  $n!$  distinct permutations. These can be ordered in a sequence such that every two consecutive permutations differ in exactly one transposition. Every transposition changes parity.

For any chosen permutation  $\sigma$  there is such a sequence starting with  $\sigma$ .

**PROOF.** For  $n = 1$  or  $n = 2$ , the claim is trivial. We prove the theorem by induction on the size  $n$  of the set  $X$ .

Assume that the claim holds for all sets with  $n - 1$  elements and consider a permutation  $\sigma(1) = a_1, \dots, \sigma(n) =$

We compute

$$\begin{aligned}
 (A \mid E) \quad R_1 \rightarrow \widetilde{R_1 - R_3} & \begin{pmatrix} 1 & -2 & 0 & \mid & 1 & 0 & -1 \\ 5 & 6 & 3 & \mid & 0 & 1 & 0 \\ 3 & 5 & 2 & \mid & 0 & 0 & 1 \end{pmatrix} \\
 R_2 \rightarrow \widetilde{R_2 - 5R_1} \\
 R_3 \rightarrow \widetilde{R_3 - 3R_1} & \begin{pmatrix} 1 & -2 & 0 & \mid & 1 & 0 & -1 \\ 0 & 16 & 3 & \mid & -5 & 1 & 5 \\ 0 & 11 & 2 & \mid & -3 & 0 & 4 \end{pmatrix} \\
 R_2 \rightarrow \widetilde{R_2 - R_3} & \begin{pmatrix} 1 & -2 & 0 & \mid & 1 & 0 & -1 \\ 0 & 5 & 1 & \mid & -2 & 1 & 1 \\ 0 & 11 & 2 & \mid & -3 & 0 & 4 \end{pmatrix} \\
 R_3 \rightarrow \widetilde{R_3 - 2R_2} & \begin{pmatrix} 1 & -2 & 0 & \mid & 1 & 0 & -1 \\ 0 & 5 & 1 & \mid & -2 & 1 & 1 \\ 0 & 1 & 0 & \mid & 1 & -2 & 2 \end{pmatrix} \\
 R_1 \rightarrow \widetilde{R_1 + 2R_3} \\
 R_2 \rightarrow \widetilde{R_2 - 5R_3} & \begin{pmatrix} 1 & 0 & 0 & \mid & 3 & -4 & 3 \\ 0 & 0 & 1 & \mid & -7 & 11 & -9 \\ 0 & 1 & 0 & \mid & 1 & -2 & 2 \end{pmatrix} \\
 R_2 \leftrightarrow R_3 & \begin{pmatrix} 1 & 0 & 0 & \mid & 3 & -4 & 3 \\ 0 & 1 & 0 & \mid & 1 & -2 & 2 \\ 0 & 0 & 1 & \mid & -7 & 11 & -9 \end{pmatrix},
 \end{aligned}$$

where the row operations performed at each step are indicated for clarity. This means that

$$A^{-1} = \begin{pmatrix} 3 & -4 & 3 \\ 1 & -2 & 2 \\ -7 & 11 & -9 \end{pmatrix}.$$

As a verification it is easy to see that  $AA^{-1} = A^{-1}A = E$ , or we can directly use the command `A.inverse()` in Sage:

```
A=matrix([[4, 3, 2],[5, 6, 3],[3, 5, 2]])
show(A); show(A.inverse())
```

Observe now that when calculating  $A^{-1}$ , we did not have to cope with fractions thanks to the suitably chosen row transformations (and the fact, that  $A^{-1}$  is an integer matrix, too!). We leave the similar steps leading to  $B^{-1}$  to the reader (again, the result happens to be an integer matrix):

$$B^{-1} = \begin{pmatrix} 1 & 2 & -3 \\ -1 & 1 & -1 \\ 0 & -2 & 3 \end{pmatrix}.$$

Based now on the identity

$$(A^T \cdot B)^{-1} = B^{-1} \cdot (A^T)^{-1} = B^{-1} \cdot (A^{-1})^T$$

we finally obtain  $(A^T \cdot B)^{-1} = \begin{pmatrix} -14 & -9 & 42 \\ -10 & -5 & 27 \\ 17 & 10 & -49 \end{pmatrix}.$

To describe this result in Sage one can continue typing in the previous cell, by adding the code

```
B=matrix([[1, 0, 1],[3, 3, 4],[2, 2, 3]])
show(B.inverse())
show((transpose(A)*B).inverse())
```

$a_n$ . According to the induction assumption, all the permutations that end with  $a_n$  can be obtained in a sequence, where every two consecutive permutations differ in one transposition. There are  $(n-1)!$  such permutations. In order to proceed further, we select the last of them, and use the transposition of  $\sigma(n) = a_n$  with some element  $a_i$  which has not been at the last position yet. Once again, we form a sequence of all permutations that end with  $a_i$ . After doing this procedure  $n$ -times, we obtain  $n(n-1)! = n!$  distinct permutations – that is, all permutations on  $n$  elements. The resulting sequence satisfies the condition.

Note that the last sentence of the theorem does not seem to be useful in practice. But it is a very important part for proving the theorem by induction over the size of  $X$ .

It remains to prove the part of the theorem about parities. Consider the ordering

$$(a_1, \dots, a_i, a_{i+1}, \dots, a_n),$$

containing  $r$  inversions. Then in the ordering

$$(a_1, \dots, a_{i+1}, a_i, \dots, a_n)$$

there are either  $r-1$  or  $r+1$  inversions. Every transposition  $(a_i, a_j)$  is obtainable by doing  $(j-i) + (j-i-1) = 2(j-i)-1$  transpositions of neighbouring elements.

Therefore any transposition changes the parity. Also, we already know that all permutations can be obtained by applying transpositions.  $\square$

We found that applying a transposition changes the parity of a permutation and any ordering of numbers  $\{1, 2, \dots, n\}$  can be obtained through transposing of neighbouring elements. Therefore we have proven

**Corollary.** *On every finite set  $X = \{1, \dots, n\}$  with  $n$  elements,  $n > 1$ , there are exactly  $\frac{1}{2}n!$  even permutations, and  $\frac{1}{2}n!$  odd permutations.*

If we compose two permutations, it means first doing all transpositions forming the first permutation and then all the transpositions forming the second one. Therefore for any two permutations  $\sigma, \eta : X \rightarrow X$  we have

$$\text{sgn}(\sigma \circ \eta) = \text{sgn}(\sigma) \cdot \text{sgn}(\eta)$$

and also

$$\text{sgn}(\sigma^{-1}) = \text{sgn}(\sigma).$$

**2.2.3. Decomposing permutations into cycles.** A good tool for practical work with permutations is the cycle decomposition, which is also a good exercise on the concept of equivalence.

which also verifies the given expression for  $B^{-1}$ . □

**2.A.19.** Compute the inverse of the following matrices and next provide a verification by Sage:

$$A = \begin{pmatrix} 1 & 0 & -2 \\ 2 & -2 & 1 \\ 5 & -5 & 2 \end{pmatrix}, \quad B = \begin{pmatrix} 8 & 3 & 0 & 0 & 0 \\ 5 & 2 & 0 & 0 & 0 \\ 0 & 0 & -1 & 0 & 0 \\ 0 & 0 & 0 & 1 & 2 \\ 0 & 0 & 0 & 3 & 5 \end{pmatrix},$$

$$C = \begin{pmatrix} 1 & 1 & 1 & 1 \\ 1 & 1 & -1 & 1 \\ 1 & -1 & 1 & -1 \\ 1 & -1 & -1 & 1 \end{pmatrix}, \quad D = \begin{pmatrix} 1 & i \\ -i & 3 \end{pmatrix},$$

where as usual  $i = \sqrt{-1}$ . ○

*We have seen that a system of linear equations  $Ax = b$  may have: (1) no solution; (2) a unique solution; (3) infinitely many solutions, depending on one or more free parameters.*

*In the homogeneous case, where  $b = 0$ , there is always (at least) one solution. The collections of all solutions forms a vector space (computed as the kernel of the mapping  $x \mapsto Ax$ , we shall come back to these concepts in more abstract way later).*

*If the right-hand side vector  $b$  has at least one non-zero entry, we say that the system is non-homogeneous. Then, the space of all solutions is closely related to the ranks of the matrices  $A$  and  $(A | b)$ .*

*The rank of a matrix is defined as the maximal number of its linearly independent rows (which is the same as the maximal number of linearly independent columns in  $A$ , cf. 2.1.11). This corresponds to the fact that solutions  $x$  of the system  $Ax = b$  are the coefficients in the expression of  $b$  as a linear combination of the columns of  $A$ . We have seen that the case (1) happens if the rank of the augmented matrix is bigger than that of  $A$  (which of course cannot happen if  $b = 0$ ). The number of free parameters for the cases (2) and (3) is the difference between the size of  $b$  and the rank of  $A$ . Later we will see that the rank is closely related to the nullity of the matrix, see for example the description in ??.*

**2.A.20.** Determine the rank of the matrix

$$A = \begin{pmatrix} 1 & -3 & 0 & 1 \\ 1 & -2 & 2 & -4 \\ 1 & -1 & 0 & 1 \\ -2 & -1 & 1 & -2 \end{pmatrix}.$$

Then, determine the number of solutions of the system

$$\begin{cases} x_1 + x_2 + x_3 - 2x_4 = 4, \\ -3x_1 - 2x_2 - x_3 - x_4 = 5, \\ \quad + 2x_2 \quad \quad + x_4 = 1, \\ x_1 - 4x_2 + x_3 - 2x_4 = 3. \end{cases}$$

CYCLES

A permutation  $\sigma$  over the set  $X = \{1, \dots, n\}$  is called a cycle of length  $k$ , if we can find elements  $a_1, \dots, a_k \in X$ ,  $2 \leq k \leq n$  such that  $\sigma(a_i) = a_{i+1}$ ,  $i = 1, \dots, k - 1$ , while  $\sigma(a_k) = a_1$ , and other elements in  $X$  are fixed-points of  $\sigma$ . Cycles of length two are transpositions.

**Proposition.** *Every permutation is a composition of cycles. Cycles of even length have parity  $-1$ , cycles of odd length have parity  $1$ .*

**PROOF.** Fix a permutation  $\sigma$  and define a relation  $R$  such that two elements  $x, y \in X$  are  $R$ -related if and only if  $\sigma^\ell(x) = y$  for some iteration  $\ell \in \mathbb{Z}$  of the permutation  $\sigma$  (notice  $\sigma^{-1}$  means the inverse bijection to  $\sigma$ ). Clearly, it is an equivalence relation (check it carefully!). Because  $X$  is a finite set, for some  $\ell$  it must be that  $\sigma^\ell(x) = x$ . If we pick one equivalence class  $\{x, \sigma(x), \dots, \sigma^{\ell-1}(x)\} \subset X$  and define other elements to be fixed-points, we obtain a cycle. Evidently, the original permutation  $X$  is then the composition of all these cycles for individual equivalence classes and it does not matter in which order we compose the cycles.

For determining the parity we just have to note that cycles of even length can be written as a composition of an odd number of transposition, therefore their parity is  $-1$ . Analogously, cycle of odd length can be obtained using an even number of transpositions and therefore it has parity  $1$ . □

**2.2.4. Expansion of determinant.** Our understanding of the permutations allows to find the *expansion* method of computing the determinants. The simple idea is to collect the terms containing an element in a fixed row in the determinant sum and to add these contributions along the row.

Consider a matrix  $A = (a_{ij})$  and let us look at all terms in  $|A|$  containing the element  $a_{11}$ . By the very definition, these terms correspond to all permutations  $\sigma$  with  $\sigma(1) = 1$ . Thus, the contribution of all these terms to  $|A|$  is  $a_{11}A_{11}$ , where  $A_{11}$  is the determinant of the matrix obtained from  $A$  by omitting the first row and the first column.

Similarly, we can take any other fixed element  $a_{ij}$  in  $A$  and look for the contribution of all terms containing it. Again, we could write  $A_{ij}$  for the determinant of the matrix obtained from  $A$  by omitting the  $i$ -th row and the  $j$ -th column, and the latter contribution must have terms like in  $a_{ij}A_{ij}$ , but we have to be very careful about the signs. While the actual terms of  $|A|$  would be  $\text{sgn } \sigma a_{i_j} a_{1_{\sigma(1)}} \dots \hat{\dots} a_{n_{\sigma(n)}}$  where the hat denotes the omission of the  $i$ -th entry and  $\sigma(i) = j$ , the signatures of the permutations in  $A_{ij}$ , with the  $i$  and  $j$  omitted might be different.

In order to compare it to the previous case  $i = 1, j = 1$ , we can change the initial ordering of the elements in the domain and target of the permutations  $\sigma$ . Clearly,  $i - 1$  changes on the domain and  $j - 1$  changes on the target do the job

Moreover, find all solutions of the corresponding homogeneous system, and in addition of the system

$$\begin{cases} x_1 - 3x_2 & = & 1, \\ x_1 - 2x_2 + 2x_3 & = & -4, \\ x_1 - x_2 & = & 1, \\ -2x_1 - x_2 + x_3 & = & -2. \end{cases} \quad \circ$$

**B. Determinants**

A key object in matrix calculus is the scalar function  $\det$ , the so called determinant, which we already came across when discussing the dimension two calculus (see for example 1.E.25, 1.E.29). Now we shall handle the determinant concept for general square matrices of size  $n$ .

In dimension two, the formula was  $\det A = \det(a_{ij}) = a_{11}a_{22} - a_{12}a_{21}$ , i.e., each term picked up just one entry from each row and column and there are just two options there. Again, we want to see a function linear in all individual columns and changing the sign, whenever two columns are exchanged. Thus, we want to include all terms with any permutation of columns, to be chosen for the individual rows.

This leads us back to the permutations, i.e., bijections  $\sigma : \{1, \dots, n\} \rightarrow \{1, \dots, n\}$ , see the 3rd section of Chapter 1, and 2.2.1. In particular, by 2.2.1 we know that a convenient way to denote permutations is the so called two-row notation (a table form for the function  $\sigma$ ). This notation is adopted in this column, as well.

**2.B.1.** Decompose the permutation

$$\sigma = \begin{pmatrix} 1 & 2 & 3 & 4 & 5 & 6 & 7 & 8 & 9 \\ 3 & 1 & 6 & 7 & 8 & 9 & 5 & 4 & 2 \end{pmatrix}$$

into a product of cycles and product of transpositions.

**Solution.** The term “cycle” is closely related to invariant subsets in  $\{1, \dots, n\}$  under iterated actions of  $\sigma$ . We may easily see them from the defining table: start with the first element and look on the second row, iterating  $\sigma$ . We see that 1 is mapped to 3, while the second iteration sends 3 to 6, and so on. We continue until we again reach the starting element (which must happen since the set is finite). We obtain the following sequence of elements, which map to each other under the given permutation:

$$1 \mapsto 3 \mapsto 6 \mapsto 9 \mapsto 2 \mapsto 1.$$

Such a sequence is called a *cycle*, or better we extend it to a bijection by letting all the other elements as fixpoints (see 2.2.3), and we may denote it by  $(1, 3, 6, 9, 2)$ . Next, choose any element which belongs to the set  $\{1, 2, \dots, 9\}$  but does not belong to our cycle  $(1, 3, 6, 9, 2)$ , e.g., the integer 4. Applying the same procedure as before, we obtain the cycle  $(4, 7, 5, 8)$ . Observe that each element from the set  $\{1, 2, \dots, 9\}$  appears now in one of the previous two cycles. Thus, we can express  $\sigma$  as the composition of these two cycles, i.e.,

$$\sigma = (1, 3, 6, 9, 2) \circ (4, 7, 5, 8) = (4, 7, 5, 8) \circ (1, 3, 6, 9, 2),$$

(by “bubbling” the index in question to the first position by consecutive swaps of neighboring positions).

Thus, the sign correction is  $(-1)^{i+j-2}$  and we have to adjust the value of  $A_{ij}$  as in the following algorithm, which is the simplest version of the more general Laplace expansion formula, see 2.2.9 below. The readers not sure about the details of our argumentation here may wait for the detailed proof in the more general situation.

EXPANSION OF DETERMINANT

The algebraic complement  $A_{ij}$  of the element  $a_{ij}$  in a matrix  $A$  is the  $(-1)^{i+j}$ -multiple of the determinant of the matrix obtained from  $A$  by omitting the  $i$ -th row and the  $j$ -th column.

Fixing the  $i$ -th row or  $j$ -th column,

$$|A| = \sum_{j=1}^n a_{ij}A_{ij}, \quad |A| = \sum_{i=1}^n a_{ij}A_{ij}.$$

The latter formulae correspond to splitting the determinant sum to parts containing terms with the individual elements in the row or column.

For example, an easy application derives the Sarrus rule from the formula in dimension 2 now.

**2.2.5. Simple properties.** Knowing the properties of permutations and their parities from previous paragraphs allows us to derive quickly basic properties of determinants.

For every matrix  $A = (a_{ij})$  of the type  $m/n$  over scalars from  $\mathbb{K}$  we define the *transpose* of  $A$  as the matrix  $A^T = (a'_{ij})$  with elements  $a'_{ij} = a_{ji}$ . The matrix  $A^T$  is of the type  $n/m$ .

A square matrix  $A$  with the property  $A = A^T$  is called *symmetric*. If  $A = -A^T$ , then  $A$  is called *antisymmetric*.

SIMPLE PROPERTIES OF DETERMINANTS

**Theorem.** Every square matrix  $A = (a_{ij})$  satisfies the following conditions:

- (1)  $|A^T| = |A|$ .
- (2) If one of the rows contains only zero elements from  $\mathbb{K}$ , then  $|A| = 0$ .
- (3) If a matrix  $B$  was obtained from  $A$  by transposing two rows, then  $|A| = -|B|$ .
- (4) If a matrix  $B$  was obtained from  $A$  by multiplying one row by a scalar  $a \in \mathbb{K}$ , then  $|B| = a|A|$ .
- (5) If all elements of the  $k$ -th row in  $A$  are of the form  $a_{kj} = c_{kj} + b_{kj}$  and all remaining rows in the matrices  $A, B = (b_{ij}), C = (c_{ij})$  are identical, then  $|A| = |B| + |C|$ .
- (6) A determinant  $|A|$  does not change if we add to any row of  $A$  a linear combination of other rows.

where the second equality occurs since independent cycles commute.

Next, we notice how to decompose general cycles into the simplest ones - the transpositions  $(i, j)$  (i.e.,  $i \mapsto j \mapsto i$  and all other remain fixed). A simple check reveals (do it carefully yourselves!) that any cycle  $(i_1, i_2, \dots, i_k)$  is a composition of transpositions of the neighbouring numbers, starting from the back. Thus, in our case

$$\begin{aligned} (1, 3, 6, 9, 2) &= (1, 3) \circ (3, 6) \circ (6, 9) \circ (9, 2) \\ &\equiv (1, 3)(3, 6)(6, 9)(9, 2). \end{aligned}$$

For example, evaluating this resulting bijection on 2:

$$\begin{aligned} ((1, 3)(3, 6)(6, 9)(9, 2))(2) &= ((1, 3)(3, 6)(6, 9))(9) = \\ &= ((1, 3)(3, 6))(6) = (1, 3)(3) = 1, \end{aligned}$$

as expected.

This means  $\sigma = (1, 3)(3, 6)(6, 9)(9, 2)(4, 7)(7, 5)(5, 8)$  (notice that this is also the decomposition into the minimal number of transpositions).

As we saw in Chapter 1, Sage offers a rich portfolio of methods available for solving combinatorial tasks. To treat the given task in Sage, we need to define a permutation  $p$  of a finite set, which can be done via the command `Permutation(p)`. Also, we can determine the cycles of  $p$  by the command `Permutation(p).to_cycles()`. Let us illustrate the situation for  $p = \sigma$ , where  $\sigma$  is as above:

```
p = Permutation([3, 1, 6, 7, 8, 9, 5, 4, 2])
c = (p.to_cycles())
ts = [] # collecting transpositions
for x in c:
    for i in range(len(x) - 1):
        ts.append( (x[i], x[i + 1]) )
print(ts)
```

This block returns the following list verifying our answer:

```
[(1, 3), (3, 6), (6, 9), (9, 2), (4, 7),
(7, 5), (5, 8)]
```

We are ready to summarize: The right formula for the determinant of a matrix  $A = (a_{ij})$  of size  $n$  is

$$\det(A) = |A| = \sum_{\sigma \in \Sigma_n} \operatorname{sgn}(\sigma) a_{1\sigma(1)} \cdots a_{n\sigma(n)},$$

where the parity  $\operatorname{sgn}(\sigma)$  is  $\pm 1$ , according to the even or odd number of permutations constituting  $\sigma$ . This is well defined. Clearly this definition fulfills our wish to have an expression linear in each of the columns, while changing its sign with each transposition of columns.

Note that the minimal number of transpositions in the decomposition of a given permutation can be obtained as follows: We first decompose the permutation into a product of independent cycles, and then the cycles canonically into the transpositions (actually the length of the cycles tells their parity and they are multiplied).

You may find more details in 2.2.2, where the parity is defined in the terms of the so called inversions. In the two-row

PROOF. (1) The terms of determinants  $|A|$  and  $|A^T|$  are in bijective correspondence, where the term  $\operatorname{sgn}(\sigma) a_{1\sigma(1)} \cdots a_{n\sigma(n)}$  corresponds the following  $A^T$  term (notice, multiplication does not depend on the order of scalars)

$$\begin{aligned} \operatorname{sgn}(\sigma) a_{\sigma(1)1} \cdots a_{\sigma(n)n} &= \\ &= \operatorname{sgn}(\sigma) a_{1\sigma^{-1}(1)} \cdots a_{n\sigma^{-1}(n)}, \end{aligned}$$

and we have to ensure that this member has the correct sign. But the parities of  $\sigma$  and  $\sigma^{-1}$  are the same, and so this is really a term in the determinant  $|A^T|$  and the first claim is proved.

(2) This comes straight from the definition of determinant, because all its terms contain exactly one member from every row. Thus, if one of the rows is zero, all terms of the determinant are also zero.

(3) The only change in the terms of  $|B|$  compared to  $|A|$  is the addition of one transposition in all permutations, therefore all the signs will be reversed.

(4) This follows straight from the definition, because terms of  $|B|$  are just terms of  $|A|$  multiplied by the scalar  $a$ .

(5) In every term of  $|A|$ , there is exactly one element from the  $k$ -th row of the matrix  $A$ . By the distributive law for multiplication and addition in  $\mathbb{K}$ , the claim follows directly from the definition of determinant.

(6) If there are two identical rows in  $A$ , then there are always two identical terms among all terms in the determinant, up to the sign. Therefore in this case  $|A| = 0$ . Thus, by (5), we can add any other row to the given row, without changing the value of the determinant. In view of the claims (4) and (5), we can in fact add a scalar multiple of any other row.  $\square$

### 2.2.6. Computational corollaries.

Let us note a nice corollary of the first claim of the previous theorem about the equality of the determinants of the matrix and its transpose. It ensures that whenever we prove some claim about determinants formulated in terms of rows of the corresponding matrix, we immediately obtain an analogous claim in terms of the columns.

For instance, we can immediately formulate all the claims (2)–(6) for linear combinations of columns.

For a while, let us assume, we work with a field of scalars  $\mathbb{K}$ . Then, by the previous theorem, we can use elementary row transformations to bring any square matrix  $A$  into row echelon form, without changing the value of its determinant. We just have to be careful and add only linear combinations of other rows to a given one.

Thus let us look at the distribution of the elements in the individual terms of a determinant  $|A|$  with dimension of  $A$  equal to  $n > 1$ . There is just one term with all of its elements on the diagonal. In all other terms, there must be elements both above and below the diagonal (if we place one element outside of the diagonal, we block two diagonal entries and we leave only  $n - 2$  diagonal positions for the other  $n - 1$  elements).

notation for permutations, the number of inversions is seen when you go through the columns and count the number of those where the second row is smaller than the first one.

**2.B.2.** Determine the parity of the permutation  $\sigma$  in 2.B.1, and of the permutation  $\tau = \begin{pmatrix} 1 & 2 & 3 & 4 & 5 & 6 \\ 2 & 4 & 6 & 1 & 5 & 3 \end{pmatrix}$ .  $\circ$

**2.B.3.** Check the previous result in Sage.

**Solution.** It is very easy to obtain the parity of a permutation in Sage. This is done via the command `p.sign()`, where  $p$  is the given permutation. For instance, for the given  $\sigma$  and  $\tau$  in 2.B.2 we can type:

```
s=Permutation([3,1,6,7,8,9,5,4,2])
t=Permutation([2,4,6,1,5,3])
print(s.sign()); print(t.sign())
```

Sage says  $\sigma, \tau$  are odd by returning  $-1$  for both cases.  $\square$

**2.B.4.** Compute the determinant of the matrices

$$A = \begin{pmatrix} 1 & 2 \\ 2 & 1 \end{pmatrix}, B = \begin{pmatrix} 1 & 2 & 3 \\ 1 & -1 & 2 \\ 3 & 2 & 2 \end{pmatrix}, C = \begin{pmatrix} 1 & 1 & 1 \\ 1 & 0 & 0 \\ -2 & 0 & 1 \end{pmatrix}.$$

**Solution.** For  $A$  we compute  $\det(A) = 1 \cdot 1 - 2 \cdot 2 = -3$ . As for the  $3 \times 3$  matrices, the definition yields the so called Sarrus rule, see 2.2.1. In particular, for  $B$  we get

$$\det(B) = 1 \cdot (-1) \cdot 2 + 2 \cdot 2 \cdot 3 + 3 \cdot 1 \cdot 2 - 3 \cdot (-1) \cdot 3 - 1 \cdot 2 \cdot 2 - 1 \cdot 2 \cdot 2 = 17.$$

Another way to remember this rule:

$$\det \begin{pmatrix} a & b & c \\ d & e & f \\ \ell & m & n \end{pmatrix} = a \cdot \alpha - b \cdot \beta - c \cdot \gamma,$$

where  $\alpha = \det \begin{pmatrix} e & f \\ m & n \end{pmatrix}, \beta = \det \begin{pmatrix} d & f \\ \ell & n \end{pmatrix}, \gamma = \det \begin{pmatrix} d & e \\ \ell & m \end{pmatrix}$ .

Similarly, for the matrix  $C$  we obtain

$$\det(C) = 1 \cdot 0 \cdot 1 + 1 \cdot 0 \cdot 1 + 1 \cdot 0 \cdot (-2) - 1 \cdot 0 \cdot (-2) - 1 \cdot 1 \cdot 1 - 1 \cdot 0 \cdot 0 = -1.$$

Of course, all cases can be done in Sage, as in Chapter 1. Let us recall the relevant code:

```
B=matrix([[1,2,3],[1,-1,2],[3,2,2]])
det(B)
```

There are several methods for computing determinants of big matrices. One of them is to use the elementary row (or column) transformations. Remember though that we are allowed to add linear combinations of other rows to the transformed one, since multiplying a row clearly results in the same multiple of the resulting determinant. If  $A$  is in a row-echelon (column-echelon) form, then  $\det(A)$  is just the multiple of all diagonal elements (straight from definition!). See a more detailed review of elementary properties in 2.2.5.

Therefore, if the matrix  $A$  is in a row echelon form, then every term of  $|A|$  is zero, except the term with exclusively diagonal entries. This proves the following algorithm:

COMPUTING DETERMINANTS USING ELIMINATION

**Lemma.** If  $A$  is in the row echelon form then

$$|A| = a_{11}a_{22} \cdots a_{nn}.$$

This observation gives an effective method for computing determinants using the Gauss elimination method for matrices over a field of scalars  $\mathbb{K}$ , see the paragraph 2.1.7.

Notice that the very same argumentation allows us to stop the elimination having the first  $k$  columns in the requested form and finding the determinant of the matrix  $B$  of dimension  $n-k$  in the right bottom corner of  $A$  in another way. The result will then be  $|A| = a_{11}a_{22} \cdots a_{kk}|B|$ .

As a useful (theoretical) illustration of this principle, we shall derive the following formula for direct calculation of solutions of systems of linear equations. For sake of simplicity, we still work with field of scalars now. (But we shall see later, that Cramer rule actually works for all scalars.)

CRAMER RULE

**Proposition.** Consider the system of  $n$  linear equations for  $n$  variables with matrix of the system  $A = (a_{ij})$  and the column of values  $b = (b_1, \dots, b_n)$ . In matrix notation this means we are solving the equation  $A \cdot x = b$ .

If there exists the inverse  $|A|^{-1}$ , then the individual components of the unique solution  $x = (x_1, \dots, x_n)$  are given as

$$x_i = |A_i||A|^{-1},$$

where the matrices  $A_i$  arise from the matrix  $A$  of the system by replacing the  $i$ -th column by the column  $b$  of values.

**PROOF.** Even for general scalars, if  $A^{-1}$  exists, then there must be a unique solution. As we have already seen, working over field of scalars the inverse of the matrix of the system exists if and only if the system has a unique solution, and this in turn happens if and only if  $|A| \neq 0$ .

If we have such a solution  $x$ , we can express the column  $b$  in the matrix  $A_i$  by the corresponding linear combination of the columns of the matrix  $A$ , that is the values  $b_k = a_{k1}x_1 + \cdots + a_{kn}x_n$ . Then, by subtracting the  $x_\ell$ -multiples of all the other  $\ell$ -th columns from this  $i$ -th column in  $A_i$ , we arrive at just the  $x_i$ -multiple of the original column of  $A$ . The number  $x_i$  can thus be brought in front of the determinant to obtain the equation  $|A_i| = x_i |A|$ , and thus  $|A_i||A|^{-1} = x_i|A||A|^{-1} = x_i$ , which is our claim.  $\square$

Notice also that the properties (3)–(5) from the previous theorem say that the determinant, (considered as a mapping which assigns a scalar to  $n$  vectors of dimension  $n$ ), is an

The other option is to use the Laplace expansion with respect to one or more rows or columns, see the description in 2.2.9.

**2.B.5.** Compute  $\det(B)$  for the matrix  $B$  from the previous task by the Gauss elimination method.

**Solution.** We aim at transforming the matrix into a row echelon form, and then multiplying the numbers on the diagonal. However, we must remember that a multiplication of a row with a scalar changes the determinant of the matrix by the same multiple. Moreover, interchanging two rows changes the sign of the determinant of the matrix.

$$\begin{vmatrix} 1 & 2 & 3 \\ 1 & -1 & 2 \\ 3 & 2 & 2 \end{vmatrix} = \begin{vmatrix} 1 & 2 & 3 \\ 0 & -3 & -1 \\ 0 & -4 & -7 \end{vmatrix} = \frac{1}{-4} \cdot \frac{1}{3} \cdot \begin{vmatrix} 1 & 2 & 3 \\ 0 & 12 & 4 \\ 0 & -12 & -21 \end{vmatrix} \\ = -\frac{1}{12} \cdot \begin{vmatrix} 1 & 2 & 3 \\ 0 & 12 & 4 \\ 0 & 0 & -17 \end{vmatrix}.$$

The remaining step is the computation of the determinant of an upper triangular matrix. The latter equals to the product of the diagonal entries, thus,  $\det(B) = -\frac{1}{12}(1 \cdot 12 \cdot (-17)) = 17$ . Of course, direct application of the Sarrus rule was faster.  $\square$

**2.B.6.** Compute the determinant of the matrix

$$A = \begin{pmatrix} 1 & 3 & 5 & 6 \\ 1 & 2 & 2 & 2 \\ 1 & 1 & 1 & 2 \\ 0 & 1 & 2 & 1 \end{pmatrix}.$$

**Solution.** A standard way to compute  $\det(A)$  is the reduction of the size of the matrices by the expansion along the first column (or line, see also 2.3.10). This gives

$$\det(A) = 1 \cdot \begin{vmatrix} 2 & 2 & 2 \\ 1 & 1 & 2 \\ 1 & 2 & 1 \end{vmatrix} - 1 \cdot \begin{vmatrix} 3 & 5 & 6 \\ 1 & 1 & 2 \\ 1 & 2 & 1 \end{vmatrix} + 1 \cdot \begin{vmatrix} 3 & 5 & 6 \\ 2 & 2 & 2 \\ 1 & 2 & 1 \end{vmatrix} \\ = -2 - 2 + 6 = 2,$$

where we have exploited that the last entry of the first column is zero.

An alternative way is to convert the matrix to row echelon form, which we can do as follows:

$$\det(A) = - \begin{vmatrix} 1 & 1 & 1 & 2 \\ 1 & 2 & 2 & 2 \\ 1 & 3 & 5 & 6 \\ 0 & 1 & 2 & 1 \end{vmatrix} = - \begin{vmatrix} 1 & 1 & 1 & 2 \\ 0 & 1 & 1 & 0 \\ 0 & 2 & 4 & 4 \\ 0 & 1 & 2 & 1 \end{vmatrix} = \\ = - \begin{vmatrix} 1 & 1 & 1 & 2 \\ 0 & 1 & 1 & 0 \\ 0 & 0 & 2 & 4 \\ 0 & 0 & 1 & 1 \end{vmatrix} = \begin{vmatrix} 1 & 1 & 1 & 2 \\ 0 & 1 & 1 & 0 \\ 0 & 0 & 1 & 1 \\ 0 & 0 & 2 & 4 \end{vmatrix} = \begin{vmatrix} 1 & 1 & 1 & 2 \\ 0 & 1 & 1 & 0 \\ 0 & 0 & 1 & 1 \\ 0 & 0 & 0 & 2 \end{vmatrix} = 2.$$

Observe that here we have interchanged the rows twice. Specify the rest of the applied rules, according to 2.2.5!  $\square$

**2.B.7.** Use the Laplace theorem (see 2.2.9) to compute the determinant of the matrix  $D$  given below. Next verify your

antisymmetric mapping linear in every argument, exactly as we required in analogy to the 2-dimensional case.

**2.2.7. Further properties of the determinant.** Later we

will see that, exactly as in the dimension 2, the determinant of the matrix equals to the (oriented) volume of the parallelepiped determined by the columns of the matrix. We shall also see that considering the mapping  $x \mapsto A \cdot x$  given by the square matrix  $A$  on  $\mathbb{R}^n$  we can understand the determinant of this matrix as expressing the ratio between the volume of the parallelepipeds given by the vectors  $x_1, \dots, x_n$  and their images  $A \cdot x_1, \dots, A \cdot x_n$ .

Because the composition  $x \mapsto A \cdot x \mapsto B \cdot (A \cdot x)$  of mappings corresponds to the matrix multiplication, the Cauchy theorem below is easy to understand:

CAUCHY THEOREM

**Theorem.** Let  $A = (a_{ij}), B = (b_{ij})$  be square matrices of dimension  $n$  over the ring of scalars  $\mathbb{K}$ . Then

$$|A \cdot B| = |A| \cdot |B|.$$

In the next paragraphs, we derive this theorem in a purely algebraic way, in particular because the previous argumentation based on geometrical intuition could hardly work for arbitrary scalars. The basic tool is the *determinant expansion* using one or more of the rows or columns which we have seen in simplest case of single rows or columns in 2.2.4.

We will also need a little technical preparation. The reader who is not fond of too much abstraction can skip these paragraphs and note only the statement of the Laplace theorem and its corollaries.

Notice also, the claims (2), (3) and (6) from the theorem 2.2.5 are easily deduced from the Cauchy theorem and the representation of the elementary row transformations as multiplication by suitable matrices (cf. 2.1.8).

**2.2.8. Minors of the matrix.** When investigating matrices

and their properties we often work only with parts of the matrices. Therefore we need some new concepts.

SUBMATRICES AND MINORS

Let  $A = (a_{ij})$  be a matrix of the type  $m/n$  and let  $1 \leq i_1 < \dots < i_k \leq m, 1 \leq j_1 < \dots < j_\ell \leq n$  be fixed natural numbers. Then the matrix

$$M = \begin{pmatrix} a_{i_1 j_1} & a_{i_1 j_2} & \dots & a_{i_1 j_\ell} \\ \vdots & & & \vdots \\ a_{i_k j_1} & a_{i_k j_2} & \dots & a_{i_k j_\ell} \end{pmatrix}$$

of the type  $k/\ell$  is called a *submatrix of the matrix A* determined by the rows  $i_1, \dots, i_k$  and columns  $j_1, \dots, j_\ell$ . The remaining  $(m - k)$  rows and  $(n - \ell)$  columns determine a matrix  $M^*$  of the type  $(m - k)/(n - \ell)$ , which is called *complementary submatrix* to  $M$  in  $A$ .

answer in Sage.

$$D = \begin{pmatrix} 1 & 0 & 1 & 0 & 1 \\ 0 & 2 & 0 & 2 & 0 \\ 0 & 0 & 3 & 0 & 3 \\ 4 & 0 & 0 & 4 & 4 \\ 0 & 0 & 0 & 0 & 5 \end{pmatrix}. \quad \circ$$

**2.B.8.** This is a theoretical task. Let us fix any matrices  $A, B \in \text{Mat}_n(\mathbb{K})$ , over any ring  $\mathbb{K}$ .

(a) If  $\det(A) = 0$ , show that the product  $AB$  also has determinant zero.

(b) Prove the identity  $\det(cA) = c^n \det(A)$ , for each scalar  $c \in \mathbb{K}$ .

(c) Show by a counterexample that in general  $\det(A + B) \neq \det(A) + \det(B)$ . ○

The upcoming series of exercises will explore various methods for computing the inverse of an invertible matrix, including Cramer's rule, and other topics. As we will demonstrate, Sage can efficiently handle these computations, leveraging its extensive matrix calculus functionality.

Before diving into the problems, let us review some key points about matrix manipulation in Sage. There are several convenient shortcuts for matrix creation. As we pronounced, to specify the ring of the matrix entries use `QQ` for rationals, `RR` for reals, `CC` for complex numbers, and `ZZ` for integers. For exact computations with rational entries the results are precise. For numerical calculations with real or complex matrices, we recommend to use of `RDF` and `CDF` working with floating-point representation, instead of `RR` and `CC`.

After creating a matrix  $A$  in your favourite Sage editor, you can access its entries in a straightforward manner using the square bracket notation `A[i, j]`. Here,  $i$  and  $j$ , represent the row and column indices, respectively. Note that both Python and Sage use zero-based indexing.

For example, to access the entry  $a_{3,3}$  of a  $4 \times 4$  matrix  $A$ , we type `A[2, 2]`. Notice, Sage also allows indexing from the end of the matrix, using negative indices. For example, `A[-1, :]`, refers to the last row of  $A$ , and `A[-2, :]` refers to the second to last row of  $A$ . Additionally, indices can be specified as intervals using the format `a : b`. For instance, `A[2 : 3]` is valid and will be useful when discussing submatrices later. Another useful tip is the notation `p : q : r`, which generates all indices from  $p$  to  $q - 1$ , in steps of  $r$ .

**2.B.9.** Given the matrix  $A = \begin{pmatrix} 1 & 1 & 3 & 0 & 8 \\ 2 & 2 & -4 & -8 & 4 \\ -1 & -5 & 2 & 4 & 6 \\ 7 & -1 & 10 & 0 & 9 \end{pmatrix}$  use Sage to access the entries  $a_{33}$ ,  $a_{12}$ ,  $a_{11}$ ,  $a_{45}$  and  $a_{44}$ .

**Solution.** We can use the cell

```
A=matrix(QQ, [[1, 1, 3, 0, 8], [2, 2, -4, -8, 4],
[-1, -5, 2, 4, 6], [7, -1, 10, 0, 9]])
print(A[2, 2]); print(A[0, 1])
print(A[0, 0]); print(A[3, 4])
print(A[3, 3])
```

When  $k = \ell$  we call the determinant  $|M|$  the *subdeterminant* or *minor* of the order  $k$  of the matrix  $A$ . If  $m = n$  and  $k = \ell$ , then  $M^*$  is also a square matrix and  $|M^*|$  is called the *minor complement* to  $|M|$ , or *complementary minor* of the submatrix  $M$  in the matrix  $A$ . The scalar

$$(-1)^{i_1 + \dots + i_k + j_1 + \dots + j_l} \cdot |M^*|$$

is then called the *algebraic complement* of the minor  $|M|$ .

The submatrices formed by the first  $k$  rows and columns are called *leading principal submatrices*, and their determinants are called *leading principal minors* of the matrix  $A$ . If we choose  $k$  sequential rows and columns starting with the  $i$ -th row, we speak of *principal submatrices* and *principal minors*.

Specially, when  $k = \ell = 1$ ,  $m = n$  we call the corresponding algebraic complementary minor the *algebraic complement*  $A_{ij}$  of the element  $a_{ij}$  of the matrix  $A$ , which we met already in 2.2.4.

**2.2.9. Laplace determinant expansion.** If the leading principal minor  $|M|$  of the matrix  $A$  is of the order  $k$ , then, directly from the definition of the determinant, each of the individual  $k!(n - k)!$  terms in the product of  $|M|$  with its algebraic complement is a term of  $|A|$ .

In general, consider a square submatrix  $M$ , that is, a square matrix given by the rows  $i_1 < i_2 < \dots < i_k$  and columns  $j_1 < \dots < j_k$ . Then using  $(i_1 - 1) + \dots + (i_k - k)$  exchanges of neighbouring rows and  $(j_1 - 1) + \dots + (j_k - k)$  exchanges of neighbouring columns in  $A$  we can transform this submatrix  $M$  into a leading principal submatrix and the complementary matrix gets transformed into its complementary matrix.

The whole matrix  $A$  gets transformed into a matrix  $B$  satisfying (cf. 2.2.5 and the definition of the determinant)  $|B| = (-1)^\alpha |A|$ , where  $\alpha = \sum_{h=1}^k (i_h + j_h) - 2(1 + \dots + k)$ . But  $(-1)^\alpha = (-1)^\beta$  with  $\beta = \sum_{h=1}^k (i_h + j_h)$ . Therefore we have checked:

**Proposition.** If  $A$  is a square matrix of dimension  $n$  and  $|M|$  is its minor of the order  $k < n$ , then the product of any term of  $|M|$  with any term of its algebraic complement is a term in the determinant  $|A|$ .

This claim suggests that we could perhaps express the determinant of the matrix by using some products of smaller determinants. We see that  $|A|$  contains exactly  $n!$  distinct terms, exactly one for each permutation. These terms are mutually distinct as polynomials in the components of a general matrix  $A$ . If we can show that there are exactly that many mutually distinct expressions from the previous claim, we obtain the determinant  $|A|$  as their sum.

It remains to show that the terms of the product  $|M| \cdot |M^*|$  contain exactly  $n!$  distinct members from  $|A|$ .

From the chosen  $k$  rows we can choose  $\binom{n}{k}$  minors  $M$  and using the previous lemma each of the  $k!(n - k)!$

Sage returns 2, 1, 1, 9 and 0, respectively. Notice entering the command  $A([4, 3])$ , Sage will produce an error message: matrix index out of range, which is expected.  $\square$

**2.B.10.** For the matrices  $A, B$  given below, compute:

- (a) the corresponding null spaces;
- (b) the submatrix of  $A$  obtained by canceling the first row, and the first and third columns; Is this diagonal?
- (c) the submatrix of  $B$  obtained by canceling the first and last row, and the last column.
- (d) the submatrix of  $B$  obtained by canceling the first and third row, and the second and fourth column. Is this symmetric?

$$A = \begin{pmatrix} 1 & -1 & \pi & 0 \\ 0 & \pi & -1 & 0 \\ 1 & 0 & -1 & \pi \end{pmatrix}, \quad B = \begin{pmatrix} 1 & 2 & 3 & 4 \\ 2 & 1 & 4 & 3 \\ 3 & 4 & 1 & 2 \\ 4 & 3 & 2 & 1 \end{pmatrix}.$$

**2.B.11.** Using the Cramer’s rule solve the system posed in 2.A.9. Next demonstrate the situation in Sage.

**Solution.** Consider a linear system  $Ax = b$  of  $n$  equations and  $n$  unknowns, with  $\det(A) \neq 0$ . Recall by 2.2.6 that the Cramer’s rule describes the unique solution of such a linear system as the unique vector  $x = (x_1, \dots, x_n)^T$  of  $\mathbb{R}^n$  with entries  $x_i = \frac{\det(A_i)}{\det(A)}$ , for all  $i = 1, \dots, n$ , where  $A_i$  are the matrixes obtained from the coefficient matrix  $A$  by replacing the  $i$ th column by the vector  $b$ , for  $i = 1, \dots, n$ . The matrix  $A$  of the system in 2.A.9 is  $3 \times 3$  and the Cramer’s rule gives

$$x_1 = \frac{\begin{vmatrix} 2 & 2 & 3 \\ -3 & -3 & -1 \\ -3 & 1 & 2 \end{vmatrix}}{\begin{vmatrix} 1 & 2 & 3 \\ 2 & -3 & 1 \\ -3 & 1 & 2 \end{vmatrix}} = 1, \quad x_2 = \frac{\begin{vmatrix} 1 & 2 & 3 \\ 2 & -3 & -1 \\ -3 & -3 & 2 \end{vmatrix}}{\begin{vmatrix} 1 & 2 & 3 \\ 2 & -3 & 1 \\ -3 & 1 & 2 \end{vmatrix}} = 2,$$

$$x_3 = \frac{\begin{vmatrix} 1 & 2 & 2 \\ 2 & -3 & -3 \\ -3 & 1 & -3 \end{vmatrix}}{\begin{vmatrix} 1 & 2 & 3 \\ 2 & -3 & 1 \\ -3 & 1 & 2 \end{vmatrix}} = -1.$$

It is easy to demonstrate Cramer’s rule in Sage. For a  $3 \times 3$  system this can done really quickly, and an illustration is here:

```
A=matrix([[1, 2, 3], [2, -3, -1], [-3, 1, 2]])
b=vector([2, -3, -3])
A1=copy(A); A2=copy(A); A3=copy(A)
A1[:,0] = b #construct the matrix A_1
A2[:,1] = b #construct the matrix A_2
A3[:,2] = b #construct the matrix A_3
show(A1); show(A2); show(A3)
x1=A1.det()/A.det(); x2=A2.det()/A.det()
x3=A3.det()/A.det(); print([x1, x2, x3])
```

terms in the products of  $|M|$  with their algebraic complements is a term in  $|A|$ . But for distinct choices of  $M$  we can never obtain the same terms and the individual terms in  $(-1)^{i_1+\dots+i_k+j_1+\dots+j_l} \cdot |M| \cdot |M^*|$  are also mutually distinct. Therefore we have exactly the required number  $k!(n-k)!\binom{n}{k} = n!$  of terms, and we have proved:

LAPLACE THEOREM

**Theorem.** Let  $A = (a_{ij})$  be a square matrix of dimension  $n$  over arbitrary ring of scalars with  $k$  rows fixed. Then  $|A|$  is a sum of all  $\binom{n}{k}$  products  $(-1)^{i_1+\dots+i_k+j_1+\dots+j_l} \cdot |M| \cdot |M^*|$  of minors of the order  $k$  chosen among the fixed rows with their algebraic complements.

The Laplace theorem transforms the computation of  $|A|$  into the computation of determinants of lower dimension. This method of computation is called the *Laplace expansion* along the chosen rows (or columns). For instance, the expansion along the  $i$ -th row or the  $j$ -th column is:

$$|A| = \sum_{j=1}^n a_{ij} A_{ij} = \sum_{i=1}^n a_{ij} A_{ij}$$

where  $A_{ij}$  are the algebraic complements of the elements  $a_{ij}$  (that is, minors of order one), as deduced in 2.2.4 already.

In practical computations, it is often efficient to combine the Laplace expansion with a direct method of Gaussian elimination.

**2.2.10. Proof of the Cauchy theorem.** The theorem is based on a clever but elementary application of the Laplace theorem. We just use the Laplace expansion twice on a particular arrangement of a well chosen matrix.

Consider first the following matrix  $H$  of dimension  $2n$  (we are using the so-called block symbolics, that is, we write the matrix as if composed of the (sub)matrixes  $A, B$ , and so on).

$$H = \begin{pmatrix} A & 0 \\ -E & B \end{pmatrix} = \begin{pmatrix} a_{11} & \dots & a_{1n} & 0 & \dots & 0 \\ \vdots & & \vdots & \vdots & & \vdots \\ a_{n1} & \dots & a_{nn} & 0 & \dots & 0 \\ -1 & & 0 & b_{11} & \dots & b_{1n} \\ & \ddots & & \vdots & & \vdots \\ 0 & & -1 & b_{n1} & \dots & b_{nn} \end{pmatrix}$$

The Laplace expansion along the first  $n$  rows gives

$$|H| = |A| \cdot |B|.$$

Now in sequence, we add linear combinations of the first  $n$  columns to the last  $n$  columns in order to obtain a matrix

Notice, the `copy()` function provides a way to make a copy of a matrix before we make changes to it. This block returns the matrices  $A_1, A_2, A_3$  and the solution in the form  $[1, 2, -1]$ . In Section E we will meet another implementation of Cramer's rule via Sage, see 2.E.23.  $\square$

**2.B.12.** Is the matrix  $A$  given below invertible? In the positive case find its algebraically adjoint matrix and its inverse:

$$A = \begin{pmatrix} 1 & 0 & 2 & 0 \\ 0 & 3 & 0 & 4 \\ 5 & 0 & 6 & 0 \\ 0 & 7 & 0 & 8 \end{pmatrix}.$$

**Solution.** Recall that a square matrix  $A$  is invertible if and only if  $\det(A) \neq 0$ . Expanding the first row of the given  $A$ , we see that

$$\det(A) = \begin{vmatrix} 1 & 0 & 2 & 0 \\ 0 & 3 & 0 & 4 \\ 5 & 0 & 6 & 0 \\ 0 & 7 & 0 & 8 \end{vmatrix} = \begin{vmatrix} 3 & 0 & 4 \\ 0 & 6 & 0 \\ 7 & 0 & 8 \end{vmatrix} + 2 \begin{vmatrix} 0 & 3 & 4 \\ 5 & 0 & 0 \\ 0 & 7 & 8 \end{vmatrix} = 16.$$

Hence there exists  $A^{-1}$  such that  $AA^{-1} = E = A^{-1}A$ , where  $E$  is the  $4 \times 4$  identity matrix. To compute  $A^{-1}$  we will use the algebraic adjoint matrix of  $A$ , the latter given by

$$\text{adj}(A) = \begin{pmatrix} A_{11} & A_{12} & A_{13} & A_{14} \\ A_{21} & A_{22} & A_{23} & A_{24} \\ A_{31} & A_{32} & A_{33} & A_{34} \\ A_{41} & A_{42} & A_{43} & A_{44} \end{pmatrix}^T.$$

Here,  $A_{ij}$  is the algebraic complement of the element  $a_{ij}$  of the matrix  $A$ , that is, the product of the number  $(-1)^{i+j}$  and the determinant of the matrix given by  $A$  without the  $i$ th row and  $j$ th column. We compute:

$$\begin{aligned} A_{11} &= \begin{vmatrix} 3 & 0 & 4 \\ 0 & 6 & 0 \\ 7 & 0 & 8 \end{vmatrix} = -24, & A_{12} &= - \begin{vmatrix} 0 & 0 & 4 \\ 5 & 6 & 0 \\ 0 & 0 & 8 \end{vmatrix} = 0, \\ A_{13} &= \begin{vmatrix} 0 & 3 & 4 \\ 5 & 0 & 0 \\ 0 & 7 & 8 \end{vmatrix} = 20, & A_{14} &= - \begin{vmatrix} 0 & 3 & 0 \\ 5 & 0 & 6 \\ 0 & 7 & 0 \end{vmatrix} = 0, \\ A_{21} &= - \begin{vmatrix} 0 & 2 & 0 \\ 0 & 6 & 0 \\ 7 & 0 & 8 \end{vmatrix} = 0, & A_{22} &= \begin{vmatrix} 1 & 2 & 0 \\ 5 & 6 & 0 \\ 0 & 0 & 8 \end{vmatrix} = -32, \\ A_{23} &= - \begin{vmatrix} 1 & 0 & 0 \\ 5 & 0 & 0 \\ 0 & 7 & 8 \end{vmatrix} = 0, & A_{24} &= \begin{vmatrix} 1 & 0 & 2 \\ 5 & 0 & 6 \\ 0 & 7 & 0 \end{vmatrix} = -28, \\ A_{31} &= \begin{vmatrix} 0 & 2 & 0 \\ 3 & 0 & 4 \\ 7 & 0 & 8 \end{vmatrix} = 8, & A_{32} &= - \begin{vmatrix} 1 & 2 & 0 \\ 0 & 0 & 4 \\ 0 & 0 & 8 \end{vmatrix} = -0, \\ A_{33} &= \begin{vmatrix} 1 & 0 & 0 \\ 0 & 3 & 4 \\ 0 & 7 & 8 \end{vmatrix} = -4, & A_{34} &= - \begin{vmatrix} 1 & 0 & 2 \\ 0 & 3 & 0 \\ 0 & 7 & 0 \end{vmatrix} = -0, \\ A_{41} &= - \begin{vmatrix} 0 & 2 & 0 \\ 3 & 0 & 4 \\ 0 & 6 & 0 \end{vmatrix} = 0, & A_{42} &= \begin{vmatrix} 1 & 2 & 0 \\ 0 & 0 & 4 \\ 5 & 6 & 0 \end{vmatrix} = -16, \end{aligned}$$

with zeros in the bottom right corner. We obtain

$$K = \begin{pmatrix} a_{11} & \cdots & a_{1n} & c_{11} & \cdots & c_{1n} \\ \vdots & & \vdots & \vdots & & \vdots \\ a_{n1} & \cdots & a_{nn} & c_{n1} & \cdots & c_{nn} \\ -1 & & 0 & 0 & \cdots & 0 \\ & \ddots & & \vdots & & \vdots \\ 0 & & -1 & 0 & \cdots & 0 \end{pmatrix}.$$

The elements of the submatrix on the top right part must satisfy

$$c_{ij} = a_{i1}b_{1j} + a_{i2}b_{2j} + \cdots + a_{in}b_{nj},$$

that is, they are exactly the components of the product  $A \cdot B$  and  $|K| = |H|$ . The expansion of the last  $n$  columns gives us  $|K| = (-1)^n (-1)^{1+\cdots+2n} |A \cdot B| = (-1)^{2n \cdot (n+1)} \cdot |A \cdot B| = |A \cdot B|$ . This proves the Cauchy theorem.

**2.2.11. Determinant and the inverse matrix.** Assume first

that there is an inverse matrix of the matrix  $A$ , that is,  $A \cdot A^{-1} = E$ . Since the unit matrix always satisfies  $|E| = 1$ , it follows that for every invertible matrix its determinant is an invertible scalar and by the Cauchy theorem we have  $|A^{-1}| = |A|^{-1}$ .

But we can say more, combining the Laplace and Cauchy theorems.

#### INVERSE MATRIX DETERMINANT FORMULA

For any square matrix  $A = (a_{ij})$  of dimension  $n$  we define the matrix  $A^* = (a_{ij}^*)$ , where  $a_{ij}^* = A_{ji}$  are algebraic complements of the elements  $a_{ji}$  in  $A$ . The matrix  $A^*$  is called the *algebraically adjoint matrix* of the matrix  $A$  (or the *adjugate matrix*  $A^*$ ).

**Theorem.** For every square matrix  $A$  over a ring of scalars  $\mathbb{K}$  we have that

$$(1) \quad AA^* = A^*A = |A| \cdot E.$$

In particular,

- (i)  $A^{-1}$  exists as a matrix over the ring of scalars  $\mathbb{K}$  if and only if  $|A|^{-1}$  exists in  $\mathbb{K}$ .
- (ii) If  $A^{-1}$  exists, then  $A^{-1} = |A|^{-1} \cdot A^*$ .

**PROOF.** As already mentioned, the Cauchy theorem shows that the existence of  $A^{-1}$  implies the invertibility of  $|A| \in \mathbb{K}$ .

For an arbitrary square matrix  $A$  we can directly compute  $A \cdot A^* = (c_{ij})$ , where

$$c_{ij} = \sum_{k=1}^n a_{ik} a_{kj}^* = \sum_{k=1}^n a_{ik} A_{jk}.$$

If  $i = j$ , it is exactly the Laplace expansion of  $|A|$  along the  $i$ -th row.

If  $i \neq j$ , then we may imagine we expand the determinant along the  $j$ -th row, but plug in the values of the  $i$ -th row instead of the  $a_{jk}$ 's. This is the expansion of the determinant

$$A_{43} = - \begin{vmatrix} 1 & 0 & 0 \\ 0 & 3 & 4 \\ 5 & 0 & 0 \end{vmatrix} = 0, \quad A_{44} = \begin{vmatrix} 1 & 0 & 2 \\ 0 & 3 & 0 \\ 5 & 0 & 6 \end{vmatrix} = -12.$$

Thus, by substitution we obtain that

$$\begin{aligned} \text{adj}(A) &= \begin{pmatrix} -24 & 0 & 20 & 0 \\ 0 & -32 & 0 & 28 \\ 8 & 0 & -4 & 0 \\ 0 & 16 & 0 & -12 \end{pmatrix}^T \\ &= \begin{pmatrix} -24 & 0 & 8 & 0 \\ 0 & -32 & 0 & 16 \\ 20 & 0 & -4 & 0 \\ 0 & 28 & 0 & -12 \end{pmatrix}. \end{aligned}$$

As a verification of the given expression in Sage, you can use either the command `A.adjugate`, or its alias `A.adjoint_classical()`, as follows:

```
A=matrix([[1, 0, 2, 0],[0, 3, 0, 4],
[5, 0, 6, 0], [0, 7, 0, 8]])
show(A.adjugate())
```

The inverse matrix  $A^{-1}$  is now obtained by the rule  $A^{-1} = \frac{1}{\det(A)} \cdot \text{adj}(A)$ , that is,

$$A^{-1} = \begin{pmatrix} -3/2 & 0 & 1/2 & 0 \\ 0 & -2 & 0 & 1 \\ 5/4 & 0 & -1/4 & 0 \\ 0 & 7/4 & 0 & -3/4 \end{pmatrix}.$$

Recall that we can directly compute either the determinant of  $A$ , or the inverse of  $A$  in Sage by adding the commands `det(A)` and `A.inverse()`, respectively.  $\square$

### C. Vector spaces and linear mappings

*Intuitively, a vector space is a landscape (of any dimension  $n$ , finite or infinite) where each position corresponds to a unique set of scalar coordinates (again  $n$ ) and we add and multiply them exactly as we already saw in chapter 1, working with  $\mathbb{R}^2$  and  $\mathbb{C}$ .*

*Vector spaces can become quite abstract and unusual (as already the scalars can be) and they are fundamental building blocks in mathematics, with an amazing wide range of applications in many fields, including chemistry, physics, image processing, computer science, economics, etc. For an informative introduction to the concepts, see 2.3.1. Next we will primarily focus on finite-dimensional vector spaces.*

**2.C.1. Vector spaces.** Decide whether the following sets form a vector space over the given field:

(a) The set of real solutions of the linear system:

$$\begin{cases} x_1 + x_2 + \cdots + x_8 + x_9 + x_{10} & = & 10x_1, \\ x_1 + x_2 + \cdots + x_8 + x_9 & = & 9x_1, \\ x_1 + x_2 + \cdots + x_8 & = & 8x_1, \\ \vdots & & \\ x_1 + x_2 & = & 2x_1. \end{cases}$$

of a matrix where the  $i$ -th and  $j$ -th row is the same, therefore  $c_{ij} = 0$ .

This implies that  $A \cdot A^* = |A| \cdot E$ , and we have proven one of the equalities (1). In particular, if  $|A|^{-1}$  exists, then  $A \cdot (|A|^{-1}A^*) = E$ .

If  $|A|$  is an invertible scalar, we may repeat the previous computation for  $A^* \cdot A$ , and we obtain  $(|A|^{-1}A^*) \cdot A = E$ . Therefore our computation really gives the inverse matrix of  $A$ , as claimed in the theorem.  $\square$

Notice that for fields of scalars we have already proved that the right inverse of a matrix is automatically the left inverse and thus the inverse, too. Here we have obtained the same result for all rings of scalars, together with a strong and effective existence condition. On the other hand the exact formula for the inverse has become rather theoretical with little practical value.

As a direct corollary of this theorem we can once again prove the Cramer rule for solving the systems of linear equations, see 2.2.6. Really, for the solution of the system  $A \cdot x = b$  we just need to read in the equation

$$x = A^{-1} \cdot b = |A|^{-1}A^* \cdot b$$

the individual components of the expression  $A^* \cdot b$  as the Laplace expansions of the determinant of the matrix  $A_i$  which arose through the exchange of the  $i$ -th column of  $A$  for the column  $b$ .

## 3. Vector spaces and linear mappings

**2.3.1. Abstract vector spaces.** Let us go back for a while to the systems of  $m$  linear equations of  $n$  variables from 2.1.3 and further, let us assume that the system is homogeneous,  $A \cdot x = 0$ , i.e.,

$$\begin{pmatrix} a_{11} & \cdots & a_{1n} \\ \vdots & & \vdots \\ a_{m1} & \cdots & a_{mn} \end{pmatrix} \cdot \begin{pmatrix} x_1 \\ \vdots \\ x_n \end{pmatrix} = \begin{pmatrix} 0 \\ \vdots \\ 0 \end{pmatrix}.$$

By the distributivity of the matrix multiplication it is clear that the sum of two solutions  $x = (x_1, \dots, x_n)$  and  $y = (y_1, \dots, y_n)$  satisfies

$$A \cdot (x + y) = A \cdot x + A \cdot y = 0$$

and thus is also a solution. Similarly, a scalar multiple  $a \cdot x$  is also a solution. The set of all solutions of a fixed system of equations is therefore closed under vector addition and scalar multiplication. These are the basic properties of vectors of dimension  $n$  in  $\mathbb{K}^n$ , see 2.1.1. Now we have the vectors in the solution space with  $n$  coordinates. The “dimension” of this space is given by the difference of the number of variables and the rank of the matrix  $A$ . Thus we can easily deal with the solution of a system of 1000 equations in 1000 variables and need only one or two free parameters. Thus the whole solution space will behave as a plane or a line, as we have already seen in 1.5.3 at the page 29, although the vectors themselves are given by so many components.

(b) The set of real solutions of the equation

$$x_1 + x_2 + \cdots + x_{10} = 0.$$

(c) The set of real solutions of the equation

$$x_1 + 2x_2 + 3x_3 + \cdots + 10x_{10} = 1.$$

(d) The set of all real or complex sequences (recall that a real or a complex sequence can be viewed as a mapping  $f : \mathbb{N} \rightarrow \mathbb{R}$  or  $f : \mathbb{N} \rightarrow \mathbb{C}$ , respectively).

(e) The set  $\mathcal{F} = \{f \mid f : X \rightarrow \mathbb{R}\}$  of real-valued functions with domain a non-empty set  $X$ .

(f) The set of real solutions of a non-homogeneous difference equation.

(g) The set  $\text{Mat}_{m,n}(\mathbb{K})$  of  $m \times n$  matrices with entries over  $\mathbb{K}$ , where  $\mathbb{K} \in \{\mathbb{R}, \mathbb{C}\}$ .

(h) The set  $\mathbb{Q}(\sqrt{2}) = \{a + \sqrt{2}b : a, b \in \mathbb{Q}\}$  over  $\mathbb{Q}$ .

**Solution.** (a) This set is a vector space, since the solutions are real multiples of the vector  $u := (1, \dots, 1)^T$  (10-factors). Moreover, a sum of two multiples of the same vector is again a multiple of the vector, while the reverse vector is again a multiple of the vector. All other axioms are trivially satisfied.

(b) This provides an example of a vector space of dimension 9 (its dimension is determined by the number of free parameters of the solution). More general, recall that the set of solutions of any homogeneous linear system is a vector space, see 2.3.5.

(c) Taking twice the solution  $x_1 = 1, x_i = 0$ , for  $i = 2, \dots, 10$ , we do not obtain a solution. Hence, the given set cannot be a vector space. However, the set of solutions forms an affine space, see 4.1.1.

(d) The set of all real (respectively, complex) sequences clearly forms a real (respectively, complex) vector space. Notice that the addition and scalar multiplication is defined term-wise. Moreover, the zero vector is represented by the zero sequence  $(0, 0, 0, \dots)$ .

(e) This provides an example of an infinite-dimensional vector space, where the addition and multiplication are defined by the usual way, i.e.,  $(f + g)(x) = f(x) + g(x)$  and  $(cf)(x) = c \cdot f(x)$ , respectively, for all  $x \in X$ . Notice the zero vector is simply the constant function with zero value everywhere on  $X$ , i.e., the zero function defined on  $X$ .

(f) Consider two solutions of a non-homogeneous equation

$$\begin{aligned} a_n x_{n+k} + a_{n-1} x_{n+k-1} + \cdots + a_0 x_k &= c, \\ a_n y_{n+k} + a_{n-1} y_{n+k-1} + \cdots + a_0 y_k &= c, \end{aligned}$$

where  $c$  is some non-zero scalar. Their sum satisfies

$$\begin{aligned} a_n(x_{n+k} + y_{n+k}) + a_{n-1}(x_{n+k-1} + y_{n+k-1}) \\ + \cdots + a_0(x_k + y_k) = 2c, \end{aligned}$$

and obviously, this cannot provide a solution of the given non-homogeneous equation. Hence we do not obtain a vector space. However, the set of solutions in this case forms an affine space (see 4.1.1).

(g) This is one of the most fundamental examples of finite-dimensional vector spaces. For simplicity, let us fix  $\mathbb{K} = \mathbb{R}$  and similarly is treated the complex case, see also the task

We go further. Already in paragraph 1.2.1 we have encountered an interesting example of a space of all solutions of a homogeneous linear difference equation of first order. All solutions have been obtained from a single one by scalar multiplication and are also closed under addition and scalar multiples. These “vectors” of solutions are infinite sequences of numbers, although we intuitively expect that the “dimension” of the whole space of solutions should be one. We shall understand such phenomena with the help of a more general definition of vector space and its dimension.

#### VECTOR SPACE DEFINITION

A vector space  $V$  over a field of scalars  $\mathbb{K}$  is a set where we define the operations

- addition, which satisfies the axioms (CG1)–(CG4) from the paragraph 1.1.1 on the page 5,
- scalar multiplication, for which the axioms (V1)–(V4) from the paragraph 2.1.1 on the page 84 hold.

Recall our simple notational convention: scalars are usually denoted by letters from the beginning of the alphabet, that is,  $a, b, c, \dots$ , while for vectors we shall use letters from the end, that is,  $u, v, w, x, y, z$ . Usually,  $x, y, z$  will denote  $n$ -tuples of scalars. For completeness, the letters from the centre of the alphabet, for instance  $i, j, k, \ell$ , will mostly denote indices.

In order to gain some practice in the formal approach, we check some simple properties of vectors. These are trivial for  $n$ -tuples for scalars, but not so evident for general vectors in our new abstract sense.

**2.3.2. Proposition.** Let  $V$  be a vector space over a field of scalars  $\mathbb{K}$ . Suppose  $a, b, a_i \in \mathbb{K}$ , and  $u, v, u_j \in V$ . Then

- (1)  $a \cdot u = 0$  if and only if  $a = 0$  or  $u = 0$ ,
- (2)  $(-1) \cdot u = -u$ ,
- (3)  $a \cdot (u - v) = a \cdot u - a \cdot v$ ,
- (4)  $(a - b) \cdot u = a \cdot u - b \cdot u$ ,
- (5)  $(\sum_{i=1}^n a_i) \cdot (\sum_{j=1}^m u_j) = \sum_{i=1}^n \sum_{j=1}^m a_i \cdot u_j$ .

**PROOF.** We can expand

$$a \cdot u = (a + 0) \cdot u \stackrel{(V2)}{=} a \cdot u + 0 \cdot u$$

which, according to the axiom (CG4), implies  $0 \cdot u = 0$ . Now

$$u + (-1) \cdot u \stackrel{(V2)}{=} (1 + (-1)) \cdot u = 0 \cdot u = 0$$

and thus  $-u = (-1) \cdot u$ . Further,

$$a \cdot (u + (-1) \cdot v) \stackrel{(V2, V3)}{=} a \cdot u + (-a) \cdot v = a \cdot u - a \cdot v,$$

which proves (3). It follows that

$$(a - b) \cdot u \stackrel{(V2, V3)}{=} a \cdot u + (-b) \cdot u = a \cdot u - b \cdot u$$

which proves (4). Property (5) follows using induction with (V2) and (V1).

It remains to prove (1):  $a \cdot 0 = a \cdot (u - u) = a \cdot u - a \cdot u = 0$ , which along with the first derived proposition in

in 2.E.56 for more details on complex matrices. The vector addition on  $\text{Mat}_{m,n}(\mathbb{R})$  is given by matrix addition, i.e.,  $A + B = (a_{ij} + b_{ij}) \in \text{Mat}_{m,n}(\mathbb{R})$  for all  $A = (a_{ij})$ ,  $B = (b_{ij}) \in \text{Mat}_{m,n}(\mathbb{R})$ , and scalar multiplication is defined by multiplying each entry of the given matrix by the scalar, i.e.,  $cA = (c \cdot a_{ij}) \in \text{Mat}_{m,n}(\mathbb{R})$  for all  $c \in \mathbb{R}$  and  $A = (a_{ij}) \in \text{Mat}_{m,n}(\mathbb{R})$ , see also 2.1.2. Let us check the axioms (CG1)-(CG4) presented in 1.1.1:

- (CG1) – associativity: Indeed,  $(A+B)+C = A+(B+C)$  for all  $A, B, C \in \text{Mat}_{m,n}(\mathbb{R})$ . This property follows by the associativity of the addition of real numbers:  $(a_{ij} + b_{ij}) + c_{ij} = a_{ij} + (b_{ij} + c_{ij})$ , where we assume that  $A = (a_{ij})$ ,  $B = (b_{ij})$  and  $C = (c_{ij})$ , respectively.
  - (CG2) – commutativity: In an analogous way we can prove that  $A + B = B + A$ , for all  $A, B \in \text{Mat}_{m,n}(\mathbb{R})$ .
  - (CG3) – existence of neutral element: This is the zero matrix, which we just denote by  $0 \in \text{Mat}_{m,n}(\mathbb{R})$ . Obviously, it satisfies  $A + 0 = A = 0 + A$ , for all  $A \in \text{Mat}_{m,n}(\mathbb{R})$ .
  - (CG4) – existence of additive inverse: For  $A \in \text{Mat}_{m,n}(\mathbb{R})$ ,  $B = -A$  is the unique matrix satisfying  $A + B = 0$ .
- These axioms ensure that the pair  $(\text{Mat}_{m,n}(\mathbb{R}), +)$  has the structure of a “commutative group”.

Finally, it is very easy to check the axioms (V1) – (V4) posed in the paragraph 2.1.1, and which must satisfy the scalar multiplication. For completeness, we list them:

- (V1) –  $\alpha(A + B) = \alpha A + \alpha B$  for all  $\alpha \in \mathbb{R}$ , and  $A, B \in \text{Mat}_{m,n}(\mathbb{R})$ .
- (V2) –  $(\alpha + \beta)A = \alpha A + \beta A$  for all  $\alpha, \beta \in \mathbb{R}$  and  $A \in \text{Mat}_{m,n}(\mathbb{R})$ .
- (V3) –  $\alpha(\beta A) = (\alpha\beta)A$ , for all  $\alpha, \beta \in \mathbb{R}$  and  $A \in \text{Mat}_{m,n}(\mathbb{R})$ .
- (V4) –  $1A = A$  for all  $A \in \text{Mat}_{m,n}(\mathbb{R})$ .

(h) The final set  $\mathbb{Q}(\sqrt{2}) = \{a + \sqrt{2}b : a, b \in \mathbb{Q}\}$  provides an example of a vector space over  $\mathbb{Q}$ . Indeed, let  $x = a + \sqrt{2}b$ ,  $y = c + \sqrt{2}d$  two elements in  $\mathbb{Q}(\sqrt{2})$ . Then  $x + y = (a + c) + \sqrt{2}(b + d) \in \mathbb{Q}(\sqrt{2})$ . Moreover, for  $q \in \mathbb{Q}$  we have  $qx \in \mathbb{Q}(\sqrt{2})$ , since  $qa, qb \in \mathbb{Q}$ , for all  $a, b \in \mathbb{Q}$ .  $\square$

**2.C.2.** By the discussion in 2.3.4 we know that the space  $\mathbb{R}_m[x]$  of real polynomials of degree at most  $m$  is a vector space over  $\mathbb{R}$ . Can we claim the same for the set of real polynomials of degree exactly  $m$ ?  $\circ$

**2.C.3. Vector spaces in Sage.** (a) Use Sage to create the vector spaces  $\mathbb{R}^4$  and  $\mathbb{Q}^4$ . Next check if the vector  $u = 2v + 3w$  is an element of  $\mathbb{Q}^4$ , where  $v = (1, -2, -3, 0)^T$  and  $w = (1, 0, 3, -2)^T$ , respectively.

(b) Use Sage to create the matrix spaces  $\text{Mat}_4(\mathbb{R})$  of  $4 \times 4$  real matrices, and  $\text{Mat}_{4,1}(\mathbb{C})$  of  $4 \times 1$  complex matrices.

**Solution.** (a) An easy way to introduce a vector space in Sage, is to start by specifying the field over which the vectors are defined, and then use an exponent to indicate the dimension of the vector space. This process is compact and mimics the notation we use when working on paper.

For instance, to introduce  $\mathbb{R}^4$ , type

this proof proves one implication. For the other implication, we use an axiom for the field of scalars, and axiom (V4) for vector spaces: if  $p \cdot u = 0$  and  $p \neq 0$ , then  $u = 1 \cdot u = (p^{-1} \cdot p) \cdot u = p^{-1} \cdot 0 = 0$ .  $\square$

**2.3.3. Linear (in)dependence.** In paragraph 2.1.11 we worked with linear combinations of rows of a matrix. With vectors we work analogously:

#### LINEAR COMBINATION AND INDEPENDENCE

An expression of the form  $a_1 v_1 + \dots + a_k v_k$  is called a *linear combination* of vectors  $v_1, \dots, v_k \in V$ .

A finite sequence of vectors  $v_1, \dots, v_k$  is called *linearly independent*, if the only zero linear combination is the one with all coefficients zero. That is, for any scalars  $a_1, \dots, a_k \in \mathbb{K}$ ,  $a_1 v_1 + \dots + a_k v_k = 0$  implies  $a_1 = a_2 = \dots = a_k = 0$ . It is clear that for an independent sequence of vectors, all vectors are mutually distinct and nonzero.

The set of vectors  $M \subset V$  in a vector space  $V$  over  $\mathbb{K}$  is called *linearly independent*, if every finite  $k$ -tuple of vectors  $v_1, \dots, v_k \in M$  is linearly independent.

The set of vectors  $M$  is *linearly dependent*, if it is not linearly independent.

A nonempty subset  $M$  of vectors in a vector space over a field of scalars  $\mathbb{K}$  is dependent if and only if one of its vectors can be expressed as a finite linear combination using other vectors in  $M$ . This follows directly from the definition:

Indeed, at least one of the coefficients in the corresponding linear combination must be nonzero, and since we are over a field of scalars, we can multiply whole combination by the inverse of this nonzero coefficient and thus express its corresponding vector as a linear combination of the others.

Every subset of a linearly independent set  $M$  is clearly also linearly independent (we require the same conditions on a smaller set of vectors). Similarly, we can see that  $M \subset V$  is linearly independent if and only if every finite subset of  $M$  is linearly independent.

**2.3.4. Generators and subspaces.** A subset  $M \subset V$  is called a *vector subspace* if it forms, together with the restricted operations of addition and scalar multiplication, a vector space. That is, we require

$$\forall a, b \in \mathbb{K}, \forall v, w \in M, a \cdot v + b \cdot w \in M.$$

We investigate a couple of cases: The space of  $m$ -tuples of scalars  $\mathbb{R}^m$  with coordinate-wise addition and multiplication is a vector space over  $\mathbb{R}$ , but also a vector space over  $\mathbb{Q}$ . For instance for  $m = 2$ , the vectors  $(1, 0), (0, 1) \in \mathbb{R}^2$  are linearly independent, because from

$$a \cdot (1, 0) + b \cdot (0, 1) = (0, 0)$$

follows  $a = b = 0$ . Further, the vectors  $(1, 0), (\sqrt{2}, 0) \in \mathbb{R}^2$  are linearly dependent over  $\mathbb{R}$ , because  $\sqrt{2} \cdot (1, 0) = (\sqrt{2}, 0)$ , but over  $\mathbb{Q}$  they are linearly independent! Over  $\mathbb{R}$  these two

```
V=RR^4; V # we can also type V=RR**4
```

Sage returns the following:

```
Vector space of dimension 4 over
Real Field with 53 bits of precision
```

Similarly, to introduce the vector space  $\mathbb{Q}^4$  type `QQ^4`, etc.

We can also use the `VectorSpace()` function, which requires the name of the number system for the entries and the number of entries in each vector. For instance the cell

```
V = VectorSpace(QQ, 4); print(V)
```

prints out

```
Vector space of dimension 4
over Rational Field
```

Vectors can be constructed in the usual way, that is,

```
V=QQ^4;
v=vector(QQ, [1, -2, -3, 0])
w=vector(QQ, [1, 0, 3, -2])
```

It is also easy to perform computations with vectors (vector addition and scalar multiplication):<sup>6</sup>

```
V=QQ^4; v=vector(QQ, [1, -2, -3, 0])
w=vector(QQ, [1, 0, 3, -2])
u=2*v+3*w
print(u) # we could type show(u)
u in V
```

Here Sage returns the vector  $u$ , i.e.,  $(5, -4, 3, -6)$  and the word `True`, the latter verifying that  $u \in V$ .

(b) Sage provides built-in functions for working with matrix spaces. This cell creates the space  $\text{Mat}_4(\mathbb{R})$ :

```
M = MatrixSpace(RR, 4); M
```

Similarly, to introduce the space  $\text{Mat}_{4,1}(\mathbb{C})$  use the cell

```
M = MatrixSpace(CC, 4, 1); M
```

Notice, when the number of columns is omitted, it defaults to the number of rows.  $\square$

**2.C.4.** Describe the linear combination  $3v_1 + 2v_2 + 5v_3 + v_4$  of the vectors  $v_1, \dots, v_4$  given below in Sage, using at least two different methods:

$$\begin{aligned} v_1 &= \left(\frac{1}{2}, \frac{2}{3}, 1, 0\right)^T, & v_3 &= \left(0, \frac{1}{5}, \frac{2}{5}, 1\right)^T, \\ v_2 &= (2, 0, 1/7, 0)^T, & v_4 &= (-1, 2, 0, 3)^T. \end{aligned}$$

**2.C.5.** Consider the system  $Ax = b$  given below with a solution given by  $(-2/15, 1/5, 2/15, -11/15)^T$ ,

$$\begin{pmatrix} 3 & -9 & 9 & 0 \\ 9 & -3 & 6 & 0 \\ 9 & -6 & 0 & -6 \\ -9 & 12 & 6 & 6 \end{pmatrix} \begin{pmatrix} x_1 \\ x_2 \\ x_3 \\ x_4 \end{pmatrix} = \begin{pmatrix} -1 \\ -1 \\ 2 \\ 0 \end{pmatrix}.$$

<sup>6</sup>Be aware that Sage displays vectors using parentheses (to distinguish them from lists), and presents them horizontally. In particular, in Sage there is no inherent distinction between a “row vector” and a “column vector”. However, when dealing with matrices, it is crucial to make this distinction.

vectors “generate” a one-dimensional subspace, while over  $\mathbb{Q}$  the subspace is “larger”.

Polynomials with real coefficients and of degree at most  $m$  form a vector space  $\mathbb{R}_m[x]$ . We can consider the polynomials as mappings  $f : \mathbb{R} \rightarrow \mathbb{R}$  and define the addition and scalar multiplication like this:  $(f + g)(x) = f(x) + g(x)$ ,  $(a \cdot f)(x) = a \cdot f(x)$ .

Polynomials of all degrees also form a vector space  $\mathbb{R}[x]$  (or  $\mathbb{R}_\infty[x]$ ) and  $\mathbb{R}_m[x] \subset \mathbb{R}_n[x]$  is a vector subspace for any  $m \leq n \leq \infty$ . Further examples of subspaces is given by all even polynomials or all odd polynomials, that is, polynomials satisfying  $f(-x) = \pm f(x)$ .

In complete analogy with polynomials, we can define a vector space structure on a set of all mappings  $\mathbb{R} \rightarrow \mathbb{R}$  or of all mappings  $M \rightarrow V$  of an arbitrary fixed set  $M$  into the vector space  $V$ .

Because the condition in the definition of subspace consists only of universal quantifiers, the intersection of subspaces is still a subspace. We can see this also directly: Let  $W_i, i \in I$ , be vector subspaces in  $V$ ,  $a, b \in \mathbb{K}$ ,  $u, v \in \bigcap_{i \in I} W_i$ . Then  $a \cdot u + b \cdot v \in W_i$  for all  $i \in I$ . Hence  $a \cdot u + b \cdot v \in \bigcap_{i \in I} W_i$ .

It can be noted that the intersection of all subspaces  $W \subset V$  that contain some given set of vectors  $M \subset V$  is a subspace. It is called the *linear span* or *linear hull* of  $M$  and we write  $\text{span } M$ .

We say that a set  $M$  *generates* the subspace  $\text{span } M$ , or that the elements of  $M$  are *generators* of the subspace  $\text{span } M$ .

We formulate a few simple claims about subspace generation:

**Proposition.** For every nonempty set  $M \subset V$ , we have

- (1)  $\text{span } M = \{a_1 \cdot u_1 + \dots + a_k \cdot u_k; k \in \mathbb{N}, a_i \in \mathbb{K}, u_j \in M, j = 1, \dots, k\}$ ;
- (2)  $M = \text{span } M$  if and only if  $M$  is a vector subspace;
- (3) if  $N \subset M$  then  $\text{span } N \subset \text{span } M$  is a vector subspace; the subspace  $\text{span } \emptyset$  generated by the empty subset is the trivial subspace  $\{0\} \subset V$ .

**PROOF.** (1) The set of all linear combinations

$$a_1 u_1 + \dots + a_k u_k$$

on the right-hand side of (1) is clearly a vector subspace and of course it contains  $M$ . On the other hand, each of the linear combinations must be in  $\text{span } M$  and thus the first claim is proved.

Claim (2) follows immediately from claim (1) and from the definition of vector space. Analogously, (1) implies most of the third claim.

Finally, the smallest possible vector subspace is  $\{0\}$ . Notice that the empty set is contained in every subspace and each of them contains the vector  $0$ . This proves the last claim.  $\square$

Use Sage to illustrate that the solution gives us scalars that yield the vector of constants  $b$  as a linear combination of the columns of the coefficient matrix  $A$ . ○

**2.C.6.** Describe the vector space structure of  $\mathbb{Z}_5^3$ . What is the total number of vectors in  $\mathbb{Z}_5^3$ ? Use the cardinality command in Sage to support your answer. ○

Next we will explore problems concerning the concept of linear subspaces. A vector subspace of a vector space  $V$  is a non-empty subset  $W$  of  $V$  which is closed under addition and scalar multiplication. It can be either given as a span of some vectors (i.e., all of their linear combinations), or by some (linear) conditions.<sup>7</sup> Therefore, any subspace of  $V$  is itself a vector space and shares the same fundamental properties and significance, see also the discussion in 2.3.4.

In Sage we have numerous options to explore the properties and characteristics of subspaces. Once we have introduced a vector space  $V$ , a subspace  $W \subset V$  is defined by specifying a set of generators that span the subspace. This can be achieved by the `subspace()` function or with the `span` command.

**2.C.7. Linear subspaces.** Decide whether the following statements are true or false:

- (a) The subset  $U_1 = \{(x, y, z) \in \mathbb{R}^3 : 2x + 7y + z = 1\}$  is a linear subspace of  $\mathbb{R}^3$ .
- (b) The subset  $U_2 = \{(x, y, z) \in \mathbb{R}^3 : 2x^2 + 7y + z = 0\}$  is a linear subspace of  $\mathbb{R}^3$ .
- (c) The subset  $U_3 = \{(x, y, z) \in \mathbb{R}^3 : 2x + 7y + z = 0\}$  is a linear subspace of  $\mathbb{R}^3$ .
- (d) The subset  $U_4 = \{ax^2 + c : a, c \in \mathbb{R}\}$  is a linear subspace of the vector space  $\mathbb{R}_2[x]$  of polynomials with real coefficients and degree at most 2.
- (e) The subset  $U_5 = \{(x_1, x_2, x_3) \in \mathbb{R}^3 : |x_1| = |x_2| = |x_3|\}$  is a linear subspace of  $\mathbb{R}^3$ .
- (f) The subset  $U_6 = \{p \in \mathbb{R}_3[x] : p(1) = 0\}$  is a linear subspace of the vector space  $\mathbb{R}_3[x]$  of polynomials with real coefficients and degree at most 3.
- (g) The set of real solutions of a homogeneous difference equation is a linear subspace of the vector space of all real sequences.
- (h) The set  $\left\{ \begin{pmatrix} a & b \\ 0 & c \end{pmatrix} : a, b, c \in \mathbb{R} \right\}$  of  $2 \times 2$  upper triangular matrices is a subspace of  $\text{Mat}_2(\mathbb{R})$ .
- (i) The subset  $V_\lambda = \{x \in \mathbb{R}^n : Ax = \lambda x\}$ , where  $A \in \text{Mat}_n(\mathbb{R})$  and  $\lambda \in \mathbb{R}$ , is a linear subspace of  $\mathbb{R}^n$ .
- (j) The subset  $\{A \in \text{Mat}_n(\mathbb{R}) : A = -A^T\}$  of skew-symmetric  $n \times n$  matrices is a subspace of  $\text{Mat}_n(\mathbb{R})$ .

**Solution.** (a) The subset  $U_1$  cannot be a subspace of  $\mathbb{R}^3$ , since the zero vector does not belong to  $U_1$ .

(b) This is also false, and  $U_2$  cannot be subspace of  $\mathbb{R}^3$ . For example, the vector  $u = (1, 0, -2) \in U_2$ , but  $-u =$

<sup>7</sup>This implies that  $W$  contains the zero vector. Indeed, any  $w \in W$  will have an additive inverse  $-w \in W$  and hence  $0 = w + (-w) \in W$ .

A subset  $M \subset V$  is called a *basis of the vector space*  $V$  if  $\text{span } M = V$  and  $M$  is linearly independent.

A vector space with a finite basis is called *finitely dimensional*. The number of elements of the basis is called the *dimension* of  $V$ .

If  $V$  does not have a finite basis, we say that  $V$  is *infinite dimensional*. We write  $\dim V = k$ ,  $k \in \mathbb{N}$  or  $k = \infty$ .

In order to be satisfied with such a definition of dimension, we must know that different bases of the same space will always have the same number of elements. We shall show this below, cf. 2.3.9. But we note immediately, that the trivial subspace is generated by the empty set, which is an “empty” basis. Thus it has dimension zero.

The linearly independent vectors

$$e_i = (0, \dots, 1, \dots, 0) \in \mathbb{K}^n, \quad i = 1, \dots, n$$

(all zeros, but one value 1 at the  $i$ -th position) are the most useful example of a basis in the vector space  $\mathbb{K}^n$ . We call it the *standard basis* of  $\mathbb{K}^n$ .

**2.3.5. Linear equations again.** It is a good time now to recall the properties of systems of linear equation in terms of abstract vector spaces and their bases. As we have already noted in the introduction to this section (cf. 2.3.1), the set of all solutions of the *homogeneous system*

$$A \cdot x = 0$$

is a vector space. If  $A$  is a matrix with  $m$  rows and  $n$  columns, and the rank of the matrix is  $k$ , then using the row echelon transformation (see 2.1.7) to solve the system, we find that the dimension of the space of all solutions is exactly  $n - k$ .

Indeed, the left hand side of the equation can be understood as the linear combination of the columns of  $A$  with coefficients given by  $x$  and the rank  $k$  of the matrix provides the number of linearly independent columns in  $A$ , thus the dimension of the subspace of all possible linear combinations of the given form. Therefore, after transforming the system into row echelon form, exactly  $m - k$  zero rows remain. In the next step, we are left with exactly  $n - k$  free parameters. By setting one of them to have value one, while all others are zero, we obtain exactly  $n - k$  linearly independent solutions. Then all solutions are given by all the linear combinations of these  $n - k$  solutions. Every  $(n - k)$ -tuple of linearly independent solutions is called a *fundamental system of solutions* of the given homogeneous system of equations. We have proved:

**Proposition.** *The set of all solutions of the homogeneous system of equations  $A \cdot x = 0$ , for  $n$  variables with the matrix  $A$  of rank  $k$ , is a vector subspace in  $\mathbb{K}^n$  of dimension  $n - k$ . Every basis of this space forms a fundamental system of solutions of the given homogeneous system.*

Next, consider the general system of equations  $A \cdot x = b$ . Notice that the columns of the matrix  $A$  are actually images of the vectors of the standard basis in  $\mathbb{K}^n$  under the mapping

$(-1, 0, 2) \notin U_2$ , since  $2 \cdot (-1)^2 + 7 \cdot 0 + 2 = 4 \neq 0$ .

(c) This is true and we leave the verification for practice.

(d) The set  $U_4$  is a linear subspace of  $\mathbb{R}_2[x]$ , since

$$\begin{aligned}(a_1x^2 + c_1) + (a_2x^2 + c_2) &= (a_1 + a_2)x^2 + (c_1 + c_2), \\ k(ax^2 + c) &= (ka)x^2 + kc,\end{aligned}$$

for all real numbers  $a_1, c_1, a_2, c_2, a, c, k \in \mathbb{R}$ . Notice also that for  $a = c = 0$  we obtain the zero polynomial.

(e) The subset  $U_5$  is not a linear subspace of  $\mathbb{R}^3$ , since for example  $(1, 1, 1) + (-1, 1, 1) = (0, 2, 2) \notin U_5$ .

(f) The subset  $U_6$  is clearly a subspace of  $\mathbb{R}_3[x]$ . Indeed, if  $p, q \in U_6$ , and  $c \in \mathbb{R}$ , then we see that

$$\begin{aligned}(p + q)(1) &= p(1) + q(1) = 0, \Rightarrow (p + q) \in U_6, \\ (cp)(1) &= cp(1) = c \cdot 0 = 0, \Rightarrow (cp) \in U_6.\end{aligned}$$

(g) Consider two sequences  $(x_j)_{j=0}^\infty$  and  $(y_j)_{j=0}^\infty$  satisfying the same homogeneous difference equation, that is,

$$\begin{aligned}a_n x_{n+k} + a_{n-1} x_{n+k-1} + \cdots + a_0 x_k &= 0 \\ a_n y_{n+k} + a_{n-1} y_{n+k-1} + \cdots + a_0 y_k &= 0.\end{aligned}$$

By adding these equations, we obtain

$$\begin{aligned}a_n(x_{n+k} + y_{n+k}) + a_{n-1}(x_{n+k-1} + y_{n+k-1}) \\ + \cdots + a_0(x_k + y_k) = 0.\end{aligned}$$

This means that also the sequence  $(x_j + y_j)_{j=0}^\infty$  satisfies the given equation. Analogously, if the sequence  $(x_j)_{j=0}^\infty$  satisfies the given equation, then the same applies for  $(ux_j)_{j=0}^\infty$ , for some  $u \in \mathbb{R}$ . Thus the assertion is true.

(h) This claim is again true, as you can easily verify yourself.

(i) If  $x, y \in V_\lambda$ , then we see that

$$\begin{aligned}A(x + y) &= Ax + Ay = \lambda x + \lambda y = \lambda(x + y), \\ A(cx) &= c(Ax) = c(\lambda x) = \lambda(cx),\end{aligned}$$

and hence  $x + y \in V_\lambda$  and  $cx \in V_\lambda$ , for all  $x, y \in V_\lambda$  and  $c \in \mathbb{R}$ . Hence the claim is true. Non-zero vectors lying on  $V_\lambda$  are called *eigenvectors* of  $A$  corresponding to the *eigenvalue*  $\lambda$ . Thus we have just proved that the *eigenspace*  $V_\lambda$  corresponding to the eigenvalue  $\lambda$  is a subspace of  $\mathbb{R}^n$ . We will learn more about these notions later (see Section 2.D.1). Notice that when  $\lambda = 0$ , then  $V_0 = \text{Ker}(A)$  is the null space (kernel) of the squared matrix  $A$ .

(j) Taking  $A, B \in \text{Mat}_n(\mathbb{R})$  with  $A^T = -A$  and  $B^T = -B$ , we see that  $(A + B)^T = -(A + B)$  and  $(cA)^T = -(cA)$ , for all  $c \in \mathbb{R}$ . Hence the claim is true. Show that the subset of  $n \times n$  symmetric matrices is also a subspace of  $\text{Mat}_n(\mathbb{R})$ .  $\square$

**2.C.8.** Construct in Sage the 2-dimensional subspaces of  $\mathbb{Q}^3$ , generated over  $\mathbb{Q}$  by two vectors of the standard basis  $\underline{e} = \{e_1 = (1, 0, 0)^T, e_2 = (0, 1, 0)^T, e_3 = (0, 0, 1)^T\}$ .  $\circ$

*Dealing with vector spaces, it is crucial to understand the linear dependence or independence of vectors. A basis is an independent set of generators. In finite-dimensional cases, this is the same as a maximal set of linearly independent vectors. Every finite-dimensional  $\mathbb{K}$ -vector space  $V$  admits a basis; however, bases are not at*

assigning the vector  $A \cdot x$  to each vector  $x$ . If there should be a solution,  $b$  must be in the image under this mapping and thus it must be a linear combination of the columns in  $A$ .

If we extend the matrix  $A$  by the column  $b$ , the number of linearly independent columns and thus also rows might increase (but does not have to). If this number increases, then  $b$  is not in the image and the system of equations does not have a solution. If on the other hand the number of linearly independent rows does not change after adding the column  $b$  to the matrix  $A$ , it means that  $b$  must be a linear combination of the columns of  $A$ . Coefficients of such combinations are then exactly the solutions of our system.

Consider now two fixed solutions  $x$  and  $y$  of our system and some solution  $z$  of the homogeneous system with the same matrix. Then clearly

$$\begin{aligned}A \cdot (x - y) &= b - b = 0 \\ A \cdot (x + z) &= b + 0 = b.\end{aligned}$$

Thus we can summarise in the form of the so called *Kronecker-Capelli theorem*<sup>1</sup>:

#### KRONECKER-CAPELLI THEOREM

**Theorem.** *The solution of a non-homogeneous system of linear equations  $A \cdot x = b$  exists if and only if adding the column  $b$  to the matrix  $A$  does not increase the number of linearly independent rows. In such a case the space of all solutions is given by all sums of one fixed particular solution of the system and all solutions of the homogeneous system that has the same matrix.*

**2.3.6. Sums of subspaces.** Since we now have some intuition about generators and the subspaces generated by them, we should understand the possibilities of how some subspaces can generate the whole space  $V$ .

#### SUM OF SUBSPACES

Let  $V_i, i \in I$ , be subspaces of  $V$ . Then the subspace generated by their union, that is,  $\text{span} \cup_{i \in I} V_i$ , is called the *sum of subspaces*  $V_i$ . We denote it as  $W = \sum_{i \in I} V_i$ . Notably, for a finite number of subspaces  $V_1, \dots, V_k \subset V$  we write

$$W = V_1 + \cdots + V_k = \text{span}(V_1 \cup V_2 \cup \cdots \cup V_k).$$

We see that every element in the considered sum  $W$  can be expressed as a linear combination of vectors from the subspaces  $V_i$ . Because vector addition is commutative, we can

<sup>1</sup>A common formulation of this fact is “system has a solution if and only if the rank of its matrix equals the rank of its extended matrix”. Leopold Kronecker was a very influential German Mathematician, who dealt with algebraic equations in general and in particular pushed forward Number Theory in the middle of 19th century. Alfredo Capelli, an Italian, worked on algebraic identities. This theorem is equally often called by different names, e.g. *Rouché-Frobenius theorem* or *Rouché-Capelli theorem* etc. This is a very common feature in Mathematics.

all unique, cf. 2.3.7, 2.3.10. At the same time, the number of vectors in any basis is unique, and we call it the dimension  $\dim_{\mathbb{K}}(V)$  of  $V$ . We write just  $\dim(V)$  if the field  $\mathbb{K}$  is clear from the context. Notice, that vector spaces (over fixed field  $\mathbb{K}$ ) of the same finite dimension are isomorphic, cf. 2.3.13.

**2.C.9.** Consider any matrix  $A$  of size  $m \times n$  over a field  $\mathbb{K}$ . Besides the kernel  $\text{Ker}(A) = \{x \in \mathbb{K}^n : Ax = 0\}$  of  $A$ , there are several other fundamental subspaces associated with  $A$ :

- The *column space*  $C(A) = \{Ax : x \in \mathbb{K}^n\}$ , which is the span of the columns of  $A$ .
- The *row space*  $C(A^T) = \{A^T y : y \in \mathbb{K}^m\}$ , which is the span of the rows of  $A$ .
- The *left null space*  $\text{Ker}(A^T) = \{y \in \mathbb{K}^m : A^T y = 0\}$ , also known as the *cokernel* of  $A$ .

Prove that  $C(A^T)$  is a subspace of  $\mathbb{K}^n$ , while  $\text{Ker}(A^T)$  and  $C(A)$  are subspaces of  $\mathbb{K}^m$ . Moreover, show that  $\dim_{\mathbb{K}} C(A) = \text{rank}(A) = \dim_{\mathbb{K}} C(A^T)$ .  $\circ$

*Although vector spaces over infinite fields are always infinite sets, Sage can effectively handle them as mathematical objects. The main tool to this is proper work with the concept of basis. See our discussion in 2.C.14 for the finite case and see also the discussion in 2.3.10.*

**2.C.10.** Determine whether or not the vectors  $u_1 = (1, 2, 3, 1)^T$ ,  $u_2 = (1, 0, -1, 1)^T$ ,  $u_3 = (2, 1, -1, 3)^T$  and  $u_4 = (0, 0, 3, 2)^T$  are linearly independent. Do they provide a basis of  $\mathbb{R}^4$ ? Describe an answer using Sage, as well.

**Solution.** Given  $n$  vectors on  $\mathbb{R}^n$ , say

$$x_1 = (x_{11}, \dots, x_{1n})^T, \quad \dots, \quad x_n = (x_{n1}, \dots, x_{nn})^T,$$

it is easy to check that the condition  $\det(A) \neq 0$  is equivalent to their linear independence, where  $A$  is the coefficient matrix,

$$A = \begin{pmatrix} x_{11} & x_{12} & \dots & x_{1n} \\ x_{21} & x_{22} & \dots & x_{2n} \\ \vdots & \vdots & \dots & \vdots \\ x_{n1} & x_{n2} & \dots & x_{nn} \end{pmatrix}.$$

For the given vectors on  $\mathbb{R}^4$ , we compute

$$\det(A) = \begin{vmatrix} 1 & 2 & 3 & 1 \\ 1 & 0 & -1 & 1 \\ 2 & 1 & -1 & 3 \\ 0 & 0 & 3 & 2 \end{vmatrix} = 10 \neq 0.$$

Thus the set  $\underline{u} = (u_1, u_2, u_3, u_4)$  consists of linearly independent vectors. Since  $\dim \mathbb{R}^4 = 4$  and this set is a basis for its own linear span,  $\underline{u}$  is indeed a basis. To check the linear independence/dependence in Sage, we can rely on built-in functions, as follows:

```
u1=vector(RR, [1, 2, 3, 1])
```

aggregate summands that belong to the same subspace and for a finite sum of  $k$  subspaces we obtain

$$V_1 + V_2 + \dots + V_k = \{v_1 + \dots + v_k; v_i \in V_i, i = 1, \dots, k\}.$$

The sum  $W = V_1 + \dots + V_k \subset V$  is called the *direct sum* of subspaces if the intersection of each  $V_i$  with the sum of the other spaces is trivial, that is,  $V_i \cap \sum_{j \neq i} V_j = \{0\}$ . We show that in such a case, every vector  $w \in W$  can be written in a unique way as the sum

$$w = v_1 + \dots + v_k,$$

where  $v_i \in V_i$ . Indeed, if we could simultaneously write  $w$  as  $w = v'_1 + \dots + v'_k$ , then

$$0 = w - w = (v_1 - v'_1) + \dots + (v_k - v'_k).$$

If  $v_i - v'_i$  is the first nonzero term of the right-hand side, then this vector from  $V_i$  can be expressed using vectors from the other subspaces. This is a contradiction to the assumption that  $V_i$  has zero intersection with all the other subspaces. The only possibility is then that all the vectors on the right-hand side are zero and thus the expression of  $w$  is unique.

For direct sums of subspaces we write

$$W = V_1 \oplus \dots \oplus V_k = \bigoplus_{i=1}^k V_i.$$

**2.3.7. Basis.** Now we have everything prepared for understanding minimal sets of generators as we understood them in the plane  $\mathbb{R}^2$  and to prove the promised independence of the number of basis elements on any choices.

A basis of a  $k$ -dimensional space will usually be denoted as a  $k$ -tuple  $\underline{v} = (v_1, \dots, v_k)$  of basis vectors. This is just a matter of convention: with finitely dimensional vector spaces we shall always consider the bases along with a given order of the elements, even if we have not defined it that way (strictly speaking).

Clearly, if  $(v_1, \dots, v_n)$  is a basis of  $V$ , then the whole space  $V$  is the direct sum of the one-dimensional subspaces

$$V = \text{span}\{v_1\} \oplus \dots \oplus \text{span}\{v_n\}.$$

An immediate corollary of the derived uniqueness of decomposition of any vector  $w$  in  $V$  into the components in the direct sum gives a unique decomposition

$$w = x_1 v_1 + \dots + x_n v_n.$$

This allows us, after choosing a basis, to see the abstract vectors again as  $n$ -tuples of scalars. We shall return to this idea in paragraph 2.3.11, when we finish the discussion of the existence of bases and sums of subspaces in the general case.

**2.3.8. Theorem.** *From any finite set of generators of a vector space  $V$  we can choose a basis. Every basis of a finitely dimensional space  $V$  has the same number of elements.*

**PROOF.** The first claim is easily proved using induction on the number of generators  $k$ .

```
u2=vector(RR, [1, 0, -1, 1])
u3=vector(RR, [2, 1, -1, 3])
u4=vector(RR, [0, 0, 3, 2])
V=RR^4; V.linear_dependence([u1, u2, u3, u4])
```

Sage’s output is True. In case you want to compute only the determinant of  $A$ , then replace the last line by the syntax given here:

```
A=column_matrix([u1, u2, u3, u4])
show(det(A))
```

□

**2.C.II.** Consider the vector space  $V = \mathbb{Q}^4$  and the vectors  $v_1 = (1, 0, 1, 2)^T$  and  $v_2 = (0, 1, 0, 0)^T$ , both lying on  $V$ . What is the dimension of the vector subspace of  $V = \mathbb{Q}^4$ , spanned by  $v_1, v_2$ ? ○

**2.C.I2.** (a) Consider  $\mathbb{Q}^3$  over the rationals and let  $W$  be the subspace of  $\mathbb{Q}^3$  generated by the vectors  $v_1 = (2, -1, 3)^T$  and  $v_2 = (4, 0, 1)^T$ . Determine the expression of a general vector of  $W$  and next use Sage to determine the dimension of  $W$ . What happens if we replace  $v_2$  by a scalar multiple of  $v_1$ ? (b) Consider  $\mathbb{Q}^4$  over the rationals and let  $W$  be the subspace spanned by the vectors  $u_1 = (1, 1, 0, 0)^T$  and  $u_2 = (0, 1, 1, 0)^T$ . Describe the *quotient space*  $V/W$  (i.e., “what is left” in  $V$  viewing vectors “up to  $W$ ”, cf. 3.4.13) and next verify your answer via Sage. ○

**2.C.I3.** For the second task in 2.C.12, find a basis of the quotient space  $V/W$ . Confirm your answer by Sage by using the method `vector` in `subspace`. ○

**2.C.I4.** (a) Show that the following set of vectors is a subspace of  $\mathbb{Z}_5^3$ ,

$$U = \left\{ \begin{pmatrix} a \\ 2b \\ 3a + 4b \end{pmatrix} : a, b \in \mathbb{Z}_5 \right\}.$$

(b) Find the reduced row echelon form of the matrix  $A$  having as columns the generators of  $U$ . Next deduce that  $\dim_{\mathbb{Z}_5} U = 2$  by finding a basis of  $U$ . ○

*We can often rely on Sage to perform mathematical “experiments”. In linear algebra for example, this can be done using matrices or vectors with random coefficients. Notice that such experiments can be useful to test theoretical statements, or illustrate them in a random way. Let us describe such an example.*

**2.C.15.** Provide in Sage a short code that generates a random (ordered) tuple  $S$  of vectors within  $V = \mathbb{Q}^4$ , and checks their linear independence. Moreover, create a random  $4 \times 4$  matrix  $A$  whose columns are the vectors in  $S$ , and use the matrix’s rank to establish an alternative criterium for the linear independence of  $S$  (recall the following basic criterium for the invertibility of a square matrix  $A \in \text{Mat}_n(\mathbb{K})$ :  $A$  is invertible if and only if  $\text{rank}(A) = n$ ).

Only the zero subspace does not need a generator and thus we are able to choose an empty basis. On the other hand, we are not able to choose the zero vector (the generators would then be linearly dependent) and there is nothing else in the subspace.

In order to have our inductive step more natural, we deal with the case  $k = 1$  first. We have  $V = \text{span}\{v\}$  and  $v \neq 0$ , because  $\{v\}$  is a linearly independent set of vectors. Then  $\{v\}$  is also a basis of the vector space  $V$  and any other vector is a multiple of  $v$ , so all bases of  $V$  must contain exactly one vector, which can be chosen from any set of generators.

Assume that the claim holds for  $k = n$  and consider  $V = \text{span}\{v_1, \dots, v_{n+1}\}$ . If  $v_1, \dots, v_{n+1}$  are linearly independent, then they form a basis. If they are linearly dependent, there exists  $i$  such that

$$v_i = a_1 v_1 + \dots + a_{i-1} v_{i-1} + a_{i+1} v_{i+1} + \dots + a_{n+1} v_{n+1}.$$

Then  $V = \text{span}\{v_1, \dots, v_{i-1}, v_{i+1}, \dots, v_{n+1}\}$  and we can choose a basis, using the inductive assumption.

It remains to show that bases always have the same number of elements. Consider a basis  $\underline{v} = (v_1, \dots, v_n)$  of the space  $V$  and for an arbitrary nonzero vector  $u$ , consider

$$u = a_1 v_1 + \dots + a_n v_n \in V$$

with  $a_i \neq 0$  for some  $i$ . Then

$$v_i = \frac{1}{a_i} (u - (a_1 v_1 + \dots + a_{i-1} v_{i-1} + a_{i+1} v_{i+1} + \dots + a_n v_n))$$

and therefore also  $\text{span}\{u, v_1, \dots, v_{i-1}, v_{i+1}, \dots, v_n\} = V$ .

We show that this is again a basis. For if adding  $u$  to the linearly independent vectors  $v_1, \dots, v_{i-1}, v_{i+1}, \dots, v_n$  leads to a set of linearly dependent vectors, then

$$V = \text{span}\{v_1, \dots, v_{i-1}, v_{i+1}, \dots, v_n\},$$

which implies a basis of  $n - 1$  vectors chosen from  $\underline{v}$ , which is not possible.

Thus we have proved that for any nonzero vector  $u \in V$  there exists  $i$ ,  $1 \leq i \leq n$ , such that  $(u, v_1, \dots, v_{i-1}, v_{i+1}, \dots, v_n)$  is again a basis of  $V$ .

Similarly, instead of one vector  $u$ , we can consider a linearly independent set  $u_1, \dots, u_k$ . We will sequentially add  $u_1, u_2, \dots$ , always exchanging for some  $v_i$  using our previous approach. We have to ensure that there always is such  $v_i$  to be replaced (that is, that the vectors  $u_i$  will not consequently replace each other).

Assume thus that we have already placed  $u_1, \dots, u_\ell$  instead of some  $v_j$ ’s. Then the vector  $u_{\ell+1}$  can be expressed as a linear combination of the latter vectors  $u_i$  and the remaining  $v_j$ ’s. As we have seen,  $u_{\ell+1}$  may replace any vector with non-zero coefficient in this linear combination. If only the coefficients at  $u_1, \dots, u_\ell$  were nonzero, then it would mean that the vectors  $u_1, \dots, u_{\ell+1}$  were linearly dependent, which is a contradiction.

Summarizing, for every  $k \leq n$  we can arrive after  $k$  steps at a basis in which  $k$  vectors from the original basis were exchanged for the new  $u_i$ ’s. If  $k > n$ , then in the  $n$ -th step we

**Solution.** To introduce a random vector in Sage we can use the command `V.random_element()`, where  $V$  is the underlying vector space. For instance, the cell

```
V=QQ^4
u=V.random_element(); show(u)
```

prints a random vector of  $\mathbb{Q}^4$ . Any time that the code will be implemented, a new vector will appear in our screen. To construct simultaneously four random vectors lying on  $\mathbb{Q}^4$  and check their linear independence, we can instead type

```
V=QQ^4
S=[V.random_element() for i in range(4)]
show(S); V.linear_dependence(S)==[]
```

which will return an ordered random tuple  $S$  of vectors in  $\mathbb{Q}^4$  and moreover the message “True”, or “False”, depending on the linear independence/dependence of  $S$ . Or type

```
V=QQ^4
S=[V.random_element() for i in range(4)]
W=V.span(S); print(W)
```

In this case, if Sage confirms that  $W$  is a 4-dimensional subspace, then the set  $S$  of four random vectors should be linearly independent. Remarkably, most of the cases Sage returns a linearly independent set, and hence this method can be used when you need to locate many different (ordered) bases of a given vector space. We recommend practicing with further examples in your editor.

Finally, to introduce the required matrix  $A$  and specify a rank-based criterium for linear independence or dependence, you can add the following code in either of the previous two cells:

```
A=column_matrix(S)
if rank(A) < 4 :
    # then linear dependent
        print(False)
else :
    # then linear independent
        print(True)
```

Thus, when  $A$  is of full rank, i.e.,  $\text{rank}(A) = 4$ ,  $S$  will consist of linearly independent vectors, and Sage will type `True`. When  $\text{rank}(A) < 4$ ,  $S$  will consist of linearly dependent vectors, and its message will be `False`.  $\square$

**2.C.16.** Given arbitrary linearly independent vectors  $u, v, w, z$  in a vector space  $V$ , decide whether or not the vectors

$$u - 2v, \quad 3u + w - z, \quad u - 4v + w + 2z, \quad 4v + 8w + 4z$$

are also linearly independent.  $\circ$

**2.C.17.** Determine the coordinates of the vector  $w = (1, 1, 1)^T$  with respect to the following ordered basis of  $\mathbb{R}^3$ :

$$\underline{u} = \{u_1 = (1, 2, 1)^T, u_2 = (-1, 1, 0)^T, u_3 = (0, 1, 1)^T\}.$$

Next, verify your answer in Sage, based for example on the command `coordinates`, or any other method.

would obtain a basis consisting only of new vectors  $u_i$ , which means that the original set could not be linearly independent.

In particular, it is not possible for two bases to have a different number of elements.  $\square$

In fact, we have proved a much stronger claim, the *Steinitz exchange lemma*:

STEINITZ EXCHANGE LEMMA

For every finite basis  $\underline{v}$  of a vector space  $V$  and every set of linearly independent vectors  $u_i, i = 1, \dots, k$  in  $V$  we can find a subset of the basis vectors  $v_j$  which will complete the set of  $u_i$ 's into a new basis.

**2.3.9. Corollaries of the Steinitz lemma.** Because of the

possibility of freely choosing and replacing basis vectors we can immediately derive nice (and intuitively expectable) properties of bases of vector spaces:

**Proposition.** (1) Every two bases of a finite dimensional vector space have the same number of elements, that is, our definition of dimension is basis-independent.

(2) If  $V$  has a finite basis, then every linearly independent set can be extended to a basis.

(3) A basis of a finite dimensional vector space is a maximal linearly independent set of vectors.

(4) The bases of a vector space are the minimal sets of generators.

A little more complicated, but now easy to deal with, is the situation of dimensions of subspaces and their sums:

**Corollary.** Let  $W, W_1, W_2 \subset V$  be subspaces of a space  $V$  of finite dimension. Then

- (1)  $\dim W \leq \dim V$ ,
- (2)  $V = W$  if and only if  $\dim V = \dim W$ ,
- (3)  $\dim W_1 + \dim W_2 = \dim(W_1 + W_2) + \dim(W_1 \cap W_2)$ .

**PROOF.** It remains to prove only the last claim. This is evident if the dimension of one of the spaces is zero. Assume  $\dim W_1 = r \geq 1$ ,  $\dim W_2 = s \geq 1$  and let  $(w_1 \dots, w_t)$  be a basis of  $W_1 \cap W_2$  (or empty set, if the intersection is trivial).

According to the Steinitz exchange lemma this basis of the intersection can be extended to a basis  $(w_1, \dots, w_t, u_{t+1}, \dots, u_r)$  for  $W_1$  and to a basis  $(w_1 \dots, w_t, v_{t+1}, \dots, v_s)$  for  $W_2$ . Vectors

$$w_1, \dots, w_t, u_{t+1}, \dots, u_r, v_{t+1}, \dots, v_s$$

clearly generate  $W_1 + W_2$ . We show that they are linearly independent. Let

$$a_1 w_1 + \dots + a_t w_t + b_{t+1} u_{t+1} + \dots + \dots + b_r u_r + c_{t+1} v_{t+1} + \dots + c_s v_s = 0.$$

**Solution.** When a vector  $u \in \mathbb{R}^n$  is given in coordinates, such as  $w$ , it is always understood to be expressed with respect to the standard basis, unless stated otherwise. The assumption that  $\underline{u}$  is an ordered basis, with a fixed and well defined order as indicated by the relevant positions of the vectors  $u_1, u_2, u_3$ , it is also crucial. To solve the problem we need to determine reals  $a, b$ , and  $c \in \mathbb{R}$ , which satisfy the following matrix equation:

$$a \cdot \begin{pmatrix} 1 \\ 2 \\ 1 \end{pmatrix} + b \cdot \begin{pmatrix} -1 \\ 1 \\ 0 \end{pmatrix} + c \cdot \begin{pmatrix} 0 \\ 1 \\ 1 \end{pmatrix} = \begin{pmatrix} 1 \\ 1 \\ 1 \end{pmatrix}.$$

This is equivalent to  $(a - b, 2a + b + c, a + c)^T = (1, 1, 1)^T$ , which induces the following system of equations:

$$\{a - b = 1, \quad 2a + b + c = 1, \quad a + c = 1\}.$$

It is easy to see that this system has a unique solution, given by  $a = \frac{1}{2}, b = -\frac{1}{2}, c = \frac{1}{2}$ . Thus, the coordinates of  $w$  with respect to  $\underline{u}$  are given by  $(\frac{1}{2}, -\frac{1}{2}, \frac{1}{2})$ .

There are several different methods to demonstrate a verification via Sage. Here we describe two methods. The first method uses the `coordinates` command, which is designed to determine the coordinates of a vector with respect to a given basis. Its implementation goes as follows:

```
V=RR^3
u1=vector([1, 2, 1]); u2=vector([-1, 1, 0])
u3=vector([0, 1, 1]); w=vector([1, 1, 1])
L=[u1, u2, u3]
W=V.subspace_with_basis(L)
cord=W.coordinates(w); show(cord)
sum([cord[i]*L[i] for i in range(3)])==w
```

This cell returns the coefficients of  $w$  with respect to  $\underline{u}$ , along with the message `True`. The latter indicates that the command in the last row verifies the accuracy of the result from `show(cord)` (i.e., Sage is used to verify its own output).

The second method relies on computing the reduced row echelon form of the matrix having as columns the vectors of the given basis, together with  $w$ , and so of the extended matrix corresponding to the linear system posed above. For this, add in the previous cell the code

```
B=column_matrix([u1, u2, u3, w])
B1=B.rref(); show(B1[:, 3])
```

By executing the block, Sage prints out the fourth column of the reduced row echelon form, which indeed consists of the coefficients of  $w$  with respect to the ordered basis  $\underline{u}$ .  $\square$

*So far we have demonstrated a straightforward algorithm to identify a maximal linearly independent set from a given collection of vectors. The steps are as follows:*

- Arrange the given vectors as columns in a matrix.
- Transform the matrix into reduced row echelon form using row operations.
- Identify the vectors corresponding to the pivot columns; these form a maximal linearly independent set.

Then necessarily

$$\begin{aligned} &-(c_{t+1} \cdot v_{t+1} + \dots + c_s \cdot v_s) = \\ &= a_1 \cdot w_1 + \dots + a_t \cdot w_t + b_{t+1} \cdot u_{t+1} + \dots + b_r \cdot u_r \end{aligned}$$

must belong to  $W_2 \cap W_1$ . This implies that

$$b_{t+1} = \dots = b_r = 0,$$

since this is the way we have defined our bases. Then also

$$a_1 \cdot w_1 + \dots + a_t \cdot w_t + c_{t+1} \cdot v_{t+1} + \dots + c_s \cdot v_s = 0$$

and because the corresponding vectors form a basis  $W_2$ , all the coefficients are zero.

The claim (3) now follows by directly counting the generators.  $\square$

**2.3.10. Examples.** (1)  $\mathbb{K}^n$  has (as a vector space over  $\mathbb{K}$ ) dimension  $n$ . The  $n$ -tuple of vectors

$$((1, 0, \dots, 0), (0, 1, \dots, 0), \dots, (0, \dots, 0, 1))$$

is clearly a basis, called the *standard basis* of  $\mathbb{K}^n$ .

Note that in the case of a finite field of scalars, say  $\mathbb{Z}_k$  with  $k$  prime, the whole space  $\mathbb{K}^n$  has only a finite number  $k^n$  of elements.

(2)  $\mathbb{C}$  as a vector space over  $\mathbb{R}$  has dimension 2. A basis is for instance the pair of numbers 1 and  $i$ , or any other two complex numbers which are not a real multiple of each other, eg.  $1 + i$  and  $1 - i$ .

(3)  $\mathbb{K}_m[x]$ , that is, the space of all polynomials with coefficients in  $\mathbb{K}$  of degree at most  $m$ , has dimension  $m + 1$ . A basis is for instance the sequence  $1, x, x^2, \dots, x^m$ .

The vector space of all polynomials  $\mathbb{K}[x]$  has dimension  $\infty$ , but we can still find a basis (although infinite in size):  $1, x, x^2, \dots$ .

(4) The vector space  $\mathbb{R}$  over  $\mathbb{Q}$  has dimension  $\infty$ . It does not have a countable basis.

(5) The vector space of all mappings  $f : \mathbb{R} \rightarrow \mathbb{R}$  has also dimension  $\infty$ . It does not have any countable basis.

**2.3.11. Vector coordinates.** If we fix a basis  $(v_1, \dots, v_n)$  of a finite dimensional space  $V$ , then every vector  $w \in V$  can be expressed as a linear combination  $w = a_1 v_1 + \dots + a_n v_n$  in a unique way. Indeed, assume that we can do it in two ways:

$$w = a_1 v_1 + \dots + a_n v_n = b_1 v_1 + \dots + b_n v_n.$$

Then

$$0 = (a_1 - b_1) \cdot v_1 + \dots + (a_n - b_n) \cdot v_n$$

and thus  $a_i = b_i$  for all  $i = 1, \dots, n$ , because the vectors  $v_i$  are linearly independent. We have reached the concept of coordinates:

This approach is essentially what was utilized in the second method described in 2.C.17. For a theoretical validation and a more in-depth discussion, see the theoretical section 2.3.5.

**2.C.18.** Determine the vector subspace of the Euclidean space  $\mathbb{R}^4$ , generated by the vectors  $u_1 = (-1, 3, -2, 1)^T$ ,  $u_2 = (2, -1, -1, 2)^T$ ,  $u_3 = (-4, 7, -3, 0)^T$ , and  $u_4 = (1, 5, -5, 4)^T$ .

**Solution.** Write the vectors  $u_i$  into the columns of a matrix and transform it using elementary row transformations. This gives

$$\begin{pmatrix} -1 & 2 & -4 & 1 \\ 3 & -1 & 7 & 5 \\ -2 & -1 & -3 & -5 \\ 1 & 2 & 0 & 4 \end{pmatrix} \sim \begin{pmatrix} 1 & 2 & 0 & 4 \\ -1 & 2 & -4 & 1 \\ 3 & -1 & 7 & 5 \\ -2 & -1 & -3 & -5 \end{pmatrix} \\ \sim \begin{pmatrix} 1 & 2 & 0 & 4 \\ 0 & 4 & -4 & 5 \\ 0 & -7 & 7 & -7 \\ 0 & 3 & -3 & 3 \end{pmatrix} \sim \begin{pmatrix} 1 & 2 & 0 & 4 \\ 0 & 1 & -1 & 5/4 \\ 0 & 0 & 0 & -1/4 \\ 0 & 0 & 0 & 0 \end{pmatrix} \\ \sim \begin{pmatrix} 1 & 2 & 0 & 4 \\ 0 & 1 & -1 & 5/4 \\ 0 & 0 & 0 & -1/4 \\ 0 & 0 & 0 & 0 \end{pmatrix} \sim \begin{pmatrix} 1 & 0 & 2 & 0 \\ 0 & 1 & -1 & 0 \\ 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & 0 \end{pmatrix}.$$

Now, according to the algorithm above, a maximal linearly independent set (basis) consists of those vectors corresponding to the columns with the pivots. For our case, the pivots are circled in the reduced row echelon form<sup>8</sup> and hence a maximal linearly independent set consists of the vectors  $u_1$ ,  $u_2$  and  $u_4$ . This means that the vector subspace generated by  $\{u_1, u_2, u_3, u_4\}$  is only 3-dimensional.

Finally, let us verify the output of our algorithm via Sage (where for convenience we view the vectors as elements of  $\mathbb{Q}^4$ ). Let us check first that the given vector are indeed linearly dependent:

```
v1=vector(QQ, [-1, 3, -2, 1])
v2=vector(QQ, [2, -1, -1, 2])
v3=vector(QQ, [-4, 7, -3, 0])
v4=vector(QQ, [1, 5, -5, 4])
V=QQ^4; L=[v1, v2, v3, v4]
V.linear_dependence(L)==[]
```

Next we apply the trick with the pivot elements:

```
M=column_matrix([v1, v2, v3, v4])
M1=M.rref(); show(M1); M.pivots()
```

with the last command returning the desired  $(0, 1, 3)$ . □

**2.C.19.** Derive in Sage a method analogous to the one presented in 2.C.18, with aim to complete the following set of vectors to a basis of the vector space  $\mathbb{Q}^4$ :

$$L = \{v_1 = (2, 0, 1, 0)^T, v_2 = (1, 0, 1, 0)^T\}.$$

<sup>8</sup>We will adopt this tactic especially in Chapter 3.

COORDINATES OF VECTORS

**Definition.** The coefficients of the unique linear combination expressing the given vector  $w \in V$  in the chosen basis  $\underline{v} = (v_1, \dots, v_n)$  are called the *coordinates of the vector  $w$*  in this basis.

Whenever we speak about coordinates  $(a_1, \dots, a_n)$  of a vector  $w$ , which we express as a sequence, we must have a fixed ordering of the basis vectors  $\underline{v} = (v_1, \dots, v_n)$ . Although we have defined the basis as a minimal set of generators, in reality we work with them as with sequences (that is, with completely ordered sets).

ASSIGNING COORDINATES TO VECTORS

A mapping assigning the vector  $v = a_1v_1 + \dots + a_nv_n$  to its coordinates in the basis  $\underline{v}$  will be denoted by the same symbol  $\underline{v} : V \rightarrow \mathbb{K}^n$ . It has the following properties:

- (1)  $\underline{v}(u + w) = \underline{v}(u) + \underline{v}(w); \forall u, w \in V,$
- (2)  $\underline{v}(a \cdot u) = a \cdot \underline{v}(u); \forall a \in \mathbb{K}, \forall u \in V.$

Note that the operations on the two sides of these equations are not identical. Quite the opposite; they are operations on different vector spaces!

Sometimes it is really useful to understand vectors as mappings from fixed set of independent generators to coordinates (without having the generators ordered). In this way, we may think about the basis  $M$  of infinite dimensional vector spaces  $V$ . Even though the set  $M$  will be infinite, there can be only a finite number of non-zero values for any mapping representing a vector. The vector space of all polynomials  $\mathbb{K}_\infty[x]$ , with the basis  $M = \{1, x, x^2, \dots\}$  is a good example.

**2.3.12. Linear mappings.** The above properties of the assignments of coordinates are typical for what we have called linear mappings in the geometry of the plane  $\mathbb{R}^2$ .

For any vector space (of finite or infinite dimension) we define “linearity” of a mapping between spaces in a similar way to the case of the plane  $\mathbb{R}^2$ :

LINEAR MAPPINGS

Let  $V$  and  $W$  be vector spaces over the same field of scalars  $\mathbb{K}$ . The mapping  $f : V \rightarrow W$  is called a *linear mapping*, or *homomorphism*, if the following holds:

- (1)  $f(u + v) = f(u) + f(v), \forall u, v \in V$
- (2)  $f(a \cdot u) = a \cdot f(u), \forall a \in \mathbb{K}, \forall u \in V.$

We have seen such mappings already in the case of matrix multiplication:

$$f : \mathbb{K}^n \rightarrow \mathbb{K}^m, \quad x \mapsto A \cdot x$$

with a fixed matrix  $A$  of the type  $m/n$  over  $\mathbb{K}$ .

Analogously to the abstract definition of vector spaces, it is again necessary to prove seemingly trivial claims that follow from the axioms:

**2.C.20.** Consider the matrix  $A = \begin{pmatrix} 2 & 4 \\ 1 & 3 \\ 0 & 5 \end{pmatrix}$ .

- i) Find the column space  $C(A)$ , the row space  $C(A^T)$ , the kernel  $\text{Ker}(A)$  and the cokernel  $\text{Ker}(A^T)$  of  $A$ .
- ii) Compute the dimensions of these subspaces, using Sage as well. Hint: Use the commands `column_space`, `row_space`, `right_kernel` and `left_kernel`.

**Solution.** (i) The given matrix  $A$  has size  $3 \times 2$  and thus the column space should be a subspace of  $\mathbb{R}^3$ . Let us check the linear independency of the two column vectors of  $A$ . By performing elementary row operations we see that

$$A = \begin{pmatrix} 2 & 4 \\ 1 & 3 \\ 0 & 5 \end{pmatrix} \xrightarrow[R_3 \rightarrow \frac{1}{5}R_3]{R_1 \rightarrow \frac{1}{2}R_1} \begin{pmatrix} 1 & 2 \\ 1 & 3 \\ 0 & 1 \end{pmatrix} \xrightarrow{R_2 \rightarrow R_2 - R_1} \begin{pmatrix} 1 & 2 \\ 0 & 1 \\ 0 & 1 \end{pmatrix} \xrightarrow{R_3 \rightarrow R_3 - R_2} \begin{pmatrix} 1 & 2 \\ 0 & 1 \\ 0 & 0 \end{pmatrix} \xrightarrow{R_1 \rightarrow R_1 - 2R_2} \begin{pmatrix} 1 & 0 \\ 0 & 1 \\ 0 & 0 \end{pmatrix}.$$

Thus  $\text{rank}(A) = 2$  and the column vectors are linearly independent. Hence,  $C(A) = \text{span}\{(2, 1, 0)^T, (4, 3, 5)^T\}$  with  $\dim_{\mathbb{R}} C(A) = 2$ .

By the reduced row echelon form of  $A$  we also deduce that the first two rows of  $A$  are linearly independent. For instance, it is easy to see that the third row is a linear combination of the previous two:  $(0, 5)^T = a(2, 4)^T + b(1, 3)^T$  with  $a = -5/2$  and  $b = 5$ . Thus,  $C(A^T) = \text{span}\{(2, 4)^T, (1, 3)^T\}$  with  $\dim_{\mathbb{R}} C(A^T) = 2$ , as well.

Recall that null spaces are the solution spaces of linear homogeneous systems  $Au = 0$ . For our case, this system has the form

$$\begin{pmatrix} 2 & 4 \\ 1 & 3 \\ 0 & 5 \end{pmatrix} \begin{pmatrix} x_1 \\ x_2 \end{pmatrix} = \begin{pmatrix} 0 \\ 0 \\ 0 \end{pmatrix}$$

and it is easy to see that the unique solution is given by  $x_1 = 0 = x_2$ . Thus,  $\text{Ker}(A)$  is trivial,  $\text{Ker}(A) = \{(0, 0)^T\} \subset \mathbb{R}^2$ . In other words the linear map  $F : \mathbb{R}^2 \rightarrow \mathbb{R}^3$  corresponding to  $A$  is an injection.

On the other hand, the left null space is the kernel of the transpose matrix  $A^T$ . This space consists of vectors  $w = (w_1, w_2, w_3)^T \in \mathbb{R}^3$ , such that  $A^T w = 0$ , i.e.,

$$\begin{pmatrix} 2 & 1 & 0 \\ 4 & 3 & 5 \end{pmatrix} \begin{pmatrix} w_1 \\ w_2 \\ w_3 \end{pmatrix} = \begin{pmatrix} 0 \\ 0 \end{pmatrix}.$$

Solving the corresponding system we obtain  $\text{Ker}(A^T) = \text{span}\{(5, -10, 2)^T\} \subset \mathbb{R}^3$  and hence the cokernel of  $A$  is 1-dimensional.

(ii) In Sage, you can easily execute the commands outlined in the statement as follows:

```
A=matrix([[2, 4], [1, 3], [0, 5]])
rank(A)
print(A.column_space())
print(dim(A.column_space())==rank(A))
print(A.row_space())
```

**Proposition.** Let  $f : V \rightarrow W$  be a linear mapping between two vector spaces over the same field of scalars  $\mathbb{K}$ . The following is true for all vectors  $u, u_1, \dots, u_k \in V$  and scalars  $a_1, \dots, a_k \in \mathbb{K}$

- (1)  $f(0) = 0$ ,
- (2)  $f(-u) = -f(u)$ ,
- (3)  $f(a_1 \cdot u_1 + \dots + a_k \cdot u_k) = a_1 \cdot f(u_1) + \dots + a_k \cdot f(u_k)$ ,
- (4) for every vector subspace  $V_1 \subset V$ , its image  $f(V_1)$  is a vector subspace in  $W$ ,
- (5) for every vector subspace  $W_1 \subset W$ , the set  $f^{-1}(W_1) = \{v \in V; f(v) \in W_1\}$  is a vector subspace in  $V$ .

**PROOF.** We rely on the axioms, definitions and already proved results (in case you are not sure what has been used, look it up!):

$$f(0) = f(u - u) = f((1 - 1) \cdot u) = 0 \cdot f(u) = 0,$$

$$f(-u) = f((-1) \cdot u) = (-1) \cdot f(u) = -f(u).$$

Property (3) is derived easily from the definition for two summands, using induction on the number of summands.

Next, (3) implies  $\text{span } f(V_1) = f(V_1)$ , thus it is a vector subspace. On the other hand, if  $f(u) \in W_1$  and  $f(v) \in W_1$  then for any scalars we arrive at  $f(a \cdot u + b \cdot v) = a \cdot f(u) + b \cdot f(v) \in W_1$ .  $\square$

The *image* of a linear mapping,  $\text{Im } f = f(V) \subset W$ , is always a vector subspace, since for any set of vectors  $u_i$ , the linear combination of images  $f(u_i)$  is the image of the linear combination of the vectors  $u_i$  with the same coefficients.

Analogously, the set of all vectors  $\text{Ker } f = f^{-1}(\{0\}) \subset V$  is a subspace, since the linear combination of zero images will always be a zero vector. The subspace  $\text{Ker } f$  is called the *kernel of the linear mapping*  $f$ .

A linear mapping which is a bijection is called an *isomorphism*.

**2.3.13. Proposition** (Simple corollaries). (1) The composition  $g \circ f : V \rightarrow Z$  of two linear mappings  $f : V \rightarrow W$  and  $g : W \rightarrow Z$  is again a linear mapping.

(2) The linear mapping  $f : V \rightarrow W$  is an isomorphism if and only if  $\text{Im } f = W$  and  $\text{Ker } f = \{0\} \subset V$ . The inverse mapping of an isomorphism is again an isomorphism.

(3) For any two subspaces  $V_1, V_2 \subset V$  and linear mapping  $f : V \rightarrow W$ ,

$$f(V_1 + V_2) = f(V_1) + f(V_2),$$

$$f(V_1 \cap V_2) \subset f(V_1) \cap f(V_2).$$

(4) The “coordinate assignment” mapping  $\underline{u} : V \rightarrow \mathbb{K}^n$  given by an arbitrarily chosen basis  $\underline{u} = (u_1, \dots, u_n)$  of a vector space  $V$  is an isomorphism.

(5) Two finitely dimensional vector spaces are isomorphic if and only if they have the same dimension.

(6) The composition of two isomorphisms is an isomorphism.

```
print(dim(A.row_space())==rank(A))
print(A.right_kernel())
print((A.T).right_kernel())
print(A.left_kernel())
print((A.T).right_kernel()==A.left_kernel())
```

In this block the final line confirms that the command `(A.T).right_kernel()` can be used as an alternative to `A.left_kernel()`.  $\square$

*In linear algebra, there are several classical constructions that generate new vector spaces from existing ones. Examples include intersections, direct sums (see e.g., 2.3.6), and quotients of vector spaces. While intersection means just solving systems of linear equations on coordinates, sums require merging all generators (and leaving only a maximal independent subset). We already touched quotient spaces in 2.C.12, although they are formally introduced in Chapter 3, see 3.4.13. Since we are short in space, we display only a few tasks and further discussion appears later, see also Section E.*

**2.C.21.** In  $\mathbb{R}^4$  consider the three-dimensional linear subspaces  $U = \text{span}\{u_1, u_2, u_3\}$  and  $V = \text{span}\{v_1, v_2, v_3\}$ , where the vectors  $u_i$  and  $v_i$  ( $i = 1, 2, 3$ ) are respectively given by

$$\begin{aligned} u_1 &= (1, 1, 1, 0)^T, & v_1 &= (1, 1, -1, -1)^T, \\ u_2 &= (1, 1, 0, 1)^T, & v_2 &= (1, -1, 1, -1)^T, \\ u_3 &= (1, 0, 1, 1)^T, & v_3 &= (1, -1, -1, 1)^T. \end{aligned}$$

Determine explicitly the subspace  $W := U \cap V$ , and verify your answer via Sage. Moreover, compute  $\dim(W)$  over  $\mathbb{R}$ .

**Solution.** The intersection  $U \cap V$  contains exactly these vectors which are linear combinations of the vectors  $u_i$ , and also linear combinations of the vectors  $v_i$ , for  $i = 1, 2, 3$ . Thus, we search for some  $x_1, x_2, x_3, y_1, y_2, y_3 \in \mathbb{R}$ , satisfying

$$x_1u_1 + x_2u_2 + x_3u_3 = y_1v_1 + y_2v_2 + y_3v_3.$$

This means that we are looking for a solution of the following system of linear equations:

$$\begin{cases} x_1 + x_2 + x_3 = y_1 + y_2 + y_3, \\ x_1 + x_2 = y_1 - y_2 - y_3, \\ x_1 + x_3 = -y_1 + y_2 - y_3, \\ x_2 + x_3 = -y_1 - y_2 + y_3. \end{cases}$$

We convert this to a homogeneous system of linear equations, by moving all variables to the left-hand side. Its matrix reads as

$$A = \begin{pmatrix} 1 & 1 & 1 & -1 & -1 & -1 \\ 1 & 1 & 0 & -1 & 1 & 1 \\ 1 & 0 & 1 & 1 & -1 & 1 \\ 0 & 1 & 1 & 1 & 1 & -1 \end{pmatrix}.$$

Let us now apply row operations to find an echelon form:

$$A \sim \begin{pmatrix} 1 & 1 & 1 & -1 & -1 & -1 \\ 0 & 0 & -1 & 0 & 2 & 2 \\ 0 & -1 & 0 & 2 & 0 & 2 \\ 0 & 1 & 1 & 1 & 1 & -1 \end{pmatrix}$$

**PROOF.** Proving the first claim is a very easy exercise left to the reader. In order to verify (2), notice that  $f$  is surjective if and only if  $\text{Im } f = W$ . If  $\text{Ker } f = \{0\}$  then  $f(u) = f(v)$  ensures  $f(u - v) = 0$ , that is,  $u = v$ . In this case  $f$  is injective. Finally, if  $f$  is a linear bijection, then the vector  $w$  is the preimage of a linear combination  $au + bv$ , that is  $w = f^{-1}(au + bv)$ , if and only if

$$f(w) = au + bv = f(a \cdot f^{-1}(u) + b \cdot f^{-1}(v)).$$

Thus we also get  $w = af^{-1}(u) + bf^{-1}(v)$  and therefore the inversion of a linear bijection is again a linear bijection.

The third property is obvious from the definition, but try finding an example showing that the inequality in the second equation can indeed be sharp.

The remaining claims all follow immediately from the definition.  $\square$

**2.3.14. Coordinates again.** Consider any two vector spaces

$V$  and  $W$  over  $\mathbb{K}$  with  $\dim V = n$ ,  $\dim W = m$  and consider some linear mapping  $f : V \rightarrow W$ . For every choice of basis  $\underline{u} = (u_1, \dots, u_n)$  on  $V$ ,  $\underline{v} = (v_1, \dots, v_m)$  on  $W$  there are the following linear mappings as shown in the diagram:

The bottom arrow  $f_{\underline{u}, \underline{v}}$  is defined by the remaining three, i.e. the composition of linear mappings

$$f_{\underline{u}, \underline{v}} = \underline{v} \circ f \circ \underline{u}^{-1}.$$

#### MATRIX OF A LINEAR MAPPING

Every linear mapping is uniquely determined by its values on an arbitrary set of generators, in particular, on the vectors of a basis  $\underline{u}$ . Denote by

$$f(u_1) = a_{11} \cdot v_1 + a_{21} \cdot v_2 + \dots + a_{m1}v_m$$

$$f(u_2) = a_{12} \cdot v_1 + a_{22} \cdot v_2 + \dots + a_{m2}v_m$$

$\vdots$

$$f(u_n) = a_{1n} \cdot v_1 + a_{2n} \cdot v_2 + \dots + a_{mn}v_m,$$

that is, scalars  $a_{ij}$  form a matrix  $A$ , where the columns are coordinates of the values  $f(u_j)$  of the mapping  $f$  on the basis vectors expressed in the basis  $\underline{v}$  on the target space  $W$ .

A matrix  $A = (a_{ij})$  is called the *matrix of the mapping*  $f$  in the bases  $\underline{u}, \underline{v}$ .

$$\begin{aligned} &\sim \begin{pmatrix} 1 & 1 & 1 & -1 & -1 & -1 \\ 0 & 1 & 1 & 1 & 1 & -1 \\ 0 & 0 & -1 & 0 & 2 & 2 \\ 0 & 0 & 1 & 3 & 1 & 1 \end{pmatrix} \sim \begin{pmatrix} 1 & 1 & 1 & -1 & -1 & -1 \\ 0 & 1 & 1 & 1 & 1 & -1 \\ 0 & 0 & 1 & 0 & -2 & -2 \\ 0 & 0 & 0 & 1 & 1 & 1 \end{pmatrix} \\ &\sim \begin{pmatrix} 1 & 1 & 1 & 0 & 0 & 0 \\ 0 & 1 & 1 & 0 & 0 & -2 \\ 0 & 0 & 1 & 0 & -2 & -2 \\ 0 & 0 & 0 & 1 & 1 & 1 \end{pmatrix} \sim \begin{pmatrix} 1 & 0 & 0 & 0 & 0 & 2 \\ 0 & 1 & 0 & 0 & 2 & 0 \\ 0 & 0 & 1 & 0 & -2 & -2 \\ 0 & 0 & 0 & 1 & 1 & 1 \end{pmatrix}. \end{aligned}$$

The final matrix is in row echelon form and gives that

$$x_1 = -2t, x_2 = -2s, x_3 = 2s + 2t, y_1 = -s - t, y_2 = s, y_3 = t, \quad t, s \in \mathbb{R}.$$

One can verify the previous computation in Sage, by typing

```
A=matrix(QQ, [[1, 1, 1, -1, -1, -1],
              [1, 1, 0, -1, 1, 1],
              [1, 0, 1, 1, -1, 1],
              [0, 1, 1, 1, 1, -1]])
show(A.echelon_form())
```

Hence we can claim that a general vector of  $W$  is written as

$$\begin{pmatrix} x_1 + x_2 + x_3 \\ x_1 + x_2 \\ x_1 + x_3 \\ x_2 + x_3 \end{pmatrix} = \begin{pmatrix} 0 \\ -2t - 2s \\ 2s \\ 2t \end{pmatrix},$$

that is,  $W = \text{span}_{\mathbb{R}}\{(0, -2t-2s, 2s, 2t)^T \mid s, t \in \mathbb{R}\}$ . Obviously,  $W$  is generated by the vectors  $w_1 = (0, -1, 1, 0)^T$  and  $w_2 = (0, -1, 0, 1)^T$  and it is easy to see that they are linearly independent. Thus  $\dim_{\mathbb{R}}(W) = 2$

In Sage we can determine the intersection  $U \cap V$  of two linear subspaces of a given vector space via the command `U.intersection(V)`. For our example, give the cell

```
u1=vector([1, 1, 1, 0])
u2=vector([1, 1, 0, 1])
u3=vector([1, 0, 1, 1])
U=(RR**4).span([u1, u2, u3], QQ)
v1=vector([1, 1, -1, -1])
v2=vector([1, -1, 1, -1])
v3=vector([1, -1, -1, 1])
V=(RR**4).span([v1, v2, v3], QQ)
W=U.intersection(V)
show(W); print(dim(W))
```

**2.C.22.** Referring to the results presented in 2.C.20, demonstrate that for the given matrix  $A$ , the following direct sum decompositions are valid:

$$\mathbb{R}^3 = C(A) \oplus \text{Ker}(A^T), \quad \mathbb{R}^2 = C(A^T) \oplus \text{Ker}(A).$$

**Solution.** In 2.C.20 we obtained the expressions

$$C(A) = \text{span}\{u_1 = (2, 1, 0)^T, u_2 = (4, 3, 5)^T\},$$

$$\text{Ker}(A^T) = \text{span}\{u_3 = (5, -10, 2)^T\}.$$

In particular, we have seen that  $\dim C(A) + \dim \text{Ker}(A^T) = 2 + 1 = 3 = \dim \mathbb{R}^3$ . This, along with the relation

$$C(A) \cap \text{Ker}(A^T) = \{0\}$$

that we are going to prove below, precisely defines the conditions for a direct sum, i.e.,  $\mathbb{R}^3 = C(A) \oplus \text{Ker}(A^T)$ . Hence, suppose that  $v \in C(A) \cap \text{Ker}(A^T)$ . Then, there exists scalars  $a, b, c \in \mathbb{R}$  such that  $v = au_1 + bu_2$  and  $v = cu_3$ , respectively,

For a general vector  $u = x_1u_1 + \dots + x_nu_n \in V$  we calculate (recall that vector addition is commutative and distributive with respect to scalar multiplication)

$$\begin{aligned} f(u) &= x_1f(u_1) + \dots + x_nf(u_n) \\ &= x_1(a_{11}v_1 + \dots + a_{m1}v_m) + \dots + x_n(a_{1n}v_1 + \dots) \\ &= (x_1a_{11} + \dots + x_na_{1n})v_1 + \dots + (x_1a_{m1} + \dots)v_m. \end{aligned}$$

Using matrix multiplication we can now very easily and clearly write down the values of the mapping  $f_{\underline{u}, \underline{v}}(w)$  defined uniquely by the previous diagram. Recall that vectors in  $\mathbb{K}^\ell$  are understood as columns, that is, matrices of the type  $\ell/1$

$$f_{\underline{u}, \underline{v}}(\underline{u}(w)) = \underline{v}(f(w)) = A \cdot \underline{u}(w).$$

On the other hand, if we have fixed bases on  $V$  and  $W$ , then every choice of a matrix  $A$  of the type  $m/n$  gives a unique linear mapping  $\mathbb{K}^n \rightarrow \mathbb{K}^m$  and thus also a mapping  $f : V \rightarrow W$ . We have found the bijective correspondence between matrices of the fixed types (determined by dimensions of  $V$  and  $W$ ) and linear mappings  $V \rightarrow W$ .

**2.3.15. Coordinate transition matrix.** If we choose  $V =$

$W$  to be the same space, but with two different bases  $\underline{u}, \underline{v}$ , and consider the identity mapping for  $f$ , then the approach from the previous paragraph expresses the vectors of the basis  $\underline{u}$  in coordinates with respect to the basis  $\underline{v}$ . Let the resulting matrix be  $T$ .

Thus, we are applying the concept of the matrix of a linear mapping to the special case of the identity mapping  $\text{id}_V$ .

The resulting matrix  $T$  is called the *coordinate transition matrix* for changing the basis from  $\underline{u}$  to the basis  $\underline{v}$ .

The fact that the matrix  $T$  of the identity mapping yields exactly the transformation of coordinates between the two bases is easily seen.

Consider the expression of  $u$  with the basis  $\underline{u}$

$$u = x_1u_1 + \dots + x_nu_n,$$

and replace the vectors  $u_i$  by their expressions as linear combinations of the vectors  $v_i$  in the basis  $\underline{v}$ . Collecting the terms properly, we obtain the coordinate expression  $\bar{x} = (\bar{x}_1, \dots, \bar{x}_n)$  of the same vector  $u$  in the basis  $\underline{v}$ . It is enough just to reorder the summands and express the individual scalars at the vectors of the basis. But this is exactly what we do when forming the matrix for the identity mapping, thus  $\bar{x} = T \cdot x$ .

We have arrived at the following instruction for building the coordinate transition matrix:

and we should have the relation  $au_1 + bu_2 = cu_3$ . This gives the matrix equation

$$a \begin{pmatrix} 2 \\ 1 \\ 0 \end{pmatrix} + b \begin{pmatrix} 4 \\ 3 \\ 5 \end{pmatrix} - c \begin{pmatrix} 5 \\ -10 \\ 2 \end{pmatrix} = \begin{pmatrix} 0 \\ 0 \\ 0 \end{pmatrix}.$$

To solve the corresponding homogeneous system, you can use Sage in the following straightforward manner:

```
var("a, b, c")
eq1=2*a+4*b-5*c; eq2=a+3*b+10*c; eq3=5*b-2*c
solve([eq1==0, eq2==0, eq3==0], a, b, c)
```

Sage's output has the form  $[[a == 0, b == 0, c == 0]]$ , and hence  $v = (0, 0, 0)^T$ , i.e.,  $C(A) \cap \text{Ker}(A^T) = \{0\}$ . This proves the first direct sum decomposition and you are encouraged to prove the second one, which is actually easier.  $\square$

*In Mathematics, the structures are best understood via mappings which preserve them. With vector spaces, these are the linear mappings, cf. 2.3.12. We met already homotheties, rotations, and reflections in Chapter 1.*

By the very definition, a linear mapping  $f : V \rightarrow W$  is uniquely determined by its action on the basis vectors of its domain.<sup>9</sup> This results in the unique matrix representation of  $f$ , once the basis on  $V$  and  $W$  are chosen. Thus, we are back at matrix calculus and composition of mappings is given by products of matrices.

Two special subspaces are associated to a linear map  $f : V \rightarrow W$ , the kernel  $\text{Ker}(f) = f^{-1}(\{0\}) \subset V$  and the image  $\text{Im}(f) = f(V) \subset W$ . Isomorphisms are those  $f$  with trivial kernels  $\text{Ker}(f) = \{0\}$  and images  $\text{Im}(f) = W$ . Hence such mappings are both surjective and injective, and their matrices are invertible. Any transformation of coordinates is such an example.

Although we usually write vectors as columns, in the sequel, we shall often write just  $x = (x_1, \dots, x_n)$  for vectors in  $\mathbb{K}^n$ .

**2.C.23.** Check which of  $F$  is a linear transformation:

- i)  $F : \mathbb{R}^3 \rightarrow \mathbb{R}^2, F((x, y, z)) = (y, z)$ ;
- ii)  $F : \mathbb{R}^3 \rightarrow \mathbb{R}^3, F((x, y, z)) = (x + z, 2x - 3 + z, -2y)$ ;
- iii)  $F : \mathbb{R}^2 \rightarrow \mathbb{R}^2, F((x, y)) = (x + a, y), 0 \neq a \in \mathbb{R}$ ;
- iv)  $F : \mathbb{R} \rightarrow \mathbb{R}, F(x) = x + a$ , where  $a \in \mathbb{R}$ ;
- v)  $F : \mathbb{R}^2 \rightarrow \mathbb{R}^2, F((x, y)) = (x^2, y)$ ;
- vi)  $F : \mathbb{R}^2 \rightarrow \mathbb{R}_1[t], F((x, y)) = y + xt$ ;
- vii)  $F : \text{Mat}_n(\mathbb{R}) \rightarrow \text{Mat}_n(\mathbb{R}), F(A) = AB - BA$ , where  $B \in \text{Mat}_n(\mathbb{R})$  is fixed;
- viii)  $F : \text{Mat}_n(\mathbb{R}) \rightarrow \text{Mat}_n(\mathbb{R}), F(A) = A^T$ ;
- ix)  $F : \mathbb{Z}_3^2 \rightarrow \mathbb{Z}_3^3, F((x, y)) = (x + y, 2x + y, x)$ , where as usual  $\mathbb{Z}_3^n = \mathbb{Z}_3 \times \dots \times \mathbb{Z}_3$  ( $n$ -factors);
- x)  $F : \mathbb{R} \rightarrow \mathbb{R}, F(t) = e^t$ , where  $e$  is the base of the natural logarithm.  $\circ$

<sup>9</sup>Linear mappings  $T : V \rightarrow W$  are also called linear transformations or operators. Linear mappings  $T : V \rightarrow V$  are also called endomorphism of  $V$ .

CALCULATING THE MATRIX FOR CHANGING THE BASIS

**Proposition.** The matrix  $T$  for the transition from the basis  $\underline{u}$  to the basis  $\underline{v}$  is obtained by taking the coordinates of the vectors of the basis  $\underline{u}$  expressed in the basis  $\underline{v}$  and writing them as the columns of the matrix  $T$ . The new coordinates  $\bar{x}$  in terms of the new basis  $\underline{v}$  are then  $\bar{x} = T \cdot x$ , where  $x$  is the coordinate vector in the original basis  $\underline{u}$ .

Because the inverse mapping to the identity mapping is again the identity mapping, the coordinate transition matrix is always invertible and its inverse  $T^{-1}$  is the coordinate transition matrix in the opposite direction, that is from the basis  $\underline{v}$  to the basis  $\underline{u}$  (just have a look at the diagram above and invert all the arrows).

**2.3.16. More coordinates.** Next, we are interested in the matrix of a composition of the linear mappings.

Thus, consider another vector space  $Z$  over  $\mathbb{K}$  of dimension  $k$  with basis  $\underline{w}$ , linear mapping  $g : W \rightarrow Z$  and denote the corresponding matrix by  $g_{\underline{v}, \underline{w}}$ .

The composition  $g \circ f$  on the upper row corresponds to the matrix of the mapping  $\mathbb{K}^n \rightarrow \mathbb{K}^k$  on the bottom and we calculate directly (we write  $A$  for the matrix of  $f$  and  $B$  for the matrix of  $g$  in the chosen bases):

$$\begin{aligned} g_{\underline{v}, \underline{w}} \circ f_{\underline{u}, \underline{v}}(x) &= \underline{w} \circ g \circ \underline{v}^{-1} \circ \underline{v} \circ f \circ \underline{u}^{-1} \\ &= B \cdot (A \cdot x) = (B \cdot A) \cdot x = (g \circ f)_{\underline{u}, \underline{w}}(x) \end{aligned}$$

for every  $x \in \mathbb{K}^n$ . By the associativity of matrix multiplications, the composition of mappings corresponds to multiplication of the corresponding matrices. Note that the isomorphisms correspond exactly to invertible matrices and that the matrix of the inverse mapping is the inverse matrix.

The same approach shows how the matrix of a linear mapping changes, if we change the coordinates on both the domain and the codomain:

where  $T$  is the coordinate transition matrix from  $\underline{u}'$  to  $\underline{u}$  and  $S$  is the coordinate change matrix from  $\underline{v}'$  to  $\underline{v}$ . If  $A$  is the original matrix of the mapping, then the matrix of the new mapping is given by  $A' = S^{-1}AT$ .

In the special case of a linear mapping  $f : V \rightarrow V$ , that is the domain and the codomain are the same space  $V$ , we express  $f$  usually in terms of a single basis  $\underline{u}$  of the space  $V$ . Then the change from the old basis to the new basis  $\underline{u}'$  with

**2.C.24.** Show that the map  $T : \mathbb{R}^2 \rightarrow \mathbb{R}^3$  defined by  $T((x, y)) = (x, y, x - y)$  is a linear transformation. Next, find the matrix  $A$  corresponding to  $T$  with respect to the standard bases of  $\mathbb{R}^2$  and  $\mathbb{R}^3$ , respectively.

**Solution.** Let  $u = (u_1, u_2)^T$  and  $v = (v_1, v_2)^T$  be two arbitrary vectors on  $\mathbb{R}^2$ . Then we see that

$$\begin{aligned} T(au + bv) &= T\left(a\begin{pmatrix} u_1 \\ u_2 \end{pmatrix} + b\begin{pmatrix} v_1 \\ v_2 \end{pmatrix}\right) = \\ T\left(\begin{pmatrix} au_1 + bv_1 \\ au_2 + bv_2 \end{pmatrix}\right) &= \begin{pmatrix} au_1 + bv_1 \\ au_2 + bv_2 \\ au_1 + bv_1 - au_2 - bv_2 \end{pmatrix} = \\ a\begin{pmatrix} u_1 \\ u_2 \\ u_1 - u_2 \end{pmatrix} + b\begin{pmatrix} v_1 \\ v_2 \\ v_1 - v_2 \end{pmatrix} &= aT(u) + bT(v), \end{aligned}$$

for all  $a, b \in \mathbb{R}$ . Thus  $T$  is a linear transformation.

Let  $\underline{e} = \{e_1 = (1, 0)^T, e_2 = (0, 1)^T\}$  be the standard basis of  $\mathbb{R}^2$  and denote by  $\underline{\varepsilon} = \{\varepsilon_1 = (1, 0, 0)^T, \varepsilon_2 = (0, 1, 0)^T, \varepsilon_3 = (0, 0, 1)^T\}$  the standard basis of  $\mathbb{R}^3$ . According to the discussion in 2.3.14, the columns of the matrix  $A = (a_{ij})$  corresponding to  $T$  consist of the coordinates of the values  $T(e_j)$ , for  $j = 1, 2$ , the latter expressed in the basis  $\underline{\varepsilon}$  on the target space  $\mathbb{R}^3$ . We compute

$$\begin{aligned} T(e_1) &= (1, 0, 1)^T = 1 \cdot e_1 + 0 \cdot e_2 + 1 \cdot e_3, \\ T(e_2) &= (0, 1, -1)^T = 0 \cdot e_1 + 1 \cdot e_2 - 1 \cdot e_3, \end{aligned}$$

hence the matrix  $A$  has the form  $A = \begin{pmatrix} 1 & 0 \\ 0 & 1 \\ 1 & -1 \end{pmatrix}$ . As a simple verification, show that

$$T(u) = Au = (x, y, x - y)^T,$$

for all vectors  $u = (x, y) \in \mathbb{R}^2$ . In fact, the matrix presentation  $T(u) = Au$  provides an easier way to verify the linearity of  $T$ . Indeed, assuming that  $a, b, u, v$  are as above we get  $T(au + bv) = A(au + bv) = a(Au) + b(Av) = aT(u) + bT(v)$ .  $\square$

**2.C.25. Remark.** In Sage we can treat linear mappings via

the command `linear_transformation`, see also the task in 2.C.27 for a complementary application. Let us use the linear mapping  $T : \mathbb{R}^2 \rightarrow \mathbb{R}^3$  given in 2.C.24 to illustrate the situation:

```
V=RR^2; W=RR^3
var("x, y"); f(x, y)=[x, y, x-y]
T=linear_transformation(V, W, f)
show(T)
```

Executing this block will display, among other information, the matrix representation of  $T$ , which we present here:

$$\begin{pmatrix} 1.000000000 & 0.000000000 & 1.000000000 \\ 0.000000000 & 1.000000000 & -1.000000000 \end{pmatrix}.$$

Notice this matrix is from the “left”, in terms of Sage, and hence the transpose of the matrix  $A$  presented above.<sup>10</sup> To ensure that Sage will print the correct matrix, add the following code:

<sup>10</sup>This means that  $A$  acts on a vector  $x$  as  $x^T A$ .

the coordinate transition matrix  $T$  leads to the new matrix  $A' = T^{-1}AT$ .

**2.3.17. Linear forms.** A simple but very important case of linear mappings on an arbitrary vector space  $V$  over the scalars  $\mathbb{K}$  appears with the codomain being the scalars themselves, i.e. mappings  $f : V \rightarrow \mathbb{K}$ . We call them *linear forms*.

If we are given the coordinates on  $V$ , the assignments of a single  $i$ -th coordinate to the vectors is an example of a linear form. More precisely, for every choice of basis  $\underline{v} = (v_1, \dots, v_n)$ , there are the linear forms  $v_i^* : V \rightarrow \mathbb{K}$  such that  $v_i^*(v_j) = \delta_{ij}$ , that is,  $v_i^*(v_j) = 1$  when  $i = j$ , and  $v_i^*(v_j) = 0$  when  $i \neq j$ .

The vector space of all linear forms on  $V$  is denoted by  $V^*$  and we call it the *dual space* of the vector space  $V$ . Let us now assume that the vector space  $V$  has finite dimension  $n$ . The basis of  $V^*$ ,  $\underline{v}^* = (v_1^*, \dots, v_n^*)$ , composed of assignments of individual coordinates as above, is called the *dual basis* to  $\underline{v}$ . Clearly this is a basis of the space  $V^*$ , because these forms are evidently linearly independent (prove it!) and if  $\alpha \in V^*$  is an arbitrary form, then for every vector  $u = x_1 v_1 + \dots + x_n v_n$

$$\begin{aligned} \alpha(u) &= x_1 \alpha(v_1) + \dots + x_n \alpha(v_n) \\ &= \alpha(v_1) v_1^*(u) + \dots + \alpha(v_n) v_n^*(u) \end{aligned}$$

and thus the linear form  $\alpha$  is a linear combination of the forms  $v_i^*$ .

Taking into account the standard basis  $\{1\}$  on the one-dimensional space of scalars  $\mathbb{K}$ , any choice of a basis  $\underline{v}$  on  $V$  identifies the linear forms  $\alpha$  with matrices of the type  $1/n$ , that is, with rows  $y$ . The components of these rows are coordinates of the general linear forms  $\alpha$  in the dual basis  $\underline{v}^*$ . Expressing such a form on a vector is then given by multiplying the corresponding row vector  $y$  with the column of the coordinates  $x$  of the vector  $u \in V$  in the basis  $\underline{v}$ :

$$\alpha(u) = y \cdot x = y_1 x_1 + \dots + y_n x_n.$$

Thus we can see that for every finitely dimensional space  $V$ , the dual space  $V^*$  is isomorphic to the space  $V$ . The choice of the dual basis provides such an isomorphism.

In this context we meet again the scalar product of a row of  $n$  scalars with a column of  $n$  scalars. We have worked with it already in the paragraph 2.1.3 on the page 85.

The situation is different for infinitely dimensional spaces. For instance the simplest example of the space of all polynomials  $\mathbb{K}[x]$  in one variable is a vector space with a countable basis with elements  $v_i = x^i$ . As before, we can define linearly independent forms  $v_i^*$ . Every formal infinite sum  $\sum_{i=0}^{\infty} a_i v_i^*$  is now a well-defined linear form on  $\mathbb{K}[x]$ , because it will be evaluated only for a finite linear combination of the basis polynomials  $x^i, i = 0, 1, 2, \dots$

The countable set of all  $v_i^*$  is thus not a basis. Actually, it can be proved that this dual space cannot have a countable basis.

```
A=T.matrix(side="right");show(A)
```

Check yourselves that now Sage prints out the matrix  $A$  posed in 2.C.24.

2.C.26. Let  $T : \mathbb{R}^3 \rightarrow \mathbb{R}^3$  be the linear mapping with type

$$T \left( \begin{pmatrix} x \\ y \\ z \end{pmatrix} \right) = \begin{pmatrix} x + y + z \\ x + y + 2z \\ x + y + 3z \end{pmatrix}.$$

Determine its matrix with respect to the standard basis of  $\mathbb{R}^3$ , and next present an answer via Sage. ○

2.C.27. Consider the matrix  $A = \begin{pmatrix} -1 & 2 & 3 \\ 4 & 2 & 0 \end{pmatrix}$ . Find the value  $f(u)$  of the linear mapping  $f : \mathbb{R}^2 \rightarrow \mathbb{R}^3$  induced by  $A$ , where  $u = (1, 2)^T \in \mathbb{R}^2$ . Next, using Sage, find a basis for the kernel and the image of  $f$ . Is  $f$  injective or surjective?

**Solution.** The function  $f$  has domain  $\mathbb{R}^2$  and target  $\mathbb{R}^3$ , thus its matrix should be  $3 \times 2$ . By our assumption, this means that matrix of  $f$  is the transpose of the given  $A$ . Thus we have

$$f(u) = \begin{pmatrix} -1 & 4 \\ 2 & 2 \\ 3 & 0 \end{pmatrix} \begin{pmatrix} 1 \\ 2 \end{pmatrix} = \begin{pmatrix} 7 \\ 6 \\ 3 \end{pmatrix}.$$

As before, use the command `linear_transformation()` in Sage to verify this result:

```
A = matrix(RR, [[-1, 2, 3], [4, 2, 0]])
f = linear_transformation(A); f
```

This gives:

```
Vector space morphism represented
by the matrix:
[-1.0000000000000000  2.0000000000000000
 3.0000000000000000]
[ 4.0000000000000000  2.0000000000000000
 0.0000000000000000]
Domain: Vector space of dimension 2
over Real Field with 53 bits of precision
Codomain: Vector space of dimension 3
over Real Field with 53 bits of precision
```

We can now evaluate  $f$  at a vector, simply by typing `f([1, 2])`. This prints the vector  $(7, 6, 3)$ . We can also compute the kernel and image of  $f$  by adding the commands

```
f.kernel(); f.image()
```

respectively. For them, the output is

```
Vector space of degree 2 and dimension
0 over Real Field with 53 bits of precision
Basis matrix: []
```

and

```
Vector space of degree 3 and dimension
2 over Rational Field
Basis matrix:
[ 1  0 -3/5]
[ 0  1  6/5]
```

**2.3.18. The length of vectors and scalar product.** When dealing with the geometry of the plane  $\mathbb{R}^2$  in the first chapter we also needed the concept of the length of vectors and their angles, see 1.5.7. For defining these concepts we used the scalar product of two vectors  $u = (x, y)$  and  $v = (x', y')$  in the form  $u \cdot v = xx' + yy'$ .

Indeed, the expression for the length of  $v = (x, y)$  is given by

$$\|v\| = \sqrt{x^2 + y^2} = \sqrt{v \cdot v},$$

while the (oriented) angle  $\varphi$  of two vectors  $u = (x, y)$  and  $v = (x', y')$  is in the planar geometry given by the formula

$$\cos \varphi = \frac{xx' + yy'}{\|v\| \|v'\|}.$$

Note that this scalar product is linear in each of its arguments, and we denote it by  $u \cdot v$  or by  $\langle u, v \rangle$ . The scalar product defined in such a way is symmetric in its arguments and of course  $\|v\| = 0$  if and only if  $v = 0$ . We also see immediately that two vectors in the Euclidean plane are perpendicular whenever their scalar product is zero.

Now we shall mimic this approach for higher dimensions. First, observe that the angle between two vectors is always a two-dimensional concept (we want the angle to be the same in the two-dimensional space containing the two vectors  $u$  and  $v$ ). In the subsequent paragraphs, we shall consider only finitely dimensional vector spaces over real scalars  $\mathbb{R}$ .

#### SCALAR PRODUCT AND ORTHOGONALITY

A *scalar product* on a vector space  $V$  over real numbers is a mapping  $\langle \cdot, \cdot \rangle : V \times V \rightarrow \mathbb{R}$  which is symmetric in its arguments, linear in each of them, and such that  $\langle v, v \rangle \geq 0$  and  $\|v\|^2 = \langle v, v \rangle = 0$  if and only if  $v = 0$ .

The number  $\|v\| = \sqrt{\langle v, v \rangle}$  is called the *length*, or *norm*, of the vector  $v$ .

Vectors  $v$  and  $w \in V$  are called *orthogonal* or *perpendicular* whenever  $\langle v, w \rangle = 0$ . We also write  $v \perp w$ . The vector  $v$  is called *normalised* whenever  $\|v\| = 1$ .

The basis of the space  $V$  composed exclusively of mutually orthogonal vectors is called an *orthogonal basis*. If the vectors in such a basis are all normalised, we call the basis *orthonormal*.

A scalar product is very often denoted by the common dot, that is,  $\langle u, v \rangle = u \cdot v$ . Thus, it is then necessary to recognize from the context whether the dot means a product of two vectors (the result is a scalar) or something different (e.g. we often denote the product of matrices and product of scalars in the same way).

Because the scalar product is linear in each of its arguments, it is completely determined by its values on pairs of basis vectors. Indeed, choose a basis  $\underline{u} = (u_1, \dots, u_n)$  of the space  $V$  and denote

$$s_{ij} = \langle u_i, u_j \rangle.$$

respectively. This means that  $\text{Ker}(f) = \{0\}$ , and so  $f$  is injective, but  $\text{Im}(f)$  is 2-dimensional, with a basis determined by the two vectors that Sage indicates in the solution. Hence  $f$  is not surjective. Note that Sage allows us to directly verify the injectivity and surjectivity of  $f$ , as follows:

```
f.is_injective()
f.is_surjective()
```

Sage's output is True and False, respectively.  $\square$

**2.C.28.** Consider  $\mathbb{R}^3$  endowed with its standard basis  $e = \{e_1, e_2, e_3\}$ , and let  $f : \mathbb{R}^3 \rightarrow \mathbb{R}^3$  be a linear mapping satisfying

$$f(e_1) = (0, 1, 2)^T, f(e_2) = (1, 0, 1)^T, f(e_3) = (-1, 1, 1)^T.$$

- (a) Determine the explicit form of  $f$ ;
- (b) Determine the matrix of  $f$  with respect to the standard basis  $e$ ;
- (c) Present bases of the kernel and the image of  $f$ ;
- (d) Find the inverse  $f^{-1}$ , provided it exists.

**Solution.** (a) By assumption we have  $f(e_1) = (0, 1, 2)^T$ ,  $f(e_2) = (1, 0, 1)^T$  and  $f(e_3) = (-1, 1, 1)^T$ . However, any vector  $u = (x, y, z) \in \mathbb{R}^3$  is written as  $u = x \cdot e_1 + y \cdot e_2 + z \cdot e_3$  (here “ $\cdot$ ” is just the scalar multiplication), and since  $f$  is linear we get

$$f(u) = x \cdot f(e_1) + y \cdot f(e_2) + z \cdot f(e_3) = x \cdot (0, 1, 2)^T + y \cdot (1, 0, 1)^T + z \cdot (-1, 1, 1)^T = (y - z, x + z, 2x + y + z)^T,$$

that is,  $f((x, y, z)) = (y - z, x + z, 2x + y + z)^T$ .

(b) We have that

$$f(e_1) = 0 \cdot e_1 + 1 \cdot e_2 + 2 \cdot e_3, \quad f(e_2) = 1 \cdot e_1 + 0 \cdot e_2 + 1 \cdot e_3, \quad f(e_3) = -1 \cdot e_1 + 1 \cdot e_2 + 1 \cdot e_3.$$

Thus, the matrix of  $f$  with respect to the standard basis on  $\mathbb{R}^3$  is given by

$$A = \begin{pmatrix} 0 & 1 & -1 \\ 1 & 0 & 1 \\ 2 & 1 & 1 \end{pmatrix}.$$

In Sage we can verify this result by executing the block

```
V=WR*RR**3; var("x, y, z")
f(x, y, z)=[y-z, x+z, 2*x+y+z]
T=linear_transformation(V, W, f)
A=T.matrix(side="right"); show(A)
```

As an alternative, compute first the matrix  $A$ , and then determine the explicit form of  $f$  by the rule  $f(u) = Au$ , for all  $u \in \mathbb{R}^3$ .

(c) Let us compute first a basis of the image  $\text{Im}(f)$  of  $f$ . By the relation  $f(u) = x \cdot f(e_1) + y \cdot f(e_2) + z \cdot f(e_3)$  it is obvious that

$$\text{Im}(f) = \text{span}_{\mathbb{R}}\{f(e_1), f(e_2), f(e_3)\} = \{(0, 1, 2)^T, (1, 0, 1)^T, (-1, 1, 1)^T\}.$$

We should now check the linear independence of these vectors. By elementary row operations on the matrix  $A$  presented above, we obtain

Then from the symmetry of the scalar product we know  $s_{ij} = s_{ji}$  and from the linearity of the product in each of its arguments we get

$$\left\langle \sum_i x_i u_i, \sum_j y_j u_j \right\rangle = \sum_{i,j} x_i y_j \langle u_i, u_j \rangle = \sum_{i,j} s_{ij} x_i y_j.$$

If the basis is orthonormal, the matrix  $S$  is the unit matrix. This proves the following useful claim:

SCALAR PRODUCT IN COORDINATES

**Proposition.** For every orthonormal basis, the scalar product is given by the coordinate expression

$$(1) \quad \langle x, y \rangle = y^T \cdot x.$$

For each basis of the space  $V$  there is the symmetric matrix  $S$  such that the coordinate expression of the scalar product is

$$(2) \quad \langle x, y \rangle = y^T \cdot S \cdot x.$$

Notice, that with symmetric matrix  $S$  it is just a matter of convention in which order we insert the vectors: the formula

$$x^T \cdot S \cdot y = (x^T \cdot S \cdot y)^T = y^T \cdot S^T \cdot x = y^T \cdot S \cdot x$$

produces the same value. However, we shall later consider the second argument as a linear form, thus it seems to be more convenient to use the expression  $y^T \cdot S \cdot x$ .

**2.3.19. Orthogonal complements and projections.** For every fixed subspace  $W \subset V$  in a space with scalar product, we define its *orthogonal complement* as

$$W^\perp = \{u \in V; u \perp v \text{ for all } v \in W\}.$$

It follows directly from the definition that  $W^\perp$  is a vector subspace. If  $W \subset V$  has a basis  $(u_1, \dots, u_k)$  then the description for  $W^\perp$  is given as  $k$  homogeneous equations for  $n$  variables. Thus  $W^\perp$  will have dimension at least  $n - k$ . Also  $u \in W \cap W^\perp$  means that  $\langle u, u \rangle = 0$ , and thus also  $u = 0$  by the definition of scalar product. Clearly then,  $V$  is the direct sum

$$V = W \oplus W^\perp.$$

A linear mapping  $f : V \rightarrow V$  on any vector space is called a *projection*, if we have

$$f \circ f = f.$$

In such a case, we can write, for every vector  $v \in V$ ,

$$v = f(v) + (v - f(v)) \in \text{Im}(f) + \text{Ker}(f) = V$$

and if  $v \in \text{Im}(f)$  and  $f(v) = 0$ , then also  $v = 0$ . Thus the above sum of the subspaces is direct. We say that  $f$  is a projection to the subspace  $W = \text{Im}(f)$  along the subspace  $U = \text{Ker}(f)$ . In words, the projection can be described naturally as follows: we decompose the given vector into a component in  $W$  and a component in  $U$ , and forget the second one.

$$A = \begin{pmatrix} 0 & 1 & -1 \\ 1 & 0 & 1 \\ 2 & 1 & 1 \end{pmatrix} \sim \begin{pmatrix} 2 & 1 & 1 \\ 1 & 0 & 1 \\ 0 & 1 & -1 \end{pmatrix} \sim \begin{pmatrix} 2 & 1 & 1 \\ 0 & 1 & -1 \\ 1 & 0 & 1 \end{pmatrix} \sim \begin{pmatrix} 1 & 1 & 0 \\ 0 & 1 & -1 \\ 1 & 0 & 1 \end{pmatrix} \sim \begin{pmatrix} 1 & 0 & 1 \\ 0 & 1 & -1 \\ 0 & 0 & 0 \end{pmatrix}.$$

The final matrix is in reduced row echelon form (recall that a quick computation of RREF in Sage occurs by adding in the previous cell the code `A1 = A.rref(); show(A1)`). Therefore, the pivots are lying on the first two columns (use the command `A.pivots()` to verify this). This means that only the vectors  $f(e_1), f(e_2)$  are linearly independent (in fact it is easy to see that  $f(e_3) = f(e_1) - f(e_2)$ ), and so a basis of  $\text{Im}(f)$  has the form  $\{(0, 1, 2)^T, (1, 0, 1)^T\}$ . Thus  $\dim \text{Im}(f) = 2$ , and in particular  $f$  is not surjective. For the kernel, we should have

$$\dim \mathbb{R}^3 = \dim \text{Ker}(f) + \dim \text{Im}(f)$$

from where we get that  $\dim \text{Ker}(f) = 3 - 2 = 1$ . We may use Sage to find a basis of  $\text{Ker}(f)$ , by one of the commands

```
print(A.right_nullity())
A.right_kernel()
```

The first command prints out the dimension of  $\text{Ker}(A)$ , while the output of the second one includes also a basis,

$$\text{Ker}(A) = \text{span}_{\mathbb{R}} \{(1, -1, -1)^T\}.$$

Of course, this also gives the required basis of  $\text{Ker}(f)$ . Indeed, recall the computation of  $\text{Ker}(f)$  relies on solving the homogeneous system  $Au = 0$ , where  $u = (x, y, z)^T \in \mathbb{R}^3$  is an arbitrary vector on  $\mathbb{R}^3$ . This exploits the identification  $\text{Ker}(A) = \text{Ker}(f)$  and gives

$$\begin{pmatrix} 0 & 1 & -1 \\ 1 & 0 & 1 \\ 2 & 1 & 1 \end{pmatrix} \begin{pmatrix} x \\ y \\ z \end{pmatrix} = \begin{pmatrix} 0 \\ 0 \\ 0 \end{pmatrix},$$

or in other words  $\{y - z = 0, x + z = 0, 2x + y + z = 0\}$ . The next step relies on the reduced row echelon form posed above, which first implies that  $z$  is a free variable, say  $z = t \in \mathbb{R}$ . Then we get  $y = z = t \in \mathbb{R}$  and  $x = -z = -t \in \mathbb{R}$ , that is, there are infinitely many solutions of the form  $t \cdot (-1, 1, 1)^T$ , with  $t \in \mathbb{R}$ . Of course, one can replace  $t$  by  $-t$  to obtain the answer that Sage provides.

(d) The given linear transformation is not injective, since we saw that  $\text{Ker}(f) \neq \{0\}$ . Therefore, the inverse  $f^{-1}$  does not exist.  $\square$

**2.C.29.** Consider the endomorphism  $T : \mathbb{C}^3 \rightarrow \mathbb{C}^3$  with  $T(e_1) = (1, 0, i)^T$ ,  $T(e_2) = (0, 1, 1)^T$ ,  $T(e_3) = (i, 1, 0)^T$ , where  $\{e_1, e_2, e_3\}$  denotes the standard basis of  $\mathbb{C}^3$ . Is  $T$  invertible? Describe a solution using Sage, as well.  $\circ$

**2.C.30.** (a) Consider the complex numbers  $\mathbb{C}$  as a real vector space with its standard basis  $\underline{u} = \{1, i\}$ . In this basis determine the matrix of the following linear mappings:

- 1) conjugation,
- 2) multiplication by the number  $(2 + i)$ .

If  $V$  has a scalar product, we say that the projection is orthogonal if the kernel is orthogonal to the image.

Every subspace  $W \neq V$  thus defines an *orthogonal projection* to  $W$ . It is a projection to  $W$  along  $W^\perp$ , given by the unique decomposition of every vector  $u$  into components  $u_W \in W$  and  $u_{W^\perp} \in W^\perp$ , that is, linear mapping which maps  $u_W + u_{W^\perp}$  to  $u_W$ .

**2.3.20. How to compute projections.** The orthogonal projections  $\text{proj}_v$  to one-dimensional subspaces  $\text{span}\{v\}$  spanned by  $v \in V$  are most simple. Indeed, for any  $u \in V$  we require the projection of  $u$  to be a scalar multiple  $cv$ , such that  $u - cv \perp v$ , i.e.,  $\langle u - cv, v \rangle = 0$  (see part (a) in the figure below). Solving this equation yields the correct value for  $c$  and we deduce

$$\text{proj}_v u = cv = \frac{\langle u, v \rangle}{\langle v, v \rangle} v = \frac{\langle u, v \rangle}{\|v\|^2} v.$$

Consequently, the vector  $u$  decomposes into a pair of orthogonal vectors:  $u = \text{proj}_v u + (u - \text{proj}_v u)$ .

Similarly, for linear subspaces  $W \subset V$  of  $(V, \langle \cdot, \cdot \rangle)$ , there is the direct decomposition  $V = W \oplus W^\perp$  and clearly any vector  $u \in V$  can be uniquely expressed as  $u = w + z$ , where  $w \in W$  and  $z \in W^\perp$ . The vector  $w$  is called the *orthogonal projection of  $u$  in  $W$* , we also write  $\text{proj}_W u$ . The other part of  $u$ , orthogonal to  $W$ , is denoted by  $\text{proj}_{W^\perp} u$  and we have (see part (b) in the figure below):

$$z = \text{proj}_{W^\perp} u = u - \text{proj}_W u.$$

**2.3.21. Existence of orthonormal bases.** It is easy to see that on every finite dimensional real vector space there exist scalar products. Just choose any basis. Define lengths so that each basis vector is of unit length. Call it orthonormal. Immediately we have a scalar product. In this basis the scalar products of vectors are computed as in the formula (1) in the Proposition 2.3.18.

More often we are given a scalar product on a vector space  $V$ , and we want to find an appropriate orthonormal basis for it. We present an algorithm using suitable orthogonal projections in order to transform any basis into an orthogonal one. It is called the *Gramm-Schmidt orthogonalization process*.

The point of this procedure is to transform a given sequence of independent generators  $v_1, \dots, v_k$  of a finite dimensional space  $V$  into an orthogonal set of independent generators of  $V$ .

(b) Determine the matrix of these mappings also in the basis  $\underline{f} = ((1 - i), (1 + i))$ . ○

**2.C.31.** Consider the vector space  $\text{Mat}_{m,n}(\mathbb{K})$  of  $m \times n$  matrices with coefficients in  $\mathbb{K}$ , where  $\mathbb{K}$  is  $\mathbb{R}$  or  $\mathbb{C}$ . Show that  $\dim_{\mathbb{K}} \text{Mat}_{m,n}(\mathbb{K}) = mn$ . Next establish an isomorphism  $\varphi : \text{Mat}_{m,n}(\mathbb{K}) \rightarrow \mathbb{K}^{mn}$ , between  $\text{Mat}_{m,n}(\mathbb{K})$  and  $\mathbb{K}^{mn}$ . ○

**2.C.32.** The vector spaces  $\mathbb{R}_n[x]$  and  $\mathbb{R}^{n+1}$  have the same dimension. Find an isomorphism between them. ○

**2.C.33.** Prove that the vectors

$$u_1 = (1, 2, 0, 0)^T, \quad u_2 = (0, 1, 0, 1)^T, \quad u_3 = (1, 0, 0, 0)^T$$

generate a subspace  $U$  of  $\mathbb{R}^4$  which is isomorphic to  $\mathbb{R}^3$ . Can you find explicitly a linear isomorphism? ○

**2.C.34.** List all subspaces of  $\mathbb{R}^3$ , up to isomorphism. ○

*The simplest linear mappings  $\alpha$  on  $\mathbb{K}^n$  are of the form  $x \mapsto \alpha(x) = c_1x_1 + \dots + c_nx_n \in \mathbb{K}$ , where  $c = (c_1, \dots, c_n)$  is a fixed  $n$ -tuple of scalars from the field  $\mathbb{K}$ , and  $x = (x_1, \dots, x_n)^T \in \mathbb{K}^n$ . Actually, these are all linear mappings  $\mathbb{K}^n \rightarrow \mathbb{K}$ , which can be expressed as  $\alpha(x) = c \cdot x^T$ , through matrix multiplication. Such linear mappings are called linear forms on  $\mathbb{K}^n$ .*

*In fact, any choice of coordinates on a finite-dimensional vector space  $V$  over a field  $\mathbb{K}$ , is actually an  $n$ -tuple of independent linear forms on  $V$ , i.e., linear mappings  $V \rightarrow \mathbb{K}$ . They form the dual vector space  $V^*$  of  $V$ , which is also a vector space over  $\mathbb{K}$ , see 2.3.17. Clearly,  $V$  and  $V^*$  are isomorphic as vector spaces over  $\mathbb{K}$ .*

**2.C.35.** Given the basis  $\underline{u} = \{u_1 = (1, 1)^T, u_2 = (3, 1)^T\}$  of  $\mathbb{R}^2$ , find the dual basis in  $(\mathbb{R}^2)^*$ .

**Solution.** We seek for linear forms  $\varphi_i : \mathbb{R}^2 \rightarrow \mathbb{R}$  satisfying

$$\varphi_1(u_1) = 1, \quad \varphi_1(u_2) = 0, \quad \text{and} \quad \varphi_2(u_1) = 0, \quad \varphi_2(u_2) = 1,$$

respectively. Suppose that  $\varphi_1(x, y) = ax + by$  and  $\varphi_2(x, y) = cx + dy$  for some reals  $a, b, c, d$ . These equations induce the systems  $\{a + b = 1, 3a + b = 0\}$  and  $\{c + d = 0, 3c + d = 1\}$ , respectively. Solving them we deduce that the dual basis to  $\underline{u}$  consists of the linear forms  $\varphi_1(x, y) = -\frac{1}{2}x + \frac{3}{2}y$  and  $\varphi_2(x, y) = \frac{1}{2}x - \frac{1}{2}y$ . □

**2.C.36.** Prove that the set

$$\underline{u} = \{u_1 = (1, 0, 0)^T, u_2 = (0, i, 0)^T, u_3 = (1, 1, i)^T\}$$

is a basis of  $\mathbb{C}^3$ . Next find the dual basis. ○

**2.C.37.** Let  $\{u_1, \dots, u_n\}$  be a basis of a vector space  $V$  over a field  $\mathbb{K}$ , and let  $\{\varphi_1, \dots, \varphi_n\}$  be the dual basis in  $V^*$ . Prove that

(a) Any  $u \in V$  is written as  $u = \sum_{i=1}^n \varphi_i(u)u_i$ .

(b) Any  $\xi \in V^*$  is written as  $\xi = \sum_{i=1}^n \xi(u_i)\varphi_i$ . ○

GRAMM-SCHMIDT ORTHOGONALIZATION

**Proposition.** Let  $(u_1, \dots, u_k)$  be a linearly independent  $k$ -tuple of vectors of a space  $V$  with scalar product. Then there exists an orthogonal system of vectors  $(v_1, \dots, v_k)$  such that  $v_i \in \text{span}\{u_1, \dots, u_i\}$ , and  $\text{span}\{u_1, \dots, u_i\} = \text{span}\{v_1, \dots, v_i\}$ , for all  $i = 1, \dots, k$ . We obtain it by the following procedure:

- The independence of the vectors  $u_i$  ensures that  $u_1 \neq 0$ ; we choose  $v_1 = u_1$ .
- If we have already constructed the vectors  $v_1, \dots, v_\ell$  with the required properties and if  $\ell < k$ , we choose  $v_{\ell+1} = u_{\ell+1} + a_1v_1 + \dots + a_\ell v_\ell$ , where  $a_i = -\frac{\langle u_{\ell+1}, v_i \rangle}{\|v_i\|^2}$ .

**PROOF.** We begin with the first (nonzero) vector  $v_1 = u_1$  and calculate the orthogonal projection  $v_2$  of  $u_2$  to

$$\text{span}\{v_1\}^\perp \subset \text{span}\{v_1, u_2\},$$

i.e., we find the right constant  $a_1$  for which  $v_2 = u_2 + a_1v_1$  is perpendicular to  $v_1$ . The result is nonzero if and only if  $u_2$  is independent of  $v_1$ . All other steps are similar:

In step  $\ell$ ,  $\ell \geq 1$  we seek the vector  $v_{\ell+1} = u_{\ell+1} + a_1v_1 + \dots + a_\ell v_\ell$  satisfying  $\langle v_{\ell+1}, v_i \rangle = 0$  for all  $i = 1, \dots, \ell$ . This implies

$$0 = \langle u_{\ell+1} + a_1v_1 + \dots + a_\ell v_\ell, v_i \rangle = \langle u_{\ell+1}, v_i \rangle + a_i \langle v_i, v_i \rangle$$

and we can see that the vectors with the desired properties are determined uniquely up to a scalar multiple. □

Whenever we have an orthogonal basis of a vector space  $V$ , we just have to normalise the vectors in order to obtain an orthonormal basis. Thus, starting the Gramm-Schmidt orthogonalization with any basis of  $V$ , we have proven:

**Corollary.** On every finite dimensional real vector space with scalar product there exists an orthonormal basis.

In an orthonormal basis, the coordinates and orthogonal projections are very easy to calculate. Indeed, suppose we have an orthonormal basis  $(e_1, \dots, e_n)$  for a space  $V$ . Then every vector  $v = x_1e_1 + \dots + x_n e_n$  satisfies

$$\langle e_i, v \rangle = \langle e_i, x_1e_1 + \dots + x_n e_n \rangle = x_i$$

and so we can always express

$$(1) \quad v = \langle e_1, v \rangle e_1 + \dots + \langle e_n, v \rangle e_n.$$

If we are given a subspace  $W \subset V$  and its orthonormal basis  $(e_1, \dots, e_k)$ , then we can extend it to an orthonormal basis  $(e_1, \dots, e_n)$  for  $V$ . Orthogonal projection of a general vector  $v \in V$  to  $W$  is then given by the expression

$$v \mapsto \langle e_1, v \rangle e_1 + \dots + \langle e_k, v \rangle e_k.$$

In particular, we need only consider an orthonormal basis of the subspace  $W$  in order to write the orthogonal projection to  $W$  explicitly.

Endomorphisms  $F$  on  $V$  are represented by square matrices  $A$  in a given basis. If we leave the choice of the bases free on both domain and target, then we may always achieve the diagonal matrix  $A$  with just ones and zeros on the diagonal, with the rank equal to the dimension of the image, see 2.1.9. But dealing with endomorphisms, we rather want to fix just one basis on  $V$ . Then the available change of the matrix is  $A \mapsto P \cdot A \cdot P^{-1} = B$ , and we call such matrices  $A$  and  $B$  similar. Of course,  $P$  provides the relevant change of basis on  $V$ , see 2.3.16.

Much of our future efforts will aim at understanding linear forms and other concepts within the matrix calculus which are invariant under the above similarity, and thus they reveal properties of the linear mappings themselves. The trace of matrices discussed in the subsequent tasks is an example.

**2.C.38.** Show that the trace  $\text{tr} : \text{Mat}_m(\mathbb{K}) \rightarrow \mathbb{K}$ ,  $\text{tr}(A) = \sum_{i=1}^m a_{ii}$ , is a linear functional, i.e.,  $\text{tr} \in \text{Mat}_m^*(\mathbb{K}) \cong (\mathbb{K}^{m^2})^*$ . Next show that  $\text{tr}(AB) = \text{tr}(BA)$ , for any  $A, B \in \text{Mat}_m(\mathbb{K})$ . Moreover, provide an example verifying that in general  $\text{tr}(AB) \neq \text{tr}(A) \text{tr}(B)$ .  $\circ$

**2.C.39.** Demonstrate with a low-dimensional example that the trace of an endomorphism remains invariant under a change of basis.  $\circ$

**2.C.40.** Prove that if  $A, B$  are two similar square matrices, then  $\text{tr}(A) = \text{tr}(B)$  and  $\det(A) = \det(B)$ . Next decide which of the given pairs of matrices are similar:

(a)  $A = \begin{pmatrix} 1 & -2 \\ 2 & 3 \end{pmatrix}$ ,  $B = \begin{pmatrix} 2 & 2 \\ -1 & 2 \end{pmatrix}$ .

(b)  $A = \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix}$ ,  $B = \begin{pmatrix} \gamma\delta & \delta^2 \\ -\gamma^2 & -\gamma\delta \end{pmatrix}$ ,

where  $\gamma, \delta$  are non-zero real numbers.

(c)  $A = \begin{pmatrix} 2 & 1 \\ 1 & 2 \end{pmatrix}$ ,  $B = \begin{pmatrix} 3 & 0 \\ 0 & 1 \end{pmatrix}$ .  $\circ$

**2.C.41. Transition matrix.** Find the transition matrix from the standard basis  $\underline{e} = \{e_1, e_2, e_3\}$  of  $\mathbb{R}^3$  to the basis

$$\underline{u} = \{u_1 = (1, 1, 3)^T, u_2 = (1, -1, 1)^T, u_3 = (3, 1, 5)^T\}.$$

Next, find the coordinates of the vector  $w = (1, 2, 3)^T \in \mathbb{R}^3$  in the new ordered basis  $\underline{u}$ .

**Solution.** We see that

$$\begin{aligned} u_1 &= e_1 + e_2 + 3e_3, \\ u_2 &= e_1 - e_2 + e_3, \\ u_3 &= 3e_1 + e_2 + 5e_3. \end{aligned}$$

Thus, the transition matrix  $T$  from  $\underline{u}$  to  $\underline{e}$  has as columns exactly the vectors of the basis  $\underline{u}$ :

$$T = \begin{pmatrix} 1 & 1 & 3 \\ 1 & -1 & 1 \\ 3 & 1 & 5 \end{pmatrix}.$$

Note that in general the projection  $f$  to the subspace  $W$  along  $U$  and the projection  $g$  to  $U$  along  $W$  is constrained by the equality  $g = \text{id}_V - f$ . Thus, when dealing with orthogonal projections to a given subspace  $W$ , it is always more efficient to calculate the orthonormal basis of that space  $W$  or  $W^\perp$  whose dimension is smaller.

Note also that the existence of an orthonormal basis guarantees that for every real space  $V$  of dimension  $n$  with a scalar product, there exists a linear mapping which is an isomorphism between  $V$  and the space  $\mathbb{R}^n$  with the standard scalar product (i.e. respecting the scalar products as well). We saw already in Theorem 2.3.18 that the desired isomorphism is exactly the coordinate assignment. In words – in every orthonormal basis the scalar product is computed by the same formula as the standard scalar product in  $\mathbb{R}^n$ .

We shall return to the questions of the length of a vector and to projections in the following chapter in a more general context.

**2.3.22. Angle between two vectors.** As we have already noted, the angle between two linearly independent vectors in the space must be the same as when we consider them in the two-dimensional subspace they generate. Basically, this is the reason why the notion of angle is independent of the dimension of the original space. If we choose an orthogonal basis such that its first two vectors generate the same subspace as the two given vectors  $u$  and  $v$  (whose angle we are measuring), we can simply take the definition from the planar geometry. Independently of the choice of coordinates we can formulate the definition as follows:

ANGLE BETWEEN TWO VECTORS

The angle  $\varphi$  between two vectors  $v$  and  $w$  in a vector space with a scalar product is given by the relation

$$\cos \varphi = \frac{\langle v, w \rangle}{\|v\| \|w\|}.$$

The angle defined in this way does not depend on the order of the vectors  $v, w$  and it is chosen in the interval  $0 \leq \varphi \leq \pi$ .

We shall return to scalar products and angles between vectors in further chapters.

**2.3.23. Multilinear forms.** The scalar product was given as a mapping from the product of two copies of a vector space  $V$  into the space of scalars, which was linear in each of its arguments. Similarly, we will work with mappings from the product of  $k$  copies of a vector space  $V$  into the scalars, which are linear in each of its  $k$  arguments. We speak of  $k$ -linear forms.

Most often we will meet *bilinear forms*, that is, the case  $\alpha : V \times V \rightarrow \mathbb{K}$ , where for any four vectors  $u, v, w, z$  and scalars  $a, b, c$  and  $d$  we have

$$\begin{aligned} \alpha(au + bv, cw + dz) &= ac \alpha(u, w) + ad \alpha(u, z) \\ &\quad + bc \alpha(v, w) + bd \alpha(v, z). \end{aligned}$$

The transition matrix from the  $\underline{e}$  to  $\underline{u}$  is now given by the inverse  $T^{-1}$  of  $T$ , see 2.3.15. By inspection, we compute

$$T^{-1} = \begin{pmatrix} -\frac{3}{2} & -\frac{1}{2} & 1 \\ -\frac{1}{2} & -1 & \frac{1}{2} \\ 1 & \frac{1}{2} & -\frac{1}{2} \end{pmatrix},$$

hence the new coordinates of  $w$  are given by the matrix multiplication

$$T^{-1}w = \begin{pmatrix} -\frac{3}{2} & -\frac{1}{2} & 1 \\ -\frac{1}{2} & -1 & \frac{1}{2} \\ 1 & \frac{1}{2} & -\frac{1}{2} \end{pmatrix} \begin{pmatrix} 1 \\ 2 \\ 3 \end{pmatrix} = \begin{pmatrix} \frac{1}{2} \\ -1 \\ \frac{1}{2} \end{pmatrix}.$$

□

2.C.42. Solve the problem in 2.C.41 using Sage. ○

2.C.43. Consider the following ordered basis  $\underline{u}_1 = \{E_1 = (1, 0, 1)^T, E_2 = (1, 1, 0)^T, E_3 = (0, 1, 1)^T\}$  of  $\mathbb{R}^3$ , and suppose that the transition matrix  $T$  from another ordered basis  $\underline{u}_2$  of  $\mathbb{R}^3$  to  $\underline{u}_1$  is given by

$$T = \begin{pmatrix} 1 & 1 & 1 \\ 1 & 2 & 1 \\ -1 & 1 & 2 \end{pmatrix}.$$

Find the basis  $\underline{u}_2$ . ○

2.C.44. Suppose that a linear mapping  $F : \mathbb{R}^3 \rightarrow \mathbb{R}^3$  has the following matrix (with respect to the standard basis)

$$A = \begin{pmatrix} 1 & -1 & 0 \\ 0 & 1 & 1 \\ 2 & 0 & 0 \end{pmatrix}.$$

Compute the matrix of this mapping in the new basis  $\underline{f} := \{f_1, f_2, f_3\} := \{(1, 1, 0)^T, (-1, 1, 1)^T, (2, 0, 1)^T\}$ . ○

*In applications, we often know the size of vectors, i.e., there is the so-called notion of norm on the vector space. We saw how to deal with this in Chapter 1 already — the norm is usually defined via the scalar product (see 1.E.20). This is closely linked with the concept of angle between vectors, which is a 2-dimensional concept and works in all dimensions, even the infinite ones, without changes.*

*The scalar product allows us to employ orthogonal projections, orthogonal bases, and other important concepts, see the theoretical column for details. In the following section, we shall come to mappings and matrices compatible with scalar products, which leads to the spectral theory discussed properly in the next chapter. Therefore, consider the remainder of this section as a gentle preparation.*

2.C.45. **Remark.** Consider the vectors  $u = (1, 2, 2)^T$  and  $v = (0, 1, -1)^T$  on  $\mathbb{R}^3$ . Then we see that  $u \cdot v = \langle u, v \rangle = 0$ , that is,  $u, v$  are orthogonal. To encode this we often write  $u \perp v$ . As we know by 1.E.20, in Sage to compute the scalar product  $\langle u, v \rangle = \sum_i u_i v_i$ , of two vectors  $u, v \in \mathbb{R}^n$  we use the command `u.dot_product(v)`. For instance, the block

If additionally we always have

$$\alpha(u, w) = \alpha(w, u),$$

then we speak of a *symmetric bilinear form*. If interchanging the arguments leads to a change of sign, we speak of an *antisymmetric bilinear form*.

Already in planar geometry we have defined the determinant as a bilinear antisymmetric form  $\alpha$ , that is,  $\alpha(u, w) = -\alpha(w, u)$ . In general, due to the theorem 2.2.5, we know that the determinant with dimension  $n$  can be seen as an  $n$ -linear antisymmetric form.

As with linear mappings it is clear that every  $k$ -linear form is completely determined by its values on all  $k$ -tuples of basis elements in a fixed basis. In analogy to linear mappings we can see these values as  $k$ -dimensional analogues to matrices. We show this by an example with  $k = 2$ , where it will correspond to matrices as we have defined them.

#### MATRIX OF A BILINEAR FORM

If we choose a basis  $\underline{u}$  on  $V$  and define for a given bilinear form  $\alpha$  scalars  $a_{ij} = \alpha(u_i, u_j)$  then we obtain for vectors  $v, w$  with coordinates  $x$  and  $y$  (as columns of coordinates)

$$\alpha(v, w) = \sum_{i,j=1}^n a_{ij} x_i y_j = y^T \cdot A \cdot x,$$

where  $A$  is a matrix  $A = (a_{ij})$ .

Directly from the definition of the matrix of a bilinear form we see that the form is symmetric or antisymmetric if and only if the corresponding matrix has this property.

Every bilinear form  $\alpha$  on a vector space  $V$  defines a mapping  $V \rightarrow V^*, v \mapsto \alpha(\cdot, v)$ . That is, by placing a fixed vector in the second argument we obtain a linear form which is the image of this vector. If we choose a fixed basis on a finitely dimensional space  $V$  and a dual basis  $V^*$ , then we have the mapping

$$y \mapsto (x \mapsto y^T \cdot A \cdot x).$$

All this is a matter of convention. Also we may fix the first vector and get a linear form again.

## 4. Properties of linear mappings

In order to exploit vector spaces and linear mappings in modelling real processes and systems in other sciences, we need a more detailed analysis of properties of diverse types of linear mappings.

2.4.1. We begin with four examples in the lowest dimension of interest. With the standard basis of the plane  $\mathbb{R}^2$  and with the standard scalar product we consider the following matrices of mappings  $f : \mathbb{R}^2 \rightarrow \mathbb{R}^2$ :

$$A = \begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix}, B = \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix}, C = \begin{pmatrix} a & 0 \\ 0 & b \end{pmatrix}, D = \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix}$$

```
u = vector(RDF, [1, 2, 2])
v = vector(RDF, [0, 1, -1])
u.dot_product(v)
```

returns the result 0.0, and verifies that  $u \perp v$ . We also know how to compute norms of vectors. For instance, for the given  $u, v$ , we can add the code

```
u.norm(); v.norm()
```

returning 3.0 and  $1.4142135 \approx \sqrt{2}$ , respectively.

Scalar products over complex vector spaces will need differnt approach, we come to them in Chapter 3. They are linked to *Hermitian forms* on  $\mathbb{C}^n$ , and are fundamental in quantum computing.

Let us now turn our attention to vectors in our 3-dimensional world. In the solution to the next task we shall see the general concepts and procedures working independent of the (finite) dimensions. One of the main concepts is that of orthogonal projections, see 2.3.20 for instructions how to compute them.

**2.C.46.** Consider the following four vectors in  $\mathbb{R}^3$ :

- i)  $u_1 = (1, 3, \sqrt{2})^T, u_2 = (-1, 1, -\sqrt{2})^T$ ;
- ii)  $v_1 = (0, 1, 2)^T, v_2 = (-1, 2, 3)^T$ ;

Compute their dot products, norms, angles. Check that the product is symmetric, and next use Sage to solve the tasks.

○

**2.C.47.** Given the linear form  $\alpha : \mathbb{R}^3 \rightarrow \mathbb{R}$  with  $\alpha(u) = 4x + 6y - 2z$  for all  $u = (x, y, z)^T \in \mathbb{R}^3$ , determine the unique vector  $v = (a, b, c)^T \in \mathbb{R}^3$  satisfying  $f(u) = \langle u, v \rangle$ , where  $\langle \cdot, \cdot \rangle$  denotes the usual dot product on  $\mathbb{R}^3$ .

**Solution.** This is an application of the fact that the standard basis  $\{e_1, e_2, e_3\}$  of  $\mathbb{R}^3$  is orthonormal with respect to the dot product, i.e.,  $\langle e_i, e_j \rangle = \delta_{i,j}$  for  $1 \leq i, j \leq 3$ . Then, we have

$$v = \sum_{i=1}^3 \langle v, e_i \rangle e_i = \sum_{i=1}^3 \alpha(e_i) e_i,$$

where we have used that  $\langle \cdot, \cdot \rangle$  is symmetric and moreover that  $\alpha(e_i) = \langle e_i, v \rangle$ , for all  $i$ . Since  $\alpha(e_1) = 4, \alpha(e_2) = 6$  and  $\alpha(e_3) = -2$ , we get  $v = 4e_1 + 6e_2 - 2e_3$ , that is  $v = (4, 6, -2)^T \in \mathbb{R}^3$ . Now one can easily verify that  $\alpha(u) = \langle u, v \rangle$  for all  $u \in \mathbb{R}^3$ . □

**2.C.48. Orthogonal projections via Sage.** It is very easy to compute orthogonal projections of vectors in Sage. For instance, suppose that we want to compute the projection of  $u = (1, 2, 4)^T \in \mathbb{R}^3$  onto  $w = (1, -2, 1)^T \in \mathbb{R}^3$ . We have  $\text{proj}_w(u) = \frac{\langle u, w \rangle}{\|w\|^2} w$ , so it is reasonable to type

```
u = vector ([1 , 2 , 4])
w = vector ([1 , -2 , 1])
proj = u.dot_product (w) / (norm (w) ^2) *w
proj
sage: (1/6, -1/3, 1/6)
```

Hence  $\text{proj}_w(u) = (1/6, -1/3, 1/6)^T \in \mathbb{R}^3$ . As a verification we can check that  $\text{proj}_w(u)$  is orthogonal to  $u - \text{proj}_w(u)$ :

The matrix  $A$  describes the orthogonal projection along the subspace

$$W = \{(0, a); a \in \mathbb{R}\} \subset \mathbb{R}^2$$

to the subspace

$$V = \{(a, 0); a \in \mathbb{R}\} \subset \mathbb{R}^2,$$

that is, the projection to the  $x$ -axis along the  $y$ -axis. Evidently for this  $f : \mathbb{R}^2 \rightarrow \mathbb{R}^2$  we have  $f \circ f = f$  and thus the restriction  $f|_V$  of the given mapping on its codomain is the identity mapping. The kernel of  $f$  is exactly the subspace  $W$ .

The matrix  $B$  has the property  $B^2 = 0$ , therefore the same holds for the corresponding mapping  $f$ . We can envision this as the differentiation of polynomials  $\mathbb{R}_1[x]$  of degree at most one in the basis  $(1, x)$  (we shall come to differentiation in chapter five, see 5.1.6).

The matrix  $C$  gives a mapping  $f$ , which rescales the first vector of the basis  $a$ -times, and the second one  $b$ -times. Therefore the whole plane divides into two subspaces, which are preserved under the mapping and where it is only a *homothety*, that is, scaling by a scalar multiple (the first case was a special case with  $a = 1, b = 0$ ). For instance the choice  $a = 1, b = -1$  corresponds to axial symmetry (mirror symmetry) under the  $x$ -axis, which is the same as complex conjugation  $x+iy \mapsto x-iy$  on the two-dimensional real space  $\mathbb{R}^2 \simeq \mathbb{C}$  in basis  $(1, i)$ . This is a linear mapping of the two-dimensional real vector space  $\mathbb{C}$ , but not of the one-dimensional complex space  $\mathbb{C}$ .

The matrix  $D$  is the matrix of rotation by 90 degrees (the angle  $\pi/2$ ) centered at the origin in the standard basis. We can see at first glance that none of the one-dimensional subspaces is preserved under this mapping.

Such a rotation is a bijection of the plane onto itself, therefore we can surely find distinct bases in the domain and codomain, where its matrix will be the unit matrix  $E$ . We simply take any basis of the domain and its image in the codomain. But we are not able to do this with the same basis for both the domain and the codomain.

Consider the matrix  $D$  as a matrix of the mapping  $g : \mathbb{C}^2 \rightarrow \mathbb{C}^2$  with the standard basis of the complex vector space  $\mathbb{C}^2$ . Then we can find vectors  $u = (i, 1), v = (-i, 1)$ , for which we have

$$g(u) = \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix} \cdot \begin{pmatrix} i \\ 1 \end{pmatrix} = \begin{pmatrix} -1 \\ i \end{pmatrix} = i \cdot u,$$

$$g(v) = \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix} \cdot \begin{pmatrix} -i \\ 1 \end{pmatrix} = \begin{pmatrix} -1 \\ -i \end{pmatrix} = -i \cdot v.$$

That means that in the basis  $(u, v)$  on  $\mathbb{C}^2$ , the mapping  $g$  has the matrix

$$K = \begin{pmatrix} i & 0 \\ 0 & -i \end{pmatrix}.$$

Notice that by extending the scalars to  $\mathbb{C}$ , we arrive at an analogy to the matrix  $C$  with diagonal elements  $a = \cos(\frac{1}{2}\pi) + i \sin(\frac{1}{2}\pi)$  and its complex conjugate  $\bar{a}$ . In other words, the

```
proj.dot_product(u-proj)
```

which gives 0.

Recall now that a nice feature of Sage is that we can easily extend its capabilities by introducing new commands. Here will create a function that computes the orthogonal projection of a vector onto another, a procedure which allows us to view (in Sage) the orthogonal projection as a function of two vectors. For this, use the cell

```
def proj (u,w):
    a = u. dot_product (w)/(norm (w)^2)*w
    return(a)
```

which defines the projection of  $u$  onto  $w$ . In such terms, the following cell in Sage gives the same result as above.

```
u1 = vector ([1 , 2 , 4])
u2 = vector ([1 , -2 , 1])
def proj (u,w):
    a = u. dot_product (w)/(norm (w)^2)*w
    return(a)
proj (u1 ,u2)
sage: (1/6, -1/3, 1/6)
```

Try implementing this block on your own. The function defined here will be useful for implementing the Gram-Schmidt procedure, which we are going to describe very soon.

**2.C.49.** Determine the matrix  $A$  which, under the standard basis of  $\mathbb{R}^3$ , gives the orthogonal projection on the vector subspace generated by the vectors  $u_1 = (-1, 1, 0)^T$  and  $u_2 = (-1, 0, 1)^T$ .

**Solution.** First observe that given subspace is a plane containing the origin of  $\mathbb{R}^3$ , with normal vector  $u_3 = (1, 1, 1)^T$ . This is because the ordered triple  $(1, 1, 1)$  is clearly a solution to the system  $\{-x_1 + x_2 = 0, -x_1 + x_3 = 0\}$ , that is, the vector  $u_3$  is perpendicular to the vectors  $u_1, u_2$ . Under the given projection the vectors  $u_1$  and  $u_2$  must map to themselves, and the vector  $u_3$  to the zero vector. Thus, with respect to the basis  $\{u_1, u_2, u_3\}$ , the matrix presentation of the projection is

$$P = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 0 \end{pmatrix}.$$

If the transition matrix from the basis  $\{u_1, u_2, u_3\}$  to the standard basis is denoted by  $T$ , then the transition matrix from the standard basis to  $\{u_1, u_2, u_3\}$  is the inverse  $T^{-1}$ . We compute

$$T = \begin{pmatrix} -1 & -1 & 1 \\ 1 & 0 & 1 \\ 0 & 1 & 1 \end{pmatrix}, \quad T^{-1} = \begin{pmatrix} -\frac{1}{3} & \frac{2}{3} & -\frac{1}{3} \\ -\frac{1}{3} & -\frac{1}{3} & \frac{2}{3} \\ \frac{1}{3} & \frac{1}{3} & \frac{1}{3} \end{pmatrix},$$

and thus we obtain

$$A = TPT^{-1} = \begin{pmatrix} \frac{2}{3} & -\frac{1}{3} & -\frac{1}{3} \\ -\frac{1}{3} & \frac{2}{3} & -\frac{1}{3} \\ -\frac{1}{3} & -\frac{1}{3} & \frac{2}{3} \end{pmatrix}.$$

argument of the number  $a$  in polar form provides the angle of the rotation.

This is easy to understand, if we denote the real and imaginary part of the vector  $u$  as follows

$$u = x_u + iy_u = \operatorname{Re} u + i \operatorname{Im} u = \begin{pmatrix} 0 \\ 1 \end{pmatrix} + i \cdot \begin{pmatrix} 1 \\ 0 \end{pmatrix}.$$

The vector  $v$  is the complex conjugate of  $u$ . We are interested in the restriction of the mapping  $g$  to the real vector subspace  $V = \mathbb{R}^2 \cap \operatorname{span}_{\mathbb{C}}\{u, v\} \subset \mathbb{C}^2$ . Evidently,

$$V = \operatorname{span}_{\mathbb{R}}\{u + \bar{u}, i(u - \bar{u})\} = \operatorname{span}_{\mathbb{R}}\{x_u, -y_u\}$$

is the whole plane  $\mathbb{R}^2$ . The restriction of  $g$  to this plane is exactly the original mapping given by the matrix  $D$  (notice this matrix is real, thus it preserves this real subspace). It is immediately seen that this is the rotation through the angle  $\frac{1}{2}\pi$  in the positive sense with respect to the chosen basis  $x_u, -y_u$ . Work it by yourself with a direct calculation. Note also why exchanging the order of the vectors  $u$  and  $v$  leads to the same result, although in a different real basis!

**2.4.2. Eigenvalues and eigenvectors of mappings.** A key

to the description of mappings in the previous examples was the answer to the question “what are the vectors satisfying the equation  $f(u) = a \cdot u$  for some suitable scalars  $a$ ?”.

We consider this question for any linear mapping  $f : V \rightarrow V$  on a vector space of dimension  $n$  over scalars  $\mathbb{K}$ . If we imagine such an equality written in coordinates, i.e. using the matrix of the mapping  $A$  in some bases, we obtain a system of linear equations

$$A \cdot x - a \cdot x = (A - a \cdot E) \cdot x = 0$$

with an unknown parameter  $a$ . We know already that such a system of equations has only the solution  $x = 0$  if the matrix  $A - aE$  is invertible. Thus we want to find such values  $a \in \mathbb{K}$  for which  $A - aE$  is not invertible, and for that, the necessary and sufficient condition reads (see Theorem 2.2.11)

$$(1) \quad \det(A - a \cdot E) = 0.$$

If we consider  $\lambda = a$  as a variable in the previous scalar equation, we are actually looking for the roots of a polynomial of degree  $n$ . As we have seen in the case of the matrix  $D$ , the roots may exist in an extension of our field of scalars, if they are not in  $\mathbb{K}$ .

EIGENVALUES AND EIGENVECTORS

Scalars  $\lambda \in \mathbb{K}$  satisfying the equation  $f(u) = \lambda \cdot u$  for some nonzero vector  $u \in V$  are called the *eigenvalues of the mapping  $f$* . The corresponding nonzero vectors  $u$  are called the *eigenvectors of the mapping  $f$* .

If  $u, v$  are eigenvectors associated with the same eigenvalue  $\lambda$ , then for every linear combination of  $u$  and  $v$ ,

$$f(au + bv) = af(u) + bf(v) = \lambda(au + bv).$$

Therefore the eigenvectors associated with the same eigenvalue  $\lambda$ , together with the zero vector, form a nontrivial vector

Our choice of basis of a given (finite dimensional) vector space corresponds to a coordinate system on it (we get the basis with fixed ordering of its elements). If the basis  $\underline{u} = \{u_1, \dots, u_m\}$  is orthonormal, i.e.  $\langle u_i, u_j \rangle = \delta_{ij}$ , the Kronecker delta, for all  $i, j$ , then the coordinates are given just by the scalar products, i.e.,  $v = \langle v, u_i \rangle u_i + \dots + \langle v, u_m \rangle u_m$  for all  $v \in V$ . With orthogonal basis, we just request that its elements are mutually perpendicular and in the latter expression, we have to divide the scalar product by the norm of the elements, i.e., the coordinates are  $\frac{\langle v, u_i \rangle}{\|u_i\|}$ .

The figure below compares a general basis and an orthonormal basis in  $\mathbb{R}^2$ . Notice that the formula for the scalar products is the same in all orthonormal bases, just the standard Euclidean dot product, as we know it from the matrix calculus. Orthogonal or orthonormal bases are easily obtained by the Gram-Schmidt procedure, see 2.3.21.

**2.C.50.** (a) Prove that the vectors  $E_1 = (1, 1, 1, 1)^T$ ,  $E_2 = (1, 1, 1, 0)^T$  and  $E_3 = (1, 1, 0, 0)^T$  of  $\mathbb{R}^4$  are linearly independent.

(b) Next find an orthonormal basis of the 3-dimensional space  $W = \text{span}_{\mathbb{R}}\{E_1, E_2, E_3\}$  of  $\mathbb{R}^4$ .

(c) Find the new coordinates of the vector  $w = (4, 4, 2, 1)^T \in W$  with respect to the orthonormal basis that you described in part (b).

**Solution.** (a) We check the linear independence by Sage

```
V = RR^4
E1 = vector(RR, [1, 1, 1, 1])
E2 = vector(RR, [1, 1, 1, 0])
E3 = vector(RR, [1, 1, 0, 0])
V.linear_dependence([E1, E2, E3]) == []
```

Sage's output is indeed True.

(b) Let us apply the Gram-Schmidt method to obtain an orthonormal basis of  $W$ . Set  $w_1 = E_1$  and

$$\begin{aligned} w_2 &= E_2 - \text{proj}_{w_1}(E_2) \\ &= E_2 - \frac{\langle E_2, w_1 \rangle}{\|w_1\|^2} w_1, \\ w_3 &= E_3 - \text{proj}_{w_2}(E_3) - \text{proj}_{w_1}(E_3) \\ &= E_3 - \frac{\langle E_3, w_2 \rangle}{\|w_2\|^2} w_2 - \frac{\langle E_3, w_1 \rangle}{\|w_1\|^2} w_1. \end{aligned}$$

We compute  $\|w_1\|^2 = 4$  and  $\langle E_2, E_1 \rangle = 3$ , hence  $w_2 = (1/4, 1/4, 1/4, -3/4)^T$  with  $\|w_2\|^2 = 3/4$ . We proceed by computing  $\langle E_3, w_2 \rangle = 1/2$ ,  $\langle E_3, w_1 \rangle = 2$  and hence

subspace  $V_\lambda \subset V$ . We call it the *eigenspace associated with*  $\lambda$ . For instance, if  $\lambda = 0$  is an eigenvalue, the kernel  $\text{Ker } f$  is the eigenspace  $V_0$ .

We have seen how to compute the eigenvalues in coordinates. The independence of the eigenvalues from the choice of coordinates is clear from their definition. But let us look explicitly what happens if we change the basis. As a direct corollary of the transformation properties from the paragraph 2.3.16 and the Cauchy theorem 2.2.7 for calculation of the determinant of product, the matrix  $A'$  in the new coordinates will be  $A' = P^{-1}AP$  with an invertible matrix  $P$ . Thus

$$\begin{aligned} |P^{-1}AP - \lambda E| &= |P^{-1}AP - P^{-1}\lambda EP| \\ &= |P^{-1}(A - \lambda E)P| \\ &= |P^{-1}||A - \lambda E||P| \\ &= |A - \lambda E|, \end{aligned}$$

because the scalar multiplication is commutative and we know that  $|P^{-1}| = |P|^{-1}$ .

For these reasons we use the same terminology for matrices and mappings:

CHARACTERISTIC POLYNOMIALS

For a matrix  $A$  of dimension  $n$  over  $\mathbb{K}$  we call the polynomial  $|A - \lambda E| \in \mathbb{K}_n[\lambda]$  the *characteristic polynomial of the matrix*  $A$ .

Roots of this polynomial are the *eigenvalues of the matrix*  $A$ . If  $A$  is the matrix of the mapping  $f : V \rightarrow V$  in a certain basis, then  $|A - \lambda E|$  is also called the *characteristic polynomial of the mapping*  $f$ .

Because the characteristic polynomial of a linear mapping  $f : V \rightarrow V$  is independent of the choice of the basis of  $V$ , the coefficients of individual powers of the variable  $\lambda$  are scalars expressing some properties of  $f$ . In particular, they too cannot depend on the choice of the basis. Suppose  $\dim V = n$  and  $A = (a_{ij})$  is the matrix of the mapping in some basis. Then

$$\begin{aligned} |A - \lambda \cdot E| &= (-1)^n \lambda^n + (-1)^{n-1} (a_{11} + \dots + a_{nn}) \lambda^{n-1} \\ &\quad + \dots + |A| \lambda^0. \end{aligned}$$

The coefficient at the highest power says whether the dimension of the space  $V$  is even or odd.

The most interesting coefficient is the sum of the diagonal elements of the matrix. We have just proved that it does not depend on the choice of the basis and we call it the *trace of the matrix*  $A$  and denote it by  $\text{Tr } A$ . The *trace of the mapping*  $f$  is defined as a trace of the matrix in an arbitrary basis.

In fact, this is not so surprising once we notice that the trace is actually the linear approximation of the determinant in the neighbourhood of the unit matrix in the direction  $A$ . We shall deal with such concepts in Chapter 8 only. But since the determinant is a polynomial, we may see easily that the only terms in  $\det(E + tA)$  which are linear in the real parameter  $t$

$w_3 = (1/3, 1/3, -2/3, 0)^T$ . The orthogonality is verified easily:  $\langle w_1, w_2 \rangle = \langle w_1, w_3 \rangle = \langle w_2, w_3 \rangle = 0$ . We also compute  $\|w_3\|^2 = 2/3$ , hence the orthonormal basis  $\{\hat{w}_i = \frac{w_i}{\|w_i\|} : i = 1, 2, 3\}$  of  $W$  has the explicit form

$$\hat{w}_1 = \begin{pmatrix} 1/2 \\ 1/2 \\ 1/2 \\ 1/2 \end{pmatrix}, \hat{w}_2 = \begin{pmatrix} \sqrt{3}/6 \\ \sqrt{3}/6 \\ \sqrt{3}/6 \\ -\sqrt{3}/2 \end{pmatrix}, \hat{w}_3 = \begin{pmatrix} \sqrt{6}/6 \\ \sqrt{6}/6 \\ -\sqrt{6}/3 \\ 0 \end{pmatrix}.$$

(c) The given vector  $w = (4, 4, 2, 1)^T$  lies on  $W$ , since we have the expression  $w = E_1 + E_2 + 2E_3$ . To find its coordinates with respect to the orthonormal basis  $\{\hat{w}_i : i = 1, 2, 3\}$  of  $W$  constructed above, we apply the formula

$$w = \sum_{i=1}^3 \langle w, \hat{w}_i \rangle \hat{w}_i.$$

We compute  $\langle w, \hat{w}_1 \rangle = 11/2$ ,  $\langle w, \hat{w}_2 \rangle = 7\sqrt{3}/6$  and  $\langle w, \hat{w}_3 \rangle = 2\sqrt{6}/3$ , thus  $w = \frac{11}{2}\hat{w}_1 + \frac{7\sqrt{3}}{6}\hat{w}_2 + \frac{2\sqrt{6}}{3}\hat{w}_3$ . Hence the initial coordinates  $(1, 1, 2)$  of  $w$  with respect to the basis  $\{E_1, E_2, E_3\}$  changed to the new coordinates  $(11/2, 7\sqrt{3}/6, 2\sqrt{6}/3)$  with respect to the basis  $\{\hat{w}_1, \hat{w}_2, \hat{w}_3\}$ .  $\square$

**2.C.51.** Use Sage via the function `proj(v, u)` introduced in 2.C.48 to confirm the expression of the orthonormal basis  $\{\hat{w}_1, \hat{w}_2, \hat{w}_3\}$  presented in 2.C.50.  $\circ$

**2.C.52.** Apply the Gram-Schmidt orthogonalisation process to obtain the orthogonal basis of the linear subspace  $U \subset \mathbb{R}^4$

$$U = \{(x_1, x_2, x_3, x_4)^T \in \mathbb{R}^4; x_1 + x_2 + x_3 + x_4 = 0\} \circ$$

**2.C.53.** Consider the linear mapping  $\varphi : \mathbb{R}^4 \rightarrow \mathbb{R}^4$  whose matrix with respect to the standard basis of  $\mathbb{R}^4$  is given by

$$A = \begin{pmatrix} 1/2 & 2 & -1/2 & -1/2 \\ 1 & 1/2 & 1 & 3/2 \\ 2 & 9/2 & 0 & 1/2 \\ 2 & 2 & 0 & 0 \end{pmatrix}.$$

Find an orthonormal basis of the kernel of  $\varphi$ .  $\circ$

**2.C.54.** Consider the Euclidean space  $\mathbb{R}^4$  with its standard dot product  $\langle \cdot, \cdot \rangle$ . Find a basis of the linear subspace of  $\mathbb{R}^4$  consisting of vectors which are orthogonal to:

- i)  $u = (1, 1, 1, 1)^T \in \mathbb{R}^4$ ;
- ii)  $w = (1, 0, 0, -1)^T$  and  $z = (-1, 0, 1, 0)^T \in \mathbb{R}^4$ .  $\circ$

**2.C.55. Orthogonal complement.** Let  $W$  be the subspace of  $\mathbb{R}^4$  spanned by the vectors  $u_1 = (-1, 1, 3, 0)^T$  and  $u_2 = (0, 0, 0, 1)^T$ . Find the orthogonal complement of  $W$ .

**Solution.** Any vector  $x \in W$  is written as  $x = au_1 + bu_2 = (-a, a, 3a, b)^T$  for some  $a, b \in \mathbb{R}$ . Vectors  $y \in W^\perp$  should satisfy  $x \cdot y = 0$ , i.e.,  $-ay_1 + ay_2 + 3ay_3 + by_4 = 0$ , for any  $a, b \in \mathbb{R}$ . For  $a = 1, b = 0$  (this corresponds to the condition  $u_1 \cdot y = 0$ ) and  $a = 0, b = 1$  (this corresponds to the condition  $u_2 \cdot y = 0$ ) we obtain the following system of equations:  $\{-y_1 + y_2 + 3y_3 = 0, y_4 = 0\}$ . Viewing  $y_2 = c \in \mathbb{R}$  and  $y_3 = d \in \mathbb{R}$  as free variables, we obtain the solution

are just the trace. We shall see relation to matrix exponential later in Chapter 8.

The coefficient at  $\lambda^0$  is the determinant  $|A|$  and we shall see later that it describes the rescaling of volumes by the mapping.

**2.4.3. Basis of eigenvectors.** We discuss a few important properties of eigenspaces now.

**Theorem.** *Eigenvectors of linear mappings  $f : V \rightarrow V$  associated to different eigenvalues are linearly independent.*

**PROOF.** Let  $a_1, \dots, a_k$  be distinct eigenvalues of the mapping  $f$  and  $u_1, \dots, u_k$  eigenvectors with these eigenvalues. The proof is by induction on the number of linearly independent vectors among the chosen ones.

Assume that  $u_1, \dots, u_\ell$  are linearly independent and  $u_{\ell+1} = \sum_i c_i u_i$  is their linear combination. We can choose  $\ell = 1$ , because the eigenvectors are nonzero. But then  $f(u_{\ell+1}) = a_{\ell+1} \cdot u_{\ell+1} = \sum_{i=1}^\ell a_{\ell+1} \cdot c_i \cdot u_i$ , that is,

$$f(u_{\ell+1}) = \sum_{i=1}^\ell a_{\ell+1} \cdot c_i \cdot u_i = \sum_{i=1}^\ell c_i \cdot f(u_i) = \sum_{i=1}^\ell c_i \cdot a_i \cdot u_i.$$

By subtracting the second and the fourth expression in the equalities we obtain  $0 = \sum_{i=1}^\ell (a_{\ell+1} - a_i) \cdot c_i \cdot u_i$ . All the differences between the eigenvalues are nonzero and at least one coefficient  $c_i$  is nonzero. This is a contradiction with the assumed linear independence  $u_1, \dots, u_\ell$ , therefore also the vector  $u_{\ell+1}$  must be linearly independent of the others.  $\square$

The latter theorem can be seen as a decomposition of a linear mapping  $f$  into a sum of much simpler mappings. If there are  $n = \dim V$  distinct eigenvalues  $\lambda_i$ , we obtain the entire  $V$  as a direct sum of one-dimensional eigenspaces  $V_{\lambda_i}$ . Each of them then describes a projection on this invariant one-dimensional subspace, where the mapping is given just as multiplication by the eigenvalue  $\lambda_i$ .

Furthermore, this decomposition can be easily calculated:

$(c + 3d, c, d, 0)$ . It follows that  $W^\perp = \text{span}_{\mathbb{R}}\{w_1, w_2\}$ , where the vectors  $w_1, w_2$  are given by  $w_1 = (1, 1, 0, 0)^T$  and  $w_2 = (3, 0, 1, 0)^T$ , respectively.  $\square$

**2.C.56.** Given the dot products on  $\mathbb{R}^m$  and  $\mathbb{R}^n$ , prove that for any  $m \times n$  real matrix  $A$  the column space  $C(A)$  is orthogonal to the left null space  $\text{Ker}(A^T)$  and the row space  $C(A^T)$  is orthogonal to the kernel  $\text{Ker}(A)$  of  $A$ . Next illustrate these statements using the matrix  $A$  described in 2.C.20.  $\circ$

**D. Properties of linear mappings**

A central attention in numerical matrix calculus is devoted to the simplest possible representation of linear mappings, i.e., the optimal choice of coordinates allowing to understand the mappings best. The most perfect understanding of  $f : V \rightarrow V$  comes if we have the mapping represented by a diagonal matrix. This leads to the concepts of “eigenvectors” and “eigenvalues” of  $f$ .

Thus, an eigenvector of an  $n \times n$  matrix  $A$  is a non-trivial solution  $x$  to the equation  $Ax = \lambda x$  with an unknown scalar  $\lambda$ . Obviously, this homogeneous system of equations has got a non-trivial solution if and only if  $\lambda$  is a root of the characteristic polynomial  $\chi_A(\lambda) := \det(A - \lambda E)$ , where  $E$  is the  $n \times n$  identity matrix. We talk about eigenvalues of  $A$ , they may come with multiplicities, and the spectrum of  $A$  consists of the eigenvalues of  $A$ , including their multiplicities (called algebraic multiplicities).

By the very definition, all this corresponds to  $f(u) = \lambda u$ , i.e., these concepts are independent of the choice of coordinates. If we find enough eigenvalues and eigenvectors, the mapping  $f$  enjoys a diagonal matrix!

This may fail for two reasons: the polynomial might not have enough roots in the chosen field  $\mathbb{K}$ , or the number of independent eigenvectors to a given eigenvalue  $\lambda$  might be smaller than the algebraic multiplicity of  $\lambda$ , i.e., the dimension of the eigen-space  $V_\lambda$  spanned by all such eigenvectors is too small (we call it the geometric multiplicity). We met both examples in the first chapter in the plane (rotations and derivatives of first order polynomials, see also the task presented in 2.E.57).

**2.D.1. Eigenvalues and eigenvectors.** Find the eigenvalues and the eigenvectors of the matrix

$$A = \begin{pmatrix} -1 & 1 & 0 \\ -1 & 3 & 0 \\ 2 & -2 & 2 \end{pmatrix}.$$

**Solution.** We begin with the characteristic polynomial of  $A$ :

$$\chi_A(\lambda) = \begin{vmatrix} -1 - \lambda & 1 & 0 \\ -1 & 3 - \lambda & 0 \\ 2 & -2 & 2 - \lambda \end{vmatrix} = \lambda^3 - 4\lambda^2 + 2\lambda + 4.$$

The eigenvalues of  $A$  are the roots of  $\chi_A(\lambda)$ . Using for example the Horner’s scheme presented in Chapter 1, we compute

BASIS OF EIGENVECTORS

**Corollary.** If there exist  $n$  mutually distinct roots  $\lambda_i$  of the characteristic polynomial of the mapping  $f : V \rightarrow V$  on the  $n$ -dimensional space  $V$ , then there exists a decomposition of  $V$  into a direct sum of eigenspaces each of dimension one. This means that there exists a basis for  $V$  consisting only of eigenvectors and in this basis the matrix for  $f$  is the diagonal matrix with the eigenvalues on the diagonal. This basis is uniquely determined up to the order of the elements and scale of the vectors.

The corresponding basis (expressed in the coordinates in an arbitrary basis of  $V$ ) is obtained by solving  $n$  systems of homogeneous linear equations of  $n$  variables with matrices  $(A - \lambda_i \cdot E)$ , where  $A$  is the matrix of  $f$  in a chosen basis.

**2.4.4. Invariant subspaces.** We have seen that every eigenvector  $v$  of the mapping  $f : V \rightarrow V$  generates a subspace  $\text{span}\{v\} \subset V$ , which is preserved by the mapping  $f$ .

More generally, we say that a vector subspace  $W \subset V$  is an invariant subspace for a linear mapping  $f$ , if  $f(W) \subset W$ .

If  $V$  is a finite dimensional vector space and we choose some basis  $(u_1, \dots, u_k)$  of a subspace  $W$ , we can always extend it to a basis  $(u_1, \dots, u_k, u_{k+1}, \dots, u_n)$  for the whole space  $V$ . For every such basis,  $f(W) \subset W$  implies the mapping  $f$  will have the matrix  $A$  of the form

$$(1) \quad A = \begin{pmatrix} B & C \\ 0 & D \end{pmatrix}$$

where  $B$  is a square matrix of dimension  $k$ ,  $D$  is a square matrix of dimension  $n - k$  and  $C$  is a matrix of the type  $n/(n - k)$ . On the other hand, if for some basis  $(u_1, \dots, u_n)$  the matrix of the mapping  $f$  is of the form (1), then  $W = \text{span}\{u_1, \dots, u_k\}$  is invariant under the mapping  $f$ .

By the same arguments, the mapping with the matrix  $A$  as in (1) leaves the subspace  $\text{span}\{u_{k+1}, \dots, u_n\}$  invariant, if and only if the submatrix  $C$  is zero.

From this point of view the eigenspaces of the mapping are special cases of invariant subspaces. Our next task is to find some conditions under which there are invariant complements of invariant subspaces.

**2.4.5.** We illustrate some typical properties of mappings on the spaces  $\mathbb{R}^3$  and  $\mathbb{R}^2$  in terms of eigenvalues and eigenvectors.

(1) Consider the mapping given in the standard basis by the matrix  $A$

$$f : \mathbb{R}^3 \rightarrow \mathbb{R}^3, A = \begin{pmatrix} 0 & 0 & 1 \\ 0 & 1 & 0 \\ 1 & 0 & 0 \end{pmatrix}.$$

$\lambda_1 = 2$ ,  $\lambda_{\pm} = 1 \pm \sqrt{3}$ , all with multiplicity one<sup>11</sup> Hence the algebraic multiplicities of  $\lambda_1$  and  $\lambda_{\pm}$  are all one. It follows that each has a 1-dimensional eigenspace, i.e., the geometric multiplicity of each eigenvalue is also one (see 3.4.10).

The eigenvector associated to  $\lambda_1$  is determined by solving the matrix equation  $(A - \lambda_1 E)x = 0$ , with  $x = (x_1, x_2, x_3)^T \in \mathbb{R}^3$ . This reduces to the system

$$\{-3x_1 + x_2 = 0, -x_1 + x_2 = 0, x_1 - x_2 = 0\}$$

and in order to find a solution we may apply what we learned in Section A. We see that  $x_3$  is a free variable,  $x_3 \in \mathbb{R}$ , and the rest two variables must satisfy  $x_1 = x_2 = 0$ .<sup>12</sup> Thus, the eigenvector associated to  $\lambda_1$  is the vector  $u_1 := (0, 0, 1)^T$  (or any multiple of it), and in particular  $V_{\lambda_1}$  is 1-dimensional (spanned by  $u_1$ ).

Similarly, the eigenvector corresponding to  $\lambda_+ = 1 + \sqrt{3}$  arises by solving the matrix equation  $(A - \lambda_+ E)x = 0$ . This gives the system

$$\begin{cases} -(2 + \sqrt{3})x_1 + x_2 = 0, \\ -x_1 + (2 - \sqrt{3})x_2 = 0, \\ 2x_1 - 2x_2 + (1 - \sqrt{3})x_3 = 0, \end{cases}$$

whose solution has the form  $\{(2 - \sqrt{3}, 1, -2)t : t \in \mathbb{R}\}$ . This implies that the eigenspace  $V_{\lambda_+}$  corresponding to  $\lambda_+$  is also 1-dimensional, as well:

$$V_{\lambda_+} = \text{span}_{\mathbb{R}} \left\{ (2 - \sqrt{3}, 1, -2)^T \right\}.$$

In an analogous way we obtain that the eigenspace associated to the third eigenvalue  $\lambda_-$  is 1-dimensional,

$$V_{\lambda_-} = \text{span}_{\mathbb{R}} \left\{ (2 + \sqrt{3}, 1, -2)^T \right\}. \quad \square$$

**2.D.2. Eigentheory via Sage.** In Sage, given a squared matrix it is easy to compute its eigenvalues and eigenvectors. Let us use the matrix  $A$  from the previous task to illustrate the situation. To introduce the characteristic polynomial and find its roots, we can type

```
A=matrix(SR, [[-1, 1, 0], [-1, 3, 0],
[2, -2, 2]])
p(t) = A.characteristic_polynomial(t)
show(p(t)); show(p.roots())
```

The output here is the characteristic polynomial (with respect to the variable  $t$ ), i.e.,  $t^3 - 4t^2 + 2t + 4$ , and its roots, presented in a list as follows:

$$\left[ (-\sqrt{3} + 1, 1), (\sqrt{3} + 1, 1), (2, 1) \right].$$

<sup>11</sup>Use also Sage to solve the equation  $\chi_A(\lambda) = 0$ , and then read below for a variety of techniques in Sage for finding the eigenvalues of a given matrix  $A$ .

<sup>12</sup>Although this case is extremely easy and the fact that  $x_3$  is a free variable is obvious (as the solution), recall that a good technique solving the homogeneous system  $(A - \lambda E)x = 0$ , where  $\lambda$  is an eigenvalue of  $A$ , relies on the description of the reduced row echelon form corresponding to the matrix  $A - \lambda E$ , especially when  $A$  is a  $n \times n$  matrix with large  $n$ .

We compute

$$|A - \lambda E| = \begin{vmatrix} -\lambda & 0 & 1 \\ 0 & 1 - \lambda & 0 \\ 1 & 0 & -\lambda \end{vmatrix} = -\lambda^3 + \lambda^2 + \lambda - 1,$$

with roots  $\lambda_1 = 1, \lambda_2 = 1, \lambda_3 = -1$ . The eigenvectors with eigenvalue  $\lambda = 1$  can be computed:

$$\begin{pmatrix} -1 & 0 & 1 \\ 0 & 0 & 0 \\ 1 & 0 & -1 \end{pmatrix} \sim \begin{pmatrix} 1 & 0 & -1 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix};$$

with the basis of the space of solutions, that is, of all eigenvectors with this eigenvalue

$$u_1 = (0, 1, 0), \quad u_2 = (1, 0, 1).$$

Similarly for  $\lambda = -1$  we obtain the third independent eigenvector

$$\begin{pmatrix} 1 & 0 & 1 \\ 0 & 2 & 0 \\ 1 & 0 & 1 \end{pmatrix} \sim \begin{pmatrix} 1 & 0 & 1 \\ 0 & 2 & 0 \\ 0 & 0 & 0 \end{pmatrix} \Rightarrow u_3 = (-1, 0, 1).$$

Under the basis  $u_1, u_2, u_3$  (note that  $u_3$  must be linearly independent of the remaining two because of the previous theorem and  $u_1, u_2$  were obtained as two independent solutions)  $f$  has the diagonal matrix

$$A = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & -1 \end{pmatrix}.$$

The whole space  $\mathbb{R}^3$  is a direct sum of eigenspaces,  $\mathbb{R}^3 = V_1 \oplus V_2$ , with  $\dim V_1 = 2$ , and  $\dim V_2 = 1$ . This decomposition is uniquely determined and says much about the geometric properties of the mapping  $f$ . The eigenspace  $V_1$  is furthermore a direct sum of one-dimensional eigenspaces, which can be selected in other ways (thus such a decomposition has no further geometrical meaning).

(2) Consider the linear mapping  $f : \mathbb{R}_2[x] \rightarrow \mathbb{R}_2[x]$  defined by polynomial differentiation, that is,  $f(1) = 0$ ,  $f(x) = 1$ ,  $f(x^2) = 2x$ . The mapping  $f$  thus has in the usual basis  $(1, x, x^2)$  the matrix

$$A = \begin{pmatrix} 0 & 1 & 0 \\ 0 & 0 & 2 \\ 0 & 0 & 0 \end{pmatrix}.$$

The characteristic polynomial is  $|A - \lambda \cdot E| = -\lambda^3$ , thus it has only one eigenvalue,  $\lambda = 0$ . We compute the eigenvectors:

$$\begin{pmatrix} 0 & 1 & 0 \\ 0 & 0 & 2 \\ 0 & 0 & 0 \end{pmatrix} \sim \begin{pmatrix} 0 & 1 & 0 \\ 0 & 0 & 1 \\ 0 & 0 & 0 \end{pmatrix}.$$

The space of the eigenvectors is thus one-dimensional, generated by the constant polynomial 1.

The striking property of this mapping is that there is no basis for which the matrix would be diagonal. There is the ‘‘chain’’ of vectors mapping the independent generators as follows:  $\frac{1}{2}x^2 \mapsto x \mapsto 1 \mapsto 0$ . This builds a sequence of invariant subspaces without invariant complements.

In case we simply type `A.characteristic_polynomial()`, then Sage returns the characteristic polynomial as a polynomial with respect to the variable  $x$ . The previous list indicates the three eigenvalues of  $A$ , together with their algebraic multiplicity. Of course, one can proceed in a more elementary way, e.g., by the block

```
A=matrix(SR, [[-1, 1, 0], [-1, 3, 0], [2, -2, 2]])
E=identity_matrix(3)
var("c"); ch(c)=det(A-c*E)
ch.factor(); show(ch.roots())
```

Another alternative to compute the eigenvalues of  $A$  has the form

```
A=matrix(SR, [[-1, 1, 0], [-1, 3, 0], [2, -2, 2]])
eigen=A.eigenvalues()
show(eigen)
```

In this case, Sage's output looks like as  $[-\sqrt{3}+1, \sqrt{3}+1, 2]$ , so the command `A.eigenvalues()` computes only the eigenvalues, without their algebraic multiplicities. As for the eigenvectors, add in some of the previous cells the code

```
A.eigenvectors_right()
```

Here Sage prints out the eigenvectors of  $A$ , together with the corresponding eigenvalues and algebraic multiplicities.

**2.D.3.** Find bases of the eigenspaces of the matrix

$$A = \begin{pmatrix} 0 & 1 & 1 \\ 1 & 0 & 1 \\ 1 & 1 & 0 \end{pmatrix}.$$

**Solution.** We first compute the determinant  $\det(A - \lambda E)$ :

$$\begin{vmatrix} -\lambda & 1 & 1 \\ 1 & -\lambda & 1 \\ 1 & 1 & -\lambda \end{vmatrix} = -\lambda \begin{vmatrix} -\lambda & 1 \\ 1 & -\lambda \end{vmatrix} - 1 \begin{vmatrix} 1 & 1 \\ 1 & -\lambda \end{vmatrix} + 1 \begin{vmatrix} 1 & -\lambda \\ 1 & 1 \end{vmatrix}$$

and hence the characteristic polynomial is given by  $\chi_A(\lambda) = -\lambda^3 + 3\lambda + 2$ . With the same method applied in 2.D.1, we see that  $\chi_A(\lambda) = -(\lambda + 1)^2(\lambda - 2)$ , hence  $\lambda_1 = -1$  is a double root, while the other root is given by  $\lambda_2 = 2$ . These are the eigenvalues of  $A$ , with algebraic multiplicities two and one, respectively. Let us describe the associated eigenspaces.

- For  $\lambda_1 = -1$  we get the matrix equation

$$\begin{pmatrix} 1 & 1 & 1 \\ 1 & 1 & 1 \\ 1 & 1 & 1 \end{pmatrix} \begin{pmatrix} x_1 \\ x_2 \\ x_3 \end{pmatrix} = \begin{pmatrix} 0 \\ 0 \\ 0 \end{pmatrix}.$$

Obviously, the reduced row echelon form of the matrix  $A+E$  is given by  $\begin{pmatrix} 1 & 1 & 1 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix}$ , hence we have two free variables,

namely  $x_2 = a \in \mathbb{R}$  and  $x_3 = b \in \mathbb{R}$ . The general solution has the form  $(-a - b, a, b)^T$ , thus the eigenspace  $V_{-1}$  is a 2-dimensional subspace of  $\mathbb{R}^3$  given by

$$V_{-1} = \left\{ \begin{pmatrix} -a-b \\ a \\ b \end{pmatrix} : a, b \in \mathbb{R} \right\} = \text{span}_{\mathbb{R}} \left\{ \begin{pmatrix} -1 \\ 1 \\ 0 \end{pmatrix}, \begin{pmatrix} -1 \\ 0 \\ 1 \end{pmatrix} \right\}.$$

**2.4.6. Orthogonal mappings.** We consider the special case of the mapping  $f : V \rightarrow W$  between spaces with scalar products, which preserve lengths for all vectors  $u \in V$ .

ORTHOGONAL MAPPINGS

A linear mapping  $f : V \rightarrow W$  between spaces with scalar product is called an *orthogonal mapping*, if for all  $u \in V$

$$\langle f(u), f(u) \rangle = \langle u, u \rangle.$$

The linearity of  $f$  and the symmetry of the scalar product imply that for all pairs of vectors the following equality holds:

$$\langle f(u+v), f(u+v) \rangle = \langle f(u), f(u) \rangle + \langle f(v), f(v) \rangle + 2\langle f(u), f(v) \rangle.$$

Therefore all orthogonal mappings satisfy also the seemingly stronger condition for all vectors  $u, v \in V$ :

$$\langle f(u), f(v) \rangle = \langle u, v \rangle,$$

i.e. the mapping  $f$  leaves the scalar product invariant if and only if it leaves invariant the length of the vectors. (We should have noticed that this is true for all fields of scalars, where  $1 + 1 \neq 0$ , but it does not hold true for  $\mathbb{Z}_2$ .)

In the initial discussion about the geometry in the plane we proved in the Theorem 1.5.10 that a linear mapping  $\mathbb{R}^2 \rightarrow \mathbb{R}^2$  preserves lengths of the vectors if and only if its matrix in the standard basis (which is orthonormal with respect to the standard scalar product) satisfies  $A^T \cdot A = E$ , that is,  $A^{-1} = A^T$ .

In general, orthogonal mappings  $f : V \rightarrow W$  must be always injective, because the condition  $\langle f(u), f(u) \rangle = 0$  implies  $\langle u, u \rangle = 0$  and thus  $u = 0$ . In such a case, the dimension of the range is always at least as large as the dimension of the domain of  $f$ . But then both dimensions are equal and  $f : V \rightarrow \text{Im } f$  is a bijection. If  $\text{Im } f \neq W$ , we extend the orthonormal basis of the image of  $f$  to an orthonormal basis of the range space and the matrix of the mapping then contains a square regular submatrix  $A$  along with zero rows so that it has the required number of rows. Without loss of generality we can assume that  $W = V$ .

Our condition for the matrix of an orthogonal mapping in any orthonormal basis requires that for all vectors  $x$  and  $y$  in the space  $\mathbb{K}^n$ :

$$(A \cdot x)^T \cdot (A \cdot y) = x^T \cdot (A^T \cdot A) \cdot y = x^T \cdot y.$$

Special choice of the standard basis vectors for  $x$  and  $y$  yields directly  $A^T \cdot A = E$ , that is, the same result as for dimension two. Thus we have proved the following theorem:

MATRIX OF ORTHOGONAL MAPPINGS

**Theorem.** Let  $V$  be a real vector space with scalar product and let  $f : V \rightarrow V$  be a linear mapping. Then  $f$  is orthogonal if and only if in some orthonormal basis (and then consequently in all of them) its matrix  $A$  satisfies  $A^T = A^{-1}$ .

These two eigenvectors form a basis of  $V_{-1}$ .

• For  $\lambda_2 = 2$  we obtain the matrix equation

$$\begin{pmatrix} -2 & 1 & 1 \\ 1 & -2 & 1 \\ 1 & 1 & -2 \end{pmatrix} \begin{pmatrix} x_1 \\ x_2 \\ x_3 \end{pmatrix} = \begin{pmatrix} 0 \\ 0 \\ 0 \end{pmatrix}.$$

It is easy to verify that the matrix  $\begin{pmatrix} 1 & 0 & -1 \\ 0 & 1 & -1 \\ 0 & 0 & 0 \end{pmatrix}$  is the re-

duced row echelon form of the matrix  $A - 2E$ . Hence we deduce that the solution has the form  $(a, a, a)^T$ , where  $a = x_3 \in \mathbb{R}$  is the free variable. Thus,  $V_2$  is 1-dimensional,  $V_2 = \text{span}_{\mathbb{R}} \{(1, 1, 1)^T\}$ .  $\square$

**2.D.4.** Present the solution of the task in 2.D.3 in Sage.  $\circ$

*In 2.D.3 we observed that the eigenspace of a multiple eigenvalue, such as the double root  $\lambda_1 = -1$ , can have a dimension greater than one. In fact, for this particular eigenvalue, the algebraic and geometric multiplicity are both equal to 2. However, be aware that, in general, the algebraic and geometric multiplicities of an eigenvalue may not always match. In particular, the algebraic multiplicity of an eigenvalue is always greater than or equal to its geometric multiplicity.*

**2.D.5.** Determine the eigenvalues of the following matrix, together with their algebraic and geometric multiplicities.

$$A = \begin{pmatrix} 1 & 1 & 0 \\ -1 & 3 & 0 \\ 2 & -2 & 2 \end{pmatrix}.$$

**2.D.6.** Compute  $\text{tr}(A)$  and  $\det(A)$  for the matrix

$$A = \begin{pmatrix} -11 & 5 & 4 & 1 \\ -3 & 0 & 1 & 0 \\ -21 & 11 & 8 & 2 \\ -9 & 5 & 3 & 1 \end{pmatrix},$$

based on the formulas

$$\begin{aligned} \det(A) &= \lambda_1 \lambda_2 \lambda_3 \lambda_4, \\ \text{tr}(A) &= \lambda_1 + \lambda_2 + \lambda_3 + \lambda_4, \end{aligned}$$

where  $\lambda_1, \lambda_2, \lambda_3, \lambda_4$  are the roots of the characteristic polynomial  $\chi_A(\lambda)$  of  $A$ . Moreover, do the computation in Sage.

**Solution.** The characteristic polynomial associated to  $A$  is of degree four,  $\chi_A(\lambda) = \lambda^4 + 2\lambda^3 - 2\lambda - 1$ . It has two roots, namely  $\lambda_+ = 1$  with multiplicity one and  $\lambda_- = -1$  with multiplicity three, that is,  $\chi_A(\lambda) = (\lambda - 1)(\lambda + 1)^3$ . It follows that  $\det(A) = \lambda_1 \lambda_2^3 = -1$  and  $\text{tr}(A) = \lambda_1 + 3\lambda_2 = 1 - 3 = -2$ . To perform these computations in Sage, use the following block:

```
A=matrix(SR, [[-11, 5, 4, 1], [-3, 0, 1, 0],
[-21, 11, 8, 2], [-9, 5, 3, 1]])
p(t) = A.characteristic_polynomial(t)
show(p(t).factor())
show(p.roots())
print(A.det()); print(A.trace())
```

**PROOF.** Indeed, if  $f$  preserves lengths, it must have the claimed property in every orthonormal basis. On the other hand, the previous calculations show that this property for the matrix in one such basis ensures length preservation.  $\square$

Square matrices which satisfy the equality  $A^T = A^{-1}$  are called *orthogonal matrices*.

The shape of the coordinate transition matrices between orthonormal bases is a direct corollary of the above theorem. Each such matrix must provide a mapping  $\mathbb{K}^n \rightarrow \mathbb{K}^n$  which preserves lengths and thus satisfies the condition  $S^{-1} = S^T$ . When changing from one orthonormal basis to another one, the matrix of any linear mapping changes according to the relation

$$A' = S^T A S.$$

**2.4.7. Decomposition of an orthogonal mapping.** We take a more detailed look at eigenvectors and eigenvalues of orthogonal mappings on a real vector space  $V$  with scalar product.

Consider a fixed orthogonal mapping  $f : V \rightarrow V$  with the matrix  $A$  in some orthonormal basis. We continue as with the matrix  $D$  of rotation in 2.4.1.

We think first about invariant subspaces of orthogonal mappings and their orthogonal complements. Namely, given any subspace  $W \subset V$  invariant with respect to an orthogonal mapping  $f : V \rightarrow V$ , then for all  $v \in W^\perp$  and  $w \in W$  we immediately see

$$\langle f(v), w \rangle = \langle f(v), f \circ f^{-1}(w) \rangle = \langle v, f^{-1}(w) \rangle = 0$$

since  $f^{-1}(w) \in W$ , too. But this means that also  $f(W^\perp) \subset W^\perp$  and we have proved a simple but very important proposition:

**Proposition.** *The orthogonal complement of a subspace invariant with respect to an orthogonal mapping is also invariant.*

If all eigenvalues of an orthogonal mapping are real, this claim ensures that there always exists a basis of  $V$  composed of eigenvectors. Indeed, the restriction of  $f$  to the orthogonal complement of an invariant subspace is again an orthogonal mapping, therefore we can add one eigenvector to the basis after another, until we obtain the whole decomposition of  $V$ . However, mostly the eigenvalues of orthogonal mappings are not real. We need to deviate into complex vector spaces. We formulate the result right away:

```
eign=A.eigenvalues(); print(eign)
bool(sum(eign)==A.trace())
bool(prod(eign)==A.det())
```

**2.D.7.** Let  $A$  be a  $n \times n$  triangular matrix over  $\mathbb{K} \in \{\mathbb{R}, \mathbb{C}\}$ , either upper or lower. Prove that the eigenvalues of  $A$  are its diagonal elements.  $\circ$

**2.D.8.** (a) Prove that a  $n \times n$  matrix  $A$  is invertible if and only if 0 is not an eigenvalue of  $A$ .  
 (b) Compute the characteristic polynomial of the  $n \times n$  matrix  $A_n$  given below. Then combine your result with the statement in (a), to determine those  $n$  for which the matrix  $A_n$  is invertible.

$$A_n = \begin{pmatrix} 1 & 0 & 0 & 0 & \cdots & 0 & 0 & 1 \\ 1 & 1 & 0 & 0 & \cdots & 0 & 0 & 0 \\ 0 & 1 & 1 & 0 & \cdots & 0 & 0 & 0 \\ 0 & 0 & 1 & 1 & \cdots & 0 & 0 & 0 \\ \vdots & \vdots & \vdots & \vdots & \ddots & \vdots & \vdots & \vdots \\ 0 & 0 & 0 & 0 & \cdots & 1 & 1 & 0 \\ 0 & 0 & 0 & 0 & \cdots & 0 & 1 & 1 \end{pmatrix}.$$

 As described in 2.4.3 the eigenvectors of a squared matrix corresponding to distinct eigenvalues, are linearly independent. This property enables us to use an “eigenvector basis” to represent the matrix as a diagonal matrix. Matrices (or endomorphisms) with this property are commonly referred to as diagonalizable.

Summarizing, a matrix  $A$  is diagonalizable if it is similar to a diagonal matrix  $D$ , meaning that there exists an invertible matrix  $P$  such that  $A = PDP^{-1}$ . This is equivalent to saying that the algebraic and geometric multiplicities of each eigenvalue of  $A$  are equal.

Diagonalizable matrices are particularly useful because they simplify many matrix computations, such as raising a matrix to a power, or solving systems of linear differential equations. As we will explore in Chapter 3, significant examples of diagonalizable endomorphisms include symmetric matrices. These matrices are important in various fields, including physics, engineering, and computer science.

**2.D.9. Diagonalization.** Consider the matrix  $A$  introduced in the tasks 2.D.1, 2.D.3 and 2.D.5, respectively. Specify the cases where  $A$  is diagonalizable, and for these cases find matrices  $P, D$  such that  $A = PDP^{-1}$ .

**Solution.** (a) Let us consider first the matrix  $A$  given in 2.D.1. There we saw that this matrix admits three eigenvalues, all distinct each other. Hence in this case  $A$  is diagonalizable. In particular, observe that for any eigenvalue of  $A$ , the corresponding algebraic and geometric multiplicity coincide (they are all equal to one). Thus we have  $A = PDP^{-1}$ , with

$$D = \begin{pmatrix} \lambda_1 & 0 & 0 \\ 0 & \lambda_+ & 0 \\ 0 & 0 & \lambda_- \end{pmatrix}, \quad P = \begin{pmatrix} 0 & 2 - \sqrt{3} & 2 + \sqrt{3} \\ 0 & 1 & 1 \\ 1 & -2 & -2 \end{pmatrix},$$

ORTHOGONAL MAPPING DECOMPOSITION

**Theorem.** Let  $f : V \rightarrow V$  be an orthogonal mapping on a real vector space  $V$  with scalar product. Then all the (in general complex) roots of the characteristic polynomial  $f$  have length one. There exists the decomposition of  $V$  into one-dimensional eigenspaces corresponding to the real eigenvalues  $\lambda = \pm 1$  and two-dimensional subspaces  $P_{\lambda, \bar{\lambda}}$  with  $\lambda \in \mathbb{C} \setminus \mathbb{R}$ , where  $f$  acts by the rotation by the angle equal to the argument of the complex number  $\lambda$  in the positive sense. All these subspaces are mutually orthogonal.

 **PROOF.** Without loss of generality we can work with the space  $V = \mathbb{R}^m$  with the standard scalar product. The mapping is thus given by an orthogonal matrix  $A$  which can be equally well seen as the matrix of a (complex) linear mapping on the complex space  $\mathbb{C}^m$  (which just happens to have all of its coefficients real).

There exist exactly  $m$  (complex) roots of the characteristic polynomial of  $A$ , counting their algebraic multiplicities (see the fundamental theorem of algebra, 1.A.6). Furthermore, because the characteristic polynomial of the mapping has only real coefficients, the roots are either real or there are pairs of roots which are complex conjugates  $\lambda$  and  $\bar{\lambda}$ . The associated eigenvectors in  $\mathbb{C}^m$  for such pairs of complex conjugates are actually solutions of two systems of linear homogeneous equations which are also complex conjugate to each other – the corresponding matrices of the systems have real components, except for the eigenvalues  $\lambda$ . Therefore the solutions of this systems are also complex conjugates (check this!).

Next, we exploit the fact that for every invariant subspace its orthogonal complement is also invariant. First we find the eigenspaces  $V_{\pm 1}$  associated with the real eigenvalues, and restrict the mapping to the orthogonal complement of their sum. Without loss of generality we can thus assume that our orthogonal mapping has no real eigenvalues and that  $\dim V = 2n > 0$ .

Now choose an eigenvalue  $\lambda$  and let  $u_\lambda$  be the eigenvector in  $\mathbb{C}^{2n}$  associated to the eigenvalue  $\lambda = \alpha + i\beta$ ,  $\beta \neq 0$ . Analogously to the case of rotation in the plane discussed in paragraph 2.4.1 in terms of the matrix  $D$ , we are interested in the real part of the sum of two one-dimensional (complex) subspaces  $W = \text{span}\{u_\lambda\} \oplus \text{span}\{\bar{u}_\lambda\}$ , where  $\bar{u}_\lambda$  is the eigenvector associated to the conjugated eigenvalue  $\bar{\lambda}$ .

Now we want the intersection of the 2-dimensional complex subspace  $W$  with the real subspace  $\mathbb{R}^{2n} \subset \mathbb{C}^{2n}$ , which is clearly generated (over  $\mathbb{R}$ ) by the vectors  $u_\lambda + \bar{u}_\lambda$  and  $i(u_\lambda - \bar{u}_\lambda)$ . We call this real 2-dimensional subspace  $P_{\lambda, \bar{\lambda}} \subset \mathbb{R}^{2n}$  and notice, this subspace is generated by the basis given by the real and imaginary part of  $u_\lambda$

$$x_\lambda = \text{Re } u_\lambda, \quad -y_\lambda = -\text{Im } u_\lambda.$$

respectively, where  $\lambda_1 = 2, \lambda_{\pm} = 1 \pm \sqrt{3}$  are the eigenvalues of  $A$ . The columns of  $P$  are the eigenvectors of  $A$ , described in 2.D.1. The block below provides a quick verification of the relation  $A = PDP^{-1}$  in Sage:

```
A=matrix(SR, [[-1, 1, 0], [-1, 3, 0],
[2, -2, 2]])
u1=vector([0, 0, 1])
u2=vector([2-sqrt(3), 1, -2])
u3=vector([2+sqrt(3), 1, -2])
P=column_matrix([u1, u2, u3])
D=diagonal_matrix([2, 1+sqrt(3), 1-sqrt(3)])
bool(A==P*D*P.inverse())
```

Note that we can replace any column of the matrix  $P$  with a non-zero scalar multiple of the corresponding eigenvector. As a result, there are infinitely many possible matrices  $P$  that satisfy the diagonalization condition.

(b) Let us now consider the matrix  $A$  given in 2.D.3. There we saw that this matrix has two eigenvalues:  $\lambda_1 = -1$  with algebraic multiplicity 2, and  $\lambda = 2$  with algebraic multiplicity 1. We also proved that the geometric multiplicity of  $\lambda_1$  coincides with its algebraic multiplicity, and similarly for  $\lambda_2$ . Hence in this case the matrix  $A$  is also diagonalizable:  $A = PDP^{-1}$ . To explicitly determine  $D$  and  $P$  we can follow the same method outline in (a). We leave this case as an exercise for practice.

(c) Finally, the matrix  $A$  presented in 2.D.5 is *not* diagonalizable. This is because its unique eigenvalue  $\lambda = 2$  has an algebraic multiplicity 3, but a geometric multiplicity 2. Consequently, it is impossible to construct a complete basis of eigenvectors for this matrix.  $\square$

**2.D.10.** Determine whether the matrices  $A_1$  and  $A_2$  given below are diagonalizable. If diagonalizable, determine the matrices  $D_i, P_i$  such that  $A_i = P_i D_i P_i^{-1}$ :

$$A_1 = \begin{pmatrix} 2 & 0 & 0 \\ 4 & 2 & 2 \\ -2 & 0 & 1 \end{pmatrix}, \quad A_2 = \begin{pmatrix} 2 & 0 & 0 \\ -4 & 2 & 2 \\ -2 & 0 & 1 \end{pmatrix}.$$

Consider a real vector space  $V$  endowed with a scalar product  $\langle \cdot, \cdot \rangle$ , and an orthogonal endomorphism  $f : V \rightarrow V$ . Thus,  $f$  preserves the scalar product, the lengths and the angles of vectors in  $V$ . A prime example of orthogonal endomorphisms are rotations, in  $\mathbb{R}^2$  or  $\mathbb{R}^3$  (cf. 1.E.17).

It is most remarkable, that in matrix terms,  $A \in \text{Mat}_n(\mathbb{R})$  is a matrix of an orthogonal transformation  $f$  (in suitable orthonormal coordinates), if and only if

$$AA^T = A^T A = E.$$

We call them orthogonal matrices and they are particularly easy to invert. This property leads to several interesting results, such as the fact that the determinant of an orthogonal matrix is always  $\pm 1$ .

Because  $A \cdot (u_\lambda + \bar{u}_\lambda) = \lambda u_\lambda + \bar{\lambda} \bar{u}_\lambda$  and similarly with the second basis vector, it is clearly an invariant subspace with respect to multiplication by the matrix  $A$  and we obtain

$$A \cdot x_\lambda = \alpha x_\lambda + \beta y_\lambda, \quad A \cdot (-y_\lambda) = -\alpha y_\lambda + \beta x_\lambda.$$

Consequently,

$$\|A \cdot x_\lambda\|^2 + \|A \cdot y_\lambda\|^2 = (\alpha^2 + \beta^2)(\|x\|^2 + \|y\|^2)$$

and, since our mapping preserves lengths, the absolute value of the eigenvalue  $\lambda$  must equal one. But that means that the restriction of our mapping to  $P_{\lambda, \bar{\lambda}}$  is the rotation by the argument of the eigenvalue  $\lambda$ . Note that the choice of the eigenvalue  $\bar{\lambda}$  instead of  $\lambda$  leads to the same subspace with the same rotation, we would just have expressed it in the basis  $x_\lambda, y_\lambda$ , that is, the same rotation will in these coordinates go by the same angle, but with the opposite sign, as expected.

The proof of the whole theorem is completed by restricting the mapping to the orthogonal complement and finding another 2-dimensional subspace, until we get the required decomposition.  $\square$

We return to the ideas in this proof once again in chapter three, where we study complex extensions of the Euclidean vector spaces, see 3.4.4.

**Remark.** The previous theorem is very powerful in dimension three. Here at least one eigenvalue must be real  $\pm 1$ , since three is odd. But then the associated eigenspace is an axis of the rotation of the three-dimensional space through the angle given by the argument of the other eigenvalues. Try to think how to detect in which direction the space is rotated. Note also that the eigenvalue  $-1$  means an additional reflection through the plane perpendicular to the axis of the rotation.

We shall return to the discussion of such properties of matrices and linear mappings in more details at the end of the next chapter, after illustrating the power of the matrix calculus in several practical applications. We close this section with a general quite widely used definition:

The next task illustrates that orthogonal endomorphisms on  $\mathbb{R}^n$  correspond to orthogonal  $n \times n$  real matrices, and conversely. For more information, see the discussion in 2.4.6.

**2.D.11.** On  $V = \mathbb{R}^n$  endowed with the dot product consider a linear mapping  $\varphi_A : V \rightarrow V$ , defined by  $\varphi_A(u) = Au$ , for some  $A \in \text{Mat}_n(\mathbb{R})$ , for all  $u \in V$ . Prove that  $A$  is orthogonal if and only if  $\varphi_A$  is an orthogonal endomorphism of  $V$ .  $\circ$

**2.D.12.** Determine which of the matrices below is orthogonal:

$$A = \begin{pmatrix} 1/\sqrt{2} & -1/\sqrt{2} \\ -1/\sqrt{2} & -1/\sqrt{2} \end{pmatrix},$$

$$B = \begin{pmatrix} 2/3 & -2/3 & 1/3 \\ 2/3 & 1/3 & -2/3 \\ 1/3 & 2/3 & 2/3 \end{pmatrix},$$

$$C = \begin{pmatrix} 3/\sqrt{11} & -1/\sqrt{6} & -1/\sqrt{66} \\ 1/\sqrt{11} & 2/\sqrt{6} & -4/\sqrt{66} \\ 1/\sqrt{11} & 1/\sqrt{6} & 7/\sqrt{66} \end{pmatrix}.$$

**Solution.** All the given matrices  $A, B$  and  $C$  are orthogonal. There are many ways to verify this fact. For  $A$  notice that  $A^T = A$  and

$$AA^T = \begin{pmatrix} 1/\sqrt{2} & -1/\sqrt{2} \\ -1/\sqrt{2} & -1/\sqrt{2} \end{pmatrix} \begin{pmatrix} 1/\sqrt{2} & -1/\sqrt{2} \\ -1/\sqrt{2} & -1/\sqrt{2} \end{pmatrix} = E.$$

On the other hand, later in Chapter 3 we will learn that a square matrix is orthogonal, if and only if its columns (or rows) form an orthonormal basis (see 3.4.4). Given our familiarity with orthonormal bases, we can use this criterion to determine whether the matrix  $B$  is orthogonal. We need to verify for example that the (column) vectors

$$v_1 = \begin{pmatrix} 2/3 \\ 2/3 \\ 1/3 \end{pmatrix}, \quad v_2 = \begin{pmatrix} -2/3 \\ 1/3 \\ 2/3 \end{pmatrix}, \quad v_3 = \begin{pmatrix} 1/3 \\ -2/3 \\ 2/3 \end{pmatrix}$$

form an orthonormal basis of  $\mathbb{R}^3$  with respect to the dot product. We compute  $\|v_1\| = \|v_2\| = \|v_3\| = 1$  and  $v_1 \cdot v_2 = -\frac{4}{9} + \frac{2}{9} + \frac{2}{9} = 0$ ,  $v_1 \cdot v_3 = \frac{2}{9} - \frac{4}{9} + \frac{2}{9} = 0$ ,  $v_2 \cdot v_3 = -\frac{2}{9} - \frac{2}{9} + \frac{4}{9} = 0$ . This proves the claim.

You can also use the command `A.is_unitary()` in Sage. This checks whether a given real matrix  $A$  is orthogonal (or if a complex matrix is unitary, as we will see in Chapter 3). Let us apply this method to verify the orthogonality of the matrix  $C$ :

```
C = matrix(SR, [[3/sqrt(11), -1/sqrt(6), -1/sqrt(66)],
[1/sqrt(11), 2/sqrt(6), -4/sqrt(66)],
[1/sqrt(11), 1/sqrt(6), 7/sqrt(66)]]
C.is_unitary()
```

Sage's output is True.  $\square$

**2.4.8. Definition.** The spectrum of a linear mapping  $f : V \rightarrow V$ , or the spectrum of a square matrix  $A$ , is a sequence of roots of the characteristic polynomial  $f$  or  $A$ , along with their multiplicities, respectively. The algebraic multiplicity of an eigenvalue means the multiplicity of the root of the characteristic polynomial, while the geometric multiplicity of the eigenvalue is the dimension of the associated subspace of eigenvectors.

The spectral diameter of a linear mapping (or matrix) is the greatest of the absolute values of the eigenvalues.

In this terminology, our results about orthogonal mappings can be formulated as follows: the spectrum of an orthogonal mapping is always a subset of the unit circle in the complex plane. Thus only the values  $\pm 1$  may appear in the real part of the spectrum and their algebraic and geometric multiplicities are always the same. Complex values of the spectrum then correspond to rotations in suitable two-dimensional subspaces which are mutually perpendicular.

Proper rotations are orthogonal matrices with determinant 1, and play a crucial role in both applied and pure mathematics. Orthogonal matrices with determinant  $-1$  correspond to reflections through the origin, which are used to model symmetry operations, such as those seen in particle physics or optics. Recall that in low dimensions, eigentheory provides a nuanced geometric perspective on both rotations and reflections (see the remark in 2.4.7, and the tasks 1.E.17, 2.E.57).

In a three-dimensional space, a general proper rotation is characterized by its axis and its angle  $\theta$ . Conventionally, a positive angle corresponds to a counterclockwise rotation when viewed from the tip of the axis, see also the discussion in ???. The rotation matrix in this case has necessarily three eigenvalues, a real one  $\lambda_1 = 1$ , and two unitary complex conjugate eigenvalues.

As explained in 2.4.7, the eigenvector  $u_1$  associated with the eigenvalue 1 represents the rotation axis, which remains invariant under the rotation. The direction of this axis can be determined using the right-hand rule: curl the fingers of your right hand around the axis of rotation, with your fingers pointing in the direction of  $\theta$ ; your thumb will then point in the direction of  $u_1$ . Additionally, the angle  $\theta$  is given by the argument of the two complex conjugate eigenvalues, which represent a 2-dimensional rotation within the plane orthogonal to the rotation axis.

**2.D.13.** Consider the matrix

$$A = \begin{pmatrix} \frac{3}{5} & \frac{16}{25} & \frac{-12}{25} \\ \frac{-16}{25} & \frac{93}{125} & \frac{24}{125} \\ \frac{12}{25} & \frac{24}{125} & \frac{107}{125} \end{pmatrix}.$$

- (a) Show that the linear mapping induced by  $A$  is a rotation.  
 (b) Find its axis, the plane rotation, and the rotation angle.

**Solution.** (a) To prove that the induced linear mapping is a rotation, it is sufficient to show that  $A$  is an orthogonal matrix with determinant 1. In Sage you may apply the method described above, i.e.,

```
A=matrix(SR, [[3/5, 16/25, -12/25],
[ -16/25, 93/125, 24/125],
[12/25, 24/125, 107/125]])
A.is_unitary()
```

Sage's output is True. Adding the command `det(A)`, Sage gives that  $\det(A) = 1$ . Compute the determinant in a formal way, as well. Thus,  $A$  is an orthogonal matrix with determinant 1. Let us also compute the eigenvalues of  $A$  by adding the command `A.eigenvalues()`. Sage returns the list

```
[-4/5*I + 3/5, 4/5*I + 3/5, 1]
```

but for our convenience we set  $\lambda_1 = 1$ ,  $\lambda_2 = \frac{3}{5} + \frac{4}{5}i$  and  $\lambda_3 = \frac{3}{5} - \frac{4}{5}i$ . All three eigenvalues have absolute value one. Combined with the fact that the matrix is orthogonal, this confirms that the matrix represents a rotation.

- (b) In this part we need to find the eigenvectors of  $A$ . Let

us use Sage to specify them. By adding the command `A.eigenvectors_right()` to the previous block, Sage will return the eigenvectors corresponding to the eigenvalues  $\lambda_1, \lambda_2, \lambda_3$ . These are given by  $v_1 = (0, 1, 4/3)^T$ ,  $v_2 = (1, 4i/5, -3i/5)^T$ , and  $v_3 = (1, -4i/5, 3i/5)^T$ , respectively. The axis of the rotation is given by the eigenvector  $v_1$ . The plane of rotation is the real plane  $\mathcal{E}$  in  $\mathbb{R}^3$  which is defined by the intersection of the 2-dimensional complex subspace of  $\mathbb{C}^3$  spanned by the remaining eigenvectors  $v_2, v_3$ , with  $\mathbb{R}^3$ . A direct computation shows that

$$\mathcal{E} = \text{span}_{\mathbb{R}} \{E_1 = (1, 0, 0)^T, E_2 = (0, -4, 3)^T\} \subset \mathbb{R}^3,$$

where the first generator is the real multiple of  $v_2 + v_3$  and the second one is the real multiple of  $i(v_2 - v_3)$ , see also 2.4.7. We are now ready to determine the rotation angle in this plane: It is a rotation by the angle  $\arccos(\frac{3}{5}) \doteq 0, 295\pi$ , which is the argument of the eigenvalue  $\frac{3}{5} + \frac{4}{5}i$  (or minus that number, if we would choose the other eigenvalue).  $\square$

---

*You can find more exercises on eigenvalues, eigenvectors, orthogonal matrices and rotations in Section E. In Chapter 3 we will return to these topics and expand our perspective by exploring their applications in eigenvalues and orthogonal diagonalization.*

---

E. Additional exercises for the whole chapter

Below we provide additional material for most of the concepts discussed in the second chapter. The goal is to gain further computational experience with matrix calculus, become more familiar with basic notions of linear transformations, and hopefully enrich our approach to solving linear problems.

A) MATERIAL ON VECTORS AND MATRICES

**2.E.1. Sage’s vocabulary in linear algebra.** This chapter has provided extensive information on using Sage with vectors and matrices. Before we begin this supplementary section, it is helpful to summarize this knowledge. Below, we list most of the Sage commands we have explored so far, along with instructions for manipulating matrices and linear mappings. We strongly recommend using Sage to aid your understanding of the problems presented below, especially in cases where our solution does not include Sage. This practice will also help expand your Sage vocabulary on linear algebra and its applications, as we will see later in Chapter 3.

Sage vocabulary for matrix calculus, vector spaces and linear mappings

zero $m/n$ matrix	<code>zero_matrix(KK, m, n)</code>	rank	<code>A.rank()</code>
identity $n/n$ matrix	<code>identity_matrix(KK, n)</code>	left kernel	<code>A.left_kernel()</code>
matrix	<code>diagonal_matrix(KK, [a, b, c])</code>	right kernel	<code>A.right_kernel()</code>
random matrix	<code>random_matrix(KK, m, n)</code>	rank of left kernel	<code>A.left_nullity()</code>
matrix multipl.	<code>A * b</code> , or <code>A * B</code> or <code>B * A</code>	rank of right kernel	<code>A.right_nullity()</code>
matrix exponent.	e.g., <code>A^3</code> , or <code>A * *3</code>	character. polyn.	<code>A.characteristic_polynomial()</code>
determinant, trace	<code>A.det()</code> , <code>A.trace()</code>	eigenvalues	<code>A.eigenvalues()</code>
row echelon form	<code>A.echelon_form()</code>	eigenvectors	<code>A.eigenvectors_right()</code>
RREF	<code>A.rref()</code>	conjugate transpose	<code>A.conjugate_transpose()</code>
pivots columns	<code>A.pivots()</code>	orthogonal	<code>A.is_unitary()</code>
inverse	<code>A.inverse()</code>	unitary	<code>A.is_unitary()</code>
minors of order $k$	<code>A.minor(k)</code>	symmetric	<code>A.is_symmetric()</code>
adjoint	<code>A.adjugate()</code>	rescale rows	<code>A.rescale_row()</code>
transpose	<code>A.transpose()</code>	add multiples of rows	<code>A.add_multiple_of_row()</code>
conjugate	<code>A.conjugate()</code>	interchange rows	<code>A.swap_rows()</code>
accessing the entry $a_{1,2}$	<code>A[0, 1]</code> or <code>A[0][1]</code>	find the size of $A$	<code>A.rows()</code> , <code>A.ncols()</code>
accessing $k$ th column	<code>A[:, k - 1]</code> , e.g. 3rd column <code>A[:, 2]</code>	introduce a vector $u$	<code>u = vector(KK, [u1, ..., un])</code>
accessing $n$ th row	<code>A[n - 1, :]</code> , e.g. 2nd row <code>A[1, :]</code>	size of $u$	<code>u.degree()</code>
submatrices of $B$	<code>B[0 : 2, 1 : 3]</code> , <code>B[0 : 2, 1 : 3]</code>	block matrix $\begin{pmatrix} A & 0 \\ 0 & B \end{pmatrix}$	<code>A.stack(B)</code>
e.g., $B$ is a $4/5$ matrix	<code>B[:, 1 : 2]</code> , <code>B[:, 1 : 3]</code> <code>B[1 : 2, :]</code> , <code>B[1 : 3, :]</code>	augmented matrix	<code>A.augment(b)</code>
		a solution of $Ax = b$	<code>A\b</code>

As we learned in the main part, many of the commands listed above come with various options, which we have not included here for simplicity. Above,  $\mathbb{K}$  represents a numerical system  $\mathbb{K}$ , e.g.  $\mathbb{Z}$  for the integers  $\mathbb{Z}$ , etc.

**2.E.2.** Consider the finite field  $\mathbb{Z}_7$  and the matrices  $A = \begin{pmatrix} 2 & 3 \\ 4 & 5 \end{pmatrix}$  and  $B = \begin{pmatrix} 6 & 1 \\ 0 & 2 \end{pmatrix}$  with elements in  $\mathbb{Z}_7$ . Describe the multiplication  $AB$  and next confirm your result using Sage. How many arithmetic operations we need to compute the product  $AB$  over  $\mathbb{Z}_7$  and why this differs from the result presented in 1.E.11?

**Solution.** The finite field  $\mathbb{Z}_7$  consists of the integers  $\{0, 1, 2, 3, 4, 5, 6\}$  with addition and multiplication defined modulo 7. Thus, to multiply the matrices  $A, B$  over  $\mathbb{Z}_7$  we follow the standard procedure for matrix multiplication but reduce each entry modulo 7. Let us denote by  $C = AB = (c_{ij})$  the product of  $A, B$ . Then, the entries  $c_{ij}$  are given by  $c_{ij} = \sum_{k=1}^2 a_{ik}b_{kj} \pmod{7}$ . We compute

$$c_{11} = (2 \cdot 6 + 3 \cdot 0) \pmod{7} = 12 \pmod{7} = 5, \quad c_{12} = (2 \cdot 1 + 3 \cdot 2) \pmod{7} = 8 \pmod{7} = 1,$$

$$c_{21} = (4 \cdot 6 + 5 \cdot 0) \pmod{7} = 24 \pmod{7} = 3, \quad c_{22} = (4 \cdot 1 + 5 \cdot 2) \pmod{7} = 14 \pmod{7} = 0.$$

Thus

$$C = AB = \begin{pmatrix} c_{11} & c_{12} \\ c_{21} & c_{22} \end{pmatrix} = \begin{pmatrix} 5 & 1 \\ 3 & 0 \end{pmatrix}.$$

A verification in Sage follows the standard procedure. However, we first need to introduce the finite field  $\mathbb{Z}_7$  and define the matrices  $A$  and  $B$  over this field.

$Z7=GF(7)$ 
 $A=Matrix(Z7, [[2, 3], [4, 5]]); B=Matrix(Z7, [[6, 1], [0, 2]]); show(A*B)$ 

Finally, according to 1.E.11 the multiplication  $AB$  of two  $2 \times 2$  real matrices requires 12 arithmetic operations: For each matrix element, we perform two multiplications and one addition. Over  $\mathbb{Z}_7$  for each matrix element we need one more operation, the modulo operation. Thus in total we will have  $12 + 4 = 16$  operations.  $\square$

*Elementary matrices are fundamental tools in linear algebra, particularly useful for understanding and performing row operations on matrices. An elementary matrix is derived from the identity matrix by performing a single elementary row operation, see 2.1.8. These operations are essential for matrix manipulations, solving systems of linear equations, and finding matrix inverses. Let us describe related tasks.*

2.E.3. Consider the matrix  $A = \begin{pmatrix} 1 & 0 & 2 \\ 3 & 1 & -1 \\ 2 & 4 & 2 \end{pmatrix}$ .

- Determine the elementary matrix representing the row operation  $R_2 \rightarrow R_2 - 3R_1$ . Next, confirm that the inverse of this elementary matrix is the elementary matrix of the row operation  $R_2 \rightarrow R_2 + 3R_1$ .
- Determine the elementary matrix representing the row operation  $R_2 \rightarrow R_2 - \frac{3}{2}R_3$ . Next, confirm that the inverse of this elementary matrix is the elementary matrix of the row operation  $R_2 \rightarrow R_2 + \frac{3}{2}R_3$ .
- Determine the elementary matrix representing the row operation  $R_3 \rightarrow \frac{1}{2}R_3$ . Next, confirm that the inverse of this elementary matrix is the elementary matrix of the row operation  $R_3 \rightarrow 2R_3$ .  $\circ$

2.E.4. Consider the matrix  $A = \begin{pmatrix} 2 & 1 & 3 \\ 1 & 0 & 1 \\ 4 & 2 & 1 \end{pmatrix}$ .

- Show that  $A$  is invertible.
- Apply elementary row operations to determine the inverse of  $A$ .
- Express  $A$  as a product of inverses of elementary matrices.

**Solution.** (a) Using the Sarrus rule (see 2.2.1) it is straightforward to verify that the determinant of  $A$  equals  $5 \neq 0$ . Therefore, the matrix is invertible.

(b) Consider the augmented matrix  $(A \mid E)$  (where  $E$  is the  $3 \times 3$  identity). The goal is to use elementary row operations to transform  $(A \mid E)$  into  $(E \mid A^{-1})$ . We compute:

$$\begin{aligned} (A \mid E) &= \left( \begin{array}{ccc|ccc} 2 & 1 & 3 & 1 & 0 & 0 \\ 1 & 0 & 1 & 0 & 1 & 0 \\ 4 & 2 & 1 & 0 & 0 & 1 \end{array} \right) \xrightarrow{R_1 \rightarrow \frac{1}{2}R_1} \left( \begin{array}{ccc|ccc} 1 & \frac{1}{2} & \frac{3}{2} & \frac{1}{2} & 0 & 0 \\ 1 & 0 & 1 & 0 & 1 & 0 \\ 4 & 2 & 1 & 0 & 0 & 1 \end{array} \right) \xrightarrow{R_2 \rightarrow R_2 - R_1} \left( \begin{array}{ccc|ccc} 1 & \frac{1}{2} & \frac{3}{2} & \frac{1}{2} & 0 & 0 \\ 0 & -\frac{1}{2} & -\frac{1}{2} & -\frac{1}{2} & 1 & 0 \\ 4 & 2 & 1 & 0 & 0 & 1 \end{array} \right) \\ &\xrightarrow{R_3 \rightarrow R_3 - 4R_1} \left( \begin{array}{ccc|ccc} 1 & \frac{1}{2} & \frac{3}{2} & \frac{1}{2} & 0 & 0 \\ 0 & -\frac{1}{2} & -\frac{1}{2} & -\frac{1}{2} & 1 & 0 \\ 0 & 0 & -5 & -2 & 0 & 1 \end{array} \right) \xrightarrow{R_2 \rightarrow -2R_2} \left( \begin{array}{ccc|ccc} 1 & \frac{1}{2} & \frac{3}{2} & \frac{1}{2} & 0 & 0 \\ 0 & 1 & 1 & 1 & -2 & 0 \\ 0 & 0 & -5 & -2 & 0 & 1 \end{array} \right) \xrightarrow{R_3 \rightarrow -\frac{1}{5}R_3} \\ &\left( \begin{array}{ccc|ccc} 1 & \frac{1}{2} & \frac{3}{2} & \frac{1}{2} & 0 & 0 \\ 0 & 1 & 1 & 1 & -2 & 0 \\ 0 & 0 & 1 & \frac{2}{5} & 0 & -\frac{1}{5} \end{array} \right) \xrightarrow{R_2 \rightarrow R_2 - R_3} \left( \begin{array}{ccc|ccc} 1 & \frac{1}{2} & \frac{3}{2} & \frac{1}{2} & 0 & 0 \\ 0 & 1 & 0 & \frac{3}{5} & -2 & \frac{1}{5} \\ 0 & 0 & 1 & \frac{2}{5} & 0 & -\frac{1}{5} \end{array} \right) \xrightarrow{R_1 \rightarrow R_1 - \frac{3}{2}R_3} \\ &\left( \begin{array}{ccc|ccc} 1 & \frac{1}{2} & 0 & -\frac{1}{10} & 0 & \frac{3}{10} \\ 0 & 1 & 0 & \frac{3}{5} & -2 & \frac{1}{5} \\ 0 & 0 & 1 & \frac{2}{5} & 0 & -\frac{1}{5} \end{array} \right) \xrightarrow{R_1 \rightarrow R_1 - \frac{1}{2}R_2} \left( \begin{array}{ccc|ccc} 1 & 0 & 0 & -\frac{2}{5} & 1 & \frac{1}{5} \\ 0 & 1 & 0 & \frac{3}{5} & -2 & \frac{1}{5} \\ 0 & 0 & 1 & \frac{2}{5} & 0 & -\frac{1}{5} \end{array} \right). \end{aligned}$$

Thus  $A^{-1} = \begin{pmatrix} -2/5 & 1 & 1/5 \\ 3/5 & -2 & 1/5 \\ 2/5 & 0 & -1/5 \end{pmatrix}$ . To confirm this expression, you can either use Sage, or verify the relation  $AA^{-1} =$

$E = A^{-1}A$  by hand. Let us present the verification in Sage:

```
A=Matrix(SR, [[2, 1, 3], [1, 0, 1], [4, 2, 1]]); print(det(A))
A_inv=A.inverse(); show(A_inv)
```

(c) In part (b) we obtained  $A^{-1}$  by applying eight elementary row operations. These operations correspond to eight elementary matrices  $E_1, \dots, E_8$ , such that  $E_8 E_7 E_6 E_5 E_4 E_3 E_2 E_1 A = E$ . Thus,  $A = (E_8 E_7 E_6 E_5 E_4 E_3 E_2 E_1)^{-1} = E_1^{-1} E_2^{-1} E_3^{-1} E_4^{-1} E_5^{-1} E_6^{-1} E_7^{-1} E_8^{-1}$ . Let us specify  $E_1, \dots, E_8$  and their inverses.

$$\text{row operation } R_1 \rightarrow \frac{1}{2}R_1 : E = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix} \xrightarrow{R_1 \rightarrow \frac{1}{2}R_1} \begin{pmatrix} 1/2 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix} =: E_1 \implies E_1^{-1} = \begin{pmatrix} 2 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix},$$

$$\text{row operation } R_2 \rightarrow R_2 - R_1 : E = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix} \xrightarrow{R_2 \rightarrow R_2 - R_1} \begin{pmatrix} 1 & 0 & 0 \\ -1 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix} =: E_2 \implies E_2^{-1} = \begin{pmatrix} 1 & 0 & 0 \\ 1 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix},$$

$$\text{row operation } R_3 \rightarrow R_3 - 4R_1 : E = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix} \xrightarrow{R_3 \rightarrow R_3 - 4R_1} \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ -4 & 0 & 1 \end{pmatrix} =: E_3 \implies E_3^{-1} = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 4 & 0 & 1 \end{pmatrix},$$

$$\text{row operation } R_2 \rightarrow -2R_2 : E = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix} \xrightarrow{R_2 \rightarrow -2R_2} \begin{pmatrix} 1 & 0 & 0 \\ 0 & -2 & 0 \\ 0 & 0 & 1 \end{pmatrix} =: E_4 \implies E_4^{-1} = \begin{pmatrix} 1 & 0 & 0 \\ 0 & -\frac{1}{2} & 0 \\ 0 & 0 & 1 \end{pmatrix},$$

$$\text{row operation } R_3 \rightarrow -\frac{1}{5}R_3 : E = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix} \xrightarrow{R_3 \rightarrow -\frac{1}{5}R_3} \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & -1/5 \end{pmatrix} =: E_5 \implies E_5^{-1} = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & -5 \end{pmatrix},$$

$$\text{row operation } R_2 \rightarrow R_2 - R_3 : E = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix} \xrightarrow{R_2 \rightarrow R_2 - R_3} \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & -1 \\ 0 & 0 & 1 \end{pmatrix} =: E_6 \implies E_6^{-1} = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 1 \\ 0 & 0 & 1 \end{pmatrix},$$

$$\text{row operation } R_1 \rightarrow R_1 - \frac{3}{2}R_3 : E = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix} \xrightarrow{R_1 \rightarrow R_1 - \frac{3}{2}R_3} \begin{pmatrix} 1 & 0 & -\frac{3}{2} \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix} =: E_7 \implies E_7^{-1} = \begin{pmatrix} 1 & 0 & \frac{3}{2} \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix},$$

$$\text{row operation } R_1 \rightarrow R_1 - \frac{1}{2}R_2 : E = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix} \xrightarrow{R_1 \rightarrow R_1 - \frac{1}{2}R_2} \begin{pmatrix} 1 & -\frac{1}{2} & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix} =: E_8 \implies E_8^{-1} = \begin{pmatrix} 1 & \frac{1}{2} & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix}.$$

It is now a straightforward (though lengthy) computation to verify that  $A = E_1^{-1} E_2^{-1} E_3^{-1} E_4^{-1} E_5^{-1} E_6^{-1} E_7^{-1} E_8^{-1}$ . To speed up this process, we can program Sage to perform the calculation for us, by adding the following cell to the previous code block:

```
E1inv=Matrix(SR, [[2, 0, 0], [0, 1, 0], [0, 0, 1]])
E2inv=Matrix(SR, [[1, 0, 0], [1, 1, 0], [0, 0, 1]])
E3inv=Matrix(SR, [[1, 0, 0], [0, 1, 0], [4, 0, 1]])
E4inv=Matrix(SR, [[1, 0, 0], [0, -1/2, 0], [0, 0, 1]])
E5inv=Matrix(SR, [[1, 0, 0], [0, 1, 0], [0, 0, -5]])
E6inv=Matrix(SR, [[1, 0, 0], [0, 1, 1], [0, 0, 1]])
E7inv=Matrix(SR, [[1, 0, 3/2], [0, 1, 0], [0, 0, 1]])
E8inv=Matrix(SR, [[1, 1/2, 0], [0, 1, 0], [0, 0, 1]])
bool(A==E1inv*E2inv*E3inv*E4inv*E5inv*E6inv*E7inv*E8inv)
```

Execute this program yourselves to verify that Sage's output is True. □

*Sage provides built-in functions to explore elementary matrices, which we can list as follows:*

- *The matrix which multiplies the  $k$ th row by  $c$ :*  
`elementary_matrix(R, n, row1 = k, scale = c)`
- *The matrix which multiplies the  $k$ th row by  $c$  and adds it to the  $m$ th row:*  
`elementary_matrix(R, n, row1 = k, row2 = m, scale = c)`
- *The matrix which swaps the  $k$ th and  $m$ th rows:*  
`elementary_matrix(R, n, row1 = k, row2 = m)`

*In each case,  $R$  is the base ring, and is optional, while  $n$  denotes the size of the square matrix.*

**2.E.5.** Use Sage to describe the elementary matrices  $E_1, \dots, E_8$  obtained in 2.E.4, using the commands mentioned above. Compute their inverses, as well. ○

**2.E.6.** Solve the system of linear equations given by the extended matrix  $B = (A \mid b) = \left( \begin{array}{cccc|c} 3 & 3 & 2 & 1 & 3 \\ 2 & 1 & 1 & 0 & 4 \\ 0 & 5 & -4 & 3 & 1 \\ 5 & 3 & 3 & -3 & 5 \end{array} \right)$ . ○

**2.E.7.** Provide a formal solution of the linear system given below. Next use Sage to verify your solution:

$$\begin{cases} x_1 + x_2 + x_3 + x_4 - 2x_5 = 3, \\ 2x_2 + 2x_3 + 2x_4 - 4x_5 = 5, \\ -x_1 - x_2 - x_3 + x_4 + 2x_5 = 0, \\ -2x_1 + 3x_2 + 3x_3 - 6x_5 = 2. \end{cases}$$

**Solution.** The extended matrix of the system is

$$B = (A \mid b) = \left( \begin{array}{ccccc|c} 1 & 1 & 1 & 1 & -2 & 3 \\ 0 & 2 & 2 & 2 & -4 & 5 \\ -1 & -1 & -1 & 1 & 2 & 0 \\ -2 & 3 & 3 & 0 & -6 & 2 \end{array} \right).$$

Adding the first row to the third, adding its 2-multiple to the fourth, and adding the  $(-5/2)$ -multiple of the second to the fourth we obtain

$$B \sim \left( \begin{array}{ccccc|c} 1 & 1 & 1 & 1 & -2 & 3 \\ 0 & 2 & 2 & 2 & -4 & 5 \\ 0 & 0 & 0 & 2 & 0 & 3 \\ 0 & 5 & 5 & 2 & -10 & 8 \end{array} \right) \sim \left( \begin{array}{ccccc|c} 1 & 1 & 1 & 1 & -2 & 3 \\ 0 & 2 & 2 & 2 & -4 & 5 \\ 0 & 0 & 0 & 2 & 0 & 3 \\ 0 & 0 & 0 & -3 & 0 & -9/2 \end{array} \right).$$

The last row is clearly a multiple of the previous one, and thus we can omit it. The pivots are located in the first, second and fourth, while  $x_3$  and  $x_5$  are free variables, which we substitute by the real parameters  $t$  and  $s$ . Thus we consider the system

$$\begin{aligned} x_1 + x_2 + t + x_4 - 2s &= 3, \\ 2x_2 + 2t + 2x_4 - 4s &= 5, \\ 2x_4 &= 3. \end{aligned}$$

We see that  $x_4 = 3/2$ , and hence the second equation gives  $x_2 = 1 - t + 2s$ . From the first equation we now obtain  $x_1 = 1/2$ . This gives the expression  $(x_1, x_2, x_3, x_4, x_5) = (1/2, 1 - t + 2s, t, 3/2, s)$  with  $t, s \in \mathbb{R}$ . Note that setting  $t_0 = -t + 2s$  and  $t_1 = t - s$ , the solution takes the forms  $(1/2, 1 + t_0, t_0 + 2t_1, 3/2, t_0 + t_1)$ , with  $t_0, t_1 \in \mathbb{R}$ .

As an alternative method, one could transform the extended matrix  $B$  to reduced row echelon form. In this procedure, we can omit the fourth equation since it is a combination of the first three. By sequentially multiplying the second and third rows by  $1/2$ , subtracting the third row from the second and first rows, and finally subtracting the second row from the first, we obtain the following:

$$B \sim \left( \begin{array}{ccccc|c} 1 & 1 & 1 & 1 & -2 & 3 \\ 0 & 2 & 2 & 2 & -4 & 5 \\ 0 & 0 & 0 & 2 & 0 & 3 \end{array} \right) \sim \left( \begin{array}{ccccc|c} 1 & 1 & 1 & 1 & -2 & 3 \\ 0 & 1 & 1 & 1 & -2 & 5/2 \\ 0 & 0 & 0 & 1 & 0 & 3/2 \end{array} \right) \sim \left( \begin{array}{ccccc|c} 1 & 1 & 1 & 0 & -2 & 3/2 \\ 0 & 1 & 1 & 0 & -2 & 1 \\ 0 & 0 & 0 & 1 & 0 & 3/2 \end{array} \right) \sim \left( \begin{array}{ccccc|c} 1 & 0 & 0 & 0 & 0 & 1/2 \\ 0 & 1 & 1 & 0 & -2 & 1 \\ 0 & 0 & 0 & 1 & 0 & 3/2 \end{array} \right).$$

This confirms that  $x_3, x_5$  are free variables, i.e.,  $x_3 = t, x_5 = s$  with  $t, s \in \mathbb{R}$ . Moreover, a short computation yields the solution presented above. These computations, particularly the (unique) reduced row echelon form of the extended matrix  $B$  and the given solution, can be obtained in Sage by applying the method proposed in 2.A.13. In particular, the commands `B.rref()` and `B.pivots()` appearing in the block below, return the reduced row echelon form of  $B$  and the pivot columns, respectively.

```
A=matrix([[1, 1, 1, 1, -2], [0, 2, 2, 2, -4],
[-1, -1, -1, 1, 2], [-2, 3, 3, 0, -6]])
b=vector([3, 5, 0, 2]); B=A.augment(b)
Br=B.rref(); show(Br); B.pivots()
x=A.solve_right(b)
k=A.right_kernel().matrix()
nrows = k.nrows()
```

```

if nrows > 0:
    t = vector ( var("t", n= nrows ))
    show (x + t*k)
else:
    show (x)
    
```

Sage's output has the form  $(\frac{1}{2}, t_0 + 1, t_0 + 2t_1, \frac{3}{2}, t_0 + t_1)$ , with  $t_0, t_1 \in \mathbb{R}$ , and this verifies our formal computations.  $\square$

**2.E.8.** Find all the solutions of the following homogeneous system of four linear equations and five unknowns  $x, y, z, u, v$ :

$$\{x + y = 2z + v, \quad z + 4u + v = 0, \quad -3u = 0, \quad z = -v\}.$$

Moreover, specify a basis of the vector space of solutions.

**Solution.** Let us first rewrite the system into the matrix form  $A\mathbf{x} = 0$ , where here  $\mathbf{x} = (x, y, z, u, v)^T \in \mathbb{R}^5$ , and as usual the first column of  $A$  consists of the coefficients of  $x$ , the second column of the coefficients of  $y$ , and so on. This gives

$$A = \begin{pmatrix} 1 & 1 & -2 & 0 & -1 \\ 0 & 0 & 1 & 4 & 1 \\ 0 & 0 & 0 & -3 & 0 \\ 0 & 0 & 1 & 0 & 1 \end{pmatrix}.$$

Such homogeneous systems with less (linear) equations than unknowns are called *underdetermined* and admit an infinite number of solutions. Indeed, let us compute the reduced row echelon form of  $A$ . For this, let us denote by  $R_1, R_2, R_3, R_4$  the rows at any step of the procedure. We see that

$$\begin{pmatrix} 1 & 1 & -2 & 0 & -1 \\ 0 & 0 & 1 & 4 & 1 \\ 0 & 0 & 0 & -3 & 0 \\ 0 & 0 & 1 & 0 & 1 \end{pmatrix} \xrightarrow{R_2 \rightarrow R_2 + \frac{4}{3} \cdot R_3} \begin{pmatrix} 1 & 1 & -2 & 0 & -1 \\ 0 & 0 & 1 & 0 & 1 \\ 0 & 0 & 0 & -3 & 0 \\ 0 & 0 & 1 & 0 & 1 \end{pmatrix} \xrightarrow{R_4 \rightarrow R_4 - R_2} \begin{pmatrix} 1 & 1 & -2 & 0 & -1 \\ 0 & 0 & 1 & 0 & 1 \\ 0 & 0 & 0 & -3 & 0 \\ 0 & 0 & 0 & 0 & 0 \end{pmatrix}$$

$$\xrightarrow{R_3 \rightarrow -\frac{1}{3} \cdot R_3} \begin{pmatrix} 1 & 1 & -2 & 0 & -1 \\ 0 & 0 & 1 & 0 & 1 \\ 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & 0 \end{pmatrix} \xrightarrow{R_1 \rightarrow R_1 + 2 \cdot R_2} \begin{pmatrix} 1 & 1 & 0 & 0 & 1 \\ 0 & 0 & 1 & 0 & 1 \\ 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & 0 \end{pmatrix}.$$

The final matrix is in reduced row echelon form. Recall that in Sage we can achieve this form in two ways: by applying the command `A.rref()`, or by manually performing the necessary elementary row operations. Let us demonstrate both methods using matrices over  $\mathbb{Q}$  instead of  $\mathbb{R}$ , for convenience, as this not affect the result.

```

A=matrix(QQ, [[1, 1, -2, 0, -1], [0, 0, 1, 4, 1],
[0, 0, 0, -3, 0],[0, 0, 1, 0, 1]])
show(A.rref())
    
```

The output is the same as the one obtained by executing the following block:

```

A=matrix(QQ, [[1, 1, -2, 0, -1], [0, 0, 1, 4, 1],
[0, 0, 0, -3, 0],[0, 0, 1, 0, 1]])
A.add_multiple_of_row(1, 2, 4/3);show(A)
A.add_multiple_of_row(3, 1, -1);show(A)
A.rescale_row(2, -1/3);show(A)
A.add_multiple_of_row(0, 1, 2);show(A)
    
```

where recall that elementary row operations should be applied successively.

Running any of these blocks verifies that our computations are accurate. Therefore, we can now pose the system  $\{x + y + v = 0, z + v = 0, u = 0\}$ , where the variable  $y, v$  are free (they correspond to the 2nd and 5th column of the REEF, since these columns do not contain a pivot). Hence, let us set  $y = t$ , and  $v = s$  with  $t, s \in \mathbb{R}$  and derive the solution by back substitution:

$$(x, y, z, u, v) = (-t - s, t, -s, 0, s), \quad t, s \in \mathbb{R}.$$

Obviously, we can rewrite the solution as

$$\begin{pmatrix} x \\ y \\ z \\ u \\ v \end{pmatrix} = t \begin{pmatrix} -1 \\ 1 \\ 0 \\ 0 \\ 0 \end{pmatrix} + s \begin{pmatrix} -1 \\ 0 \\ -1 \\ 0 \\ 1 \end{pmatrix}, \quad t, s \in \mathbb{R}.$$

It easy to prove that the vectors in the right-hand side are linearly independent, and thus they form a basis of the solution space. In other words, the kernel of the matrix  $A$  is a 2-dimensional subspace of  $\mathbb{R}^5$ .  $\square$

**2.E.9.** Determine all solutions of the following linear system:

$$\begin{cases} x_2 + x_4 = 1, \\ 3x_1 - 2x_2 - 3x_3 + 4x_4 = -2, \\ x_1 + x_2 - x_3 + x_4 = 2, \\ x_1 - x_3 = 1. \end{cases}$$

**2.E.10.** Solve the following linear system:

$$\begin{cases} 3x - 5y + 2u + 4z = 2, \\ 5x + 7y - 4u - 6z = 3, \\ 7x - 4y + u + 3z = 4, \\ x + 6y - 2u - 5z = 2. \end{cases}$$

**2.E.11.** Consider the following linear system:

$$\begin{cases} x_1 + x_2 - x_3 = 1, \\ x_1 + 2x_2 + \kappa x_3 = 2, \\ 2x_1 + \kappa x_2 + 2x_3 = 3. \end{cases}$$

Determine the values of the real parameter  $\kappa$  such that

- (a) the system has a unique solution;
- (b) the system has infinitely many solutions;
- (c) the system has no solution.

For the cases (a) and (b) determine the corresponding solutions.

**Solution.** The extended matrix of the system has the form

$$B = (A \mid b) = \left( \begin{array}{ccc|c} 1 & 1 & -1 & 1 \\ 1 & 2 & \kappa & 2 \\ 2 & \kappa & 2 & 3 \end{array} \right).$$

By applying elementary row operations we obtain that

$$B = \left( \begin{array}{ccc|c} 1 & 1 & -1 & 1 \\ 1 & 2 & \kappa & 2 \\ 2 & \kappa & 2 & 3 \end{array} \right) \begin{array}{l} R_2 \rightarrow R_2 - R_1 \\ R_3 \rightarrow R_3 - 2R_1 \end{array} \left( \begin{array}{ccc|c} 1 & 1 & -1 & 1 \\ 0 & 1 & \kappa + 1 & 1 \\ 0 & \kappa - 2 & 4 & 1 \end{array} \right) \begin{array}{l} R_3 \rightarrow R_3 - (\kappa - 2)R_2 \end{array} \\ \left( \begin{array}{ccc|c} 1 & 1 & -1 & 1 \\ 0 & 1 & \kappa + 1 & 1 \\ 0 & 0 & 4 - (\kappa + 1)(\kappa - 2) & 3 - \kappa \end{array} \right).$$

The above matrix is in row echelon form and we can rewrite it as

$$B \sim \left( \begin{array}{ccc|c} 1 & 1 & -1 & 1 \\ 0 & 1 & \kappa + 1 & 1 \\ 0 & 0 & -\kappa^2 + \kappa + 6 & 3 - \kappa \end{array} \right) = \left( \begin{array}{ccc|c} 1 & 1 & -1 & 1 \\ 0 & 1 & \kappa + 1 & 1 \\ 0 & 0 & (\kappa - 3)(\kappa + 2) & 3 - \kappa \end{array} \right). \quad (*)$$

Hence we deduce that:

(a) The system has a unique solution when  $\kappa \neq 3$  and  $\kappa \neq -2$ . Indeed, in this case we obtain

$$\begin{cases} x_1 + x_2 - x_3 = 1, \\ x_2 + (\kappa + 1)x_3 = 1, \\ (2 + \kappa)(3 - \kappa)x_3 = 3 - \kappa. \end{cases}$$

Therefore, by back substitution we obtain the solution  $(x_1, x_2, x_3)^T = (1, \frac{1}{2+\kappa}, \frac{1}{2+\kappa})^T$ .

(b) The system has infinite many solutions when  $\kappa = 3$ , since then the last row of the row echelon form presented in (\*) has only zeros, the pivots belong to the first and second column, and  $x_3$  is a free variable. Hence in this case we obtain the system

$$\begin{cases} x_1 + x_2 - x_3 = 1, \\ x_2 + 4x_3 = 1, \end{cases}$$

with  $x_3 = t \in \mathbb{R}$ , having infinite many solutions given by  $(x_1, x_2, x_3)^T = (5t, 1 - 4t, t)^T$ , ( $t \in \mathbb{R}$ ). Note that we may express these solutions as  $(x_1, x_2, x_3)^T = t(5, -4, 1)^T + (0, 1, 0)^T$ . Thus, when  $\kappa = 3$  the space of all solutions is given by summing all solutions of the corresponding homogeneous system, given by  $t(5, -4, 1)^T$ , with a particular solution of the original system, given by  $(0, 1, 0)^T$ .

(c) The system is inconsistent when  $\kappa = -2$ . Indeed, for this value of  $\kappa$  the third row of the matrix in the right-hand side of (\*) gives us  $0x_3 = 5$ , which is impossible.  $\square$

2.E.12. Solve the following parametric system of linear equations in terms of the parameter  $\mu \in \mathbb{R}$ :

$$\begin{cases} \mu x_1 + 4x_2 + 2x_3 = 0, \\ 2x_1 + 3x_2 - x_3 = 0. \end{cases}$$

2.E.13. Determine the number of solutions of the following parametric linear system, in terms of the parameter  $a \in \mathbb{R}$ :

$$\begin{pmatrix} 4 & 1 & 4 & a \\ 2 & 3 & 6 & 8 \\ 3 & 2 & 5 & 4 \\ 6 & -1 & 2 & -8 \end{pmatrix} \begin{pmatrix} x_1 \\ x_2 \\ x_3 \\ x_4 \end{pmatrix} = \begin{pmatrix} 2 \\ 5 \\ 3 \\ -3 \end{pmatrix}.$$

2.E.14. Consider the following parametric system of linear equations:

$$\begin{cases} x_1 - a x_2 - 2x_3 = b, \\ x_1 + (1-a)x_2 = b-3, \\ x_1 + (1-a)x_2 + a x_3 = 2b-1. \end{cases}$$

Find the values of the parameters  $a, b \in \mathbb{R}$ , such that:

- (a) the system has exactly one solution;
- (b) the system has no solution;
- (c) the system has infinitely many solutions.

Let us now explore an important application of linear systems in the analysis of electric circuits. This description relies on Ohm's law, the Kirchhoff's voltage and the current laws, providing an opportunity to revisit some concepts from high school physics. Readers not interested in these applications can skip this task.

2.E.15. **Kirchhoff's Circuit Laws.** Consider an electric circuit as in the figure and write down the values of the currents there if you know the values  $V_1 = 20$ ,  $V_2 = 120$ ,  $V_3 = 50$ ,  $R_1 = 10$ ,  $R_2 = 30$ ,  $R_3 = 4$ ,  $R_4 = 5$ ,  $R_5 = 10$ . Notice that the quantities  $I_i$  denote the electric currents, while  $R_j$  are resistances, and  $V_k$  are voltages.

**Solution.** There are two closed loops, namely  $ABEF$  and  $EBCD$  and two branching vertices  $B$  and  $E$  of degree no less than 3. On every segment of the circuit, bounded by branching points, the electric current is constant. Let us set this  $I_1$  for the segment  $EFAB$ ,  $I_2$  for  $EB$ , and  $I_3$  for  $BCDE$ .

Applying Kirchhoff's current law to branching points  $B$  and  $E$  we obtain:  $I_1 + I_2 = I_3$  and  $I_3 - I_1 = I_2$ , which are, of course the same equations. In case there are many branching vertices, we write all Kirchhoff's Current Law equations to the system, having at least one of those equations redundant. Choose the counter clockwise orientations of the loops  $ABEF$  and  $EBCD$ . Applying Kirchhoff Voltage Law and Ohm's Law to the loop  $ABEF$  we obtain the equation:

$$V_1 + I_1 R_3 - I_2 R_5 + V_3 + I_1 R_1 + I_1 R_4 = 0.$$

Similarly, the loop  $EBCD$  implies  $-V_2 + I_3R_2 - V_3 + R_5I_2 = 0$ . A combination of all equations yields the following system of linear equations:

$$\begin{cases} I_1 + I_2 - I_3 = 0, \\ (R_3 + R_1 + R_4)I_1 - R_5I_2 + I_3 = -V_1 - V_3, \\ R_5I_2 + R_2I_3 = V_2 + V_3. \end{cases}$$

Using the prescribed values, this finally reduce to

$$\begin{cases} I_1 + I_2 - I_3 = 0, \\ 19I_1 - 10I_2 + I_3 = -70, \\ 10I_2 + 30I_3 = 170. \end{cases}$$

It is easy to see that this has a unique solution, given by  $I_1 = -\frac{80}{53} \approx -1.509$ ,  $I_2 = \frac{219}{53} \approx 4.132$ ,  $I_3 = \frac{139}{53} \approx 2.623$ .  $\square$

**2.E.16. The general case.** In general, the method for electrical circuit analysis can be formulated along the following steps:

- ( $\alpha$ ) Identify all *branching vertices* of the circuit, i.e., vertices of degree no less than 3;
- ( $\beta$ ) Identify all *closed loops* of the circuit;
- ( $\gamma$ ) Introduce variables  $I_k$ , denoting the *oriented currents* on each segment of the circuit between two branching vertices;
- ( $\delta$ ) Write down the *Kirchhoff's current conservation law* for each branching vertex. The total incoming current equals the total outgoing current;
- ( $\varepsilon$ ) Choose an orientation on every closed loop of the circuit and write down the *Kirchhoff's voltage conservation law*, according to the chosen orientation. Here, in case you find an electric charge of voltage  $V_j$  and you go from the short bar to the long bar, then the contribution of this charge is  $V_j$ . It should be  $-V_j$  in case you go from the long bar to the short one. Notice also that if you go in the positive direction of a current  $I$  and find a resistor with resistance  $R_j$ , then the contribution is  $-R_jI$ , and it is  $R_jI$  if the orientation of the loop is opposite to the direction of the current  $I$ . The total voltage change along each closed loop must be zero.
- ( $\zeta$ ) Compose the system collecting all equations, representing the Kirchhoff's current and voltage laws and solve it with respect to the variables, representing the currents. Notice that some equations may be redundant, however, the solution should be unique!

To illustrate this general approach, consider the circuit example in the diagram below.

**Solution.** Let us apply the steps posed above:

- ( $\alpha$ ) The set of branching vertices is  $\{B, C, F, G, H\}$ .
- ( $\beta$ ) The set of closed loops is  $\{ABHG, FHBC, GHF, CDEF\}$ .
- ( $\gamma$ ) Let  $I_1$  be the current on the segment  $GAB$ ,  $I_2$  on the segment  $GH$ ,  $I_3$  on the segment  $HB$ ,  $I_4$  on the segment  $BC$ ,  $I_5$  on the segment  $FC$ ,  $I_6$  on the segment  $FH$ ,  $I_7$  on  $GF$ , and  $I_8$  on  $CDEF$ .
- ( $\delta$ ) Next we write the Kirchhoff's current conservation laws for the branching vertices:

$$B : I_1 + I_3 = I_4, \quad C : I_4 + I_5 = I_8, \quad F : I_8 = I_5 + I_6 - I_7, \quad G : -I_7 = I_1 + I_2, \quad H : I_2 + I_6 = I_3.$$

Notice that the second and third equations give  $I_8 - I_5 = I_4$  and  $I_8 - I_5 = I_6 - I_7$ , respectively. Hence we can replace any of them by the equation  $I_4 = I_6 - I_7$ .

- ( $\varepsilon$ ) Let us now write Kirchhoff's voltage conservation for each of the closed loops traversed counter-clockwise:

$$\begin{aligned} \text{loop } ABHG : -R_1I_2 + V_3 + R_2I_1 - V_2 &= 0, & \text{loop } GHF : R_1I_2 - V_1 &= 0, \\ \text{loop } FHBC : V_4 + R_3I_4 - V_3 &= 0, & \text{loop } CDEF : R_4I_8 - V_4 &= 0. \end{aligned}$$

- ( $\zeta$ ) To pass to the final step we need to use some specific values for  $R_i, V_i$  for  $i = 1, \dots, 4$ . Setting  $R_1 = 4, R_2 = 7, R_3 = 9, R_4 = 12, V_1 = 10, V_2 = 20, V_3 = 60$  and  $V_4 = 120$ , we get a unique solution (although the system is overdetermined!)

$$I_1 = -\frac{30}{7}, I_2 = \frac{5}{2}, I_3 = -\frac{50}{21}, I_4 = -\frac{20}{3}, I_5 = \frac{50}{3}, I_6 = -\frac{205}{42}, I_7 = \frac{25}{14}, I_8 = 10.$$

Below we present the solution in Sage, where first we should introduce the unknowns  $I_1, \dots, I_8$  as symbolic variables.

```
var("I1, I2, I3, I4, I5, I6, I7, I8")
eq1=I1+I3-I4; eq2=I4+I5-I8
eq3=I5+I6-I7-I8; eq4=I1+I2+I7
eq5=I2-I3+I6; eq6=7*I1-4*I2+40
eq7=9*I4+60; eq8=4*I2-10
eq9=12*I8-120
show(solve([eq1, eq2, eq3, eq4, eq5, eq6, eq7, eq8, eq9],
[I1, I2, I3, I4, I5, I6, I7, I8]))
```

□

### B) MATERIAL ON DETERMINANTS

**2.E.17.** Factor the following permutations into a product of transpositions:

$$\sigma = \begin{pmatrix} 1 & 2 & 3 & 4 & 5 & 6 & 7 \\ 7 & 6 & 5 & 4 & 3 & 2 & 1 \end{pmatrix}, \quad \tau = \begin{pmatrix} 1 & 2 & 3 & 4 & 5 & 6 & 7 & 8 \\ 6 & 4 & 1 & 2 & 5 & 8 & 3 & 7 \end{pmatrix}, \quad \rho = \begin{pmatrix} 1 & 2 & 3 & 4 & 5 & 6 & 7 & 8 & 9 & 10 \\ 4 & 6 & 1 & 10 & 2 & 5 & 9 & 8 & 3 & 7 \end{pmatrix}.$$

○

**2.E.18.** Determine the parity of the following permutations:

$$\sigma = \begin{pmatrix} 1 & 2 & 3 & 4 & 5 & 6 & 7 \\ 7 & 5 & 6 & 4 & 1 & 2 & 3 \end{pmatrix}, \quad \tau = \begin{pmatrix} 1 & 2 & 3 & 4 & 5 & 6 & 7 & 8 \\ 6 & 7 & 1 & 2 & 3 & 8 & 4 & 5 \end{pmatrix}, \quad \rho = \begin{pmatrix} 1 & 2 & 3 & 4 & 5 & 6 & 7 & 8 & 9 & 10 \\ 9 & 7 & 1 & 10 & 2 & 5 & 4 & 9 & 3 & 6 \end{pmatrix}.$$

○

**2.E.19.** For the matrix  $A$  shown below, determine all values of the complex parameter  $a \in \mathbb{C}$  that satisfy  $\det(A) = 1$ :

$$A = \begin{pmatrix} a & 1 & 1 & 1 \\ 0 & a & 1 & 1 \\ 0 & 1 & a & 1 \\ 0 & 0 & 0 & -a \end{pmatrix}.$$

**Solution.** Let us compute the determinant of  $A$  by expanding the first column of the matrix:

$$\det(A) = \begin{vmatrix} a & 1 & 1 & 1 \\ 0 & a & 1 & 1 \\ 0 & 1 & a & 1 \\ 0 & 0 & 0 & -a \end{vmatrix} = a \cdot \begin{vmatrix} a & 1 & 1 \\ 1 & a & 1 \\ 0 & 0 & -a \end{vmatrix} = -a^4 + a^2.$$

In Sage we can verify this computation by the cell

```
var("a")
A=matrix([[a, 1, 1, 1], [0, a, 1, 1], [0, 1, a, 1], [0, 0, 0, -a]]); det(A)
```

Thus, the equation  $\det(A) = 1$  is equivalent to  $a^4 - a^2 + 1 = 0$ . Substituting  $t = a^2$  we obtain  $t^2 - t + 1$  with roots

$$t_1 = \frac{1 + i\sqrt{3}}{2} = \cos(\pi/3) + i \sin(\pi/3), \quad t_2 = \frac{1 - i\sqrt{3}}{2} = \cos(\pi/3) - i \sin(\pi/3) = \cos(-\pi/3) + i \sin(-\pi/3).$$

Therefore, there are four possible values for the parameter  $a$ :

$$a_1 = \cos(\pi/6) + i \sin(\pi/6) = \sqrt{3}/2 + i/2, \quad a_2 = \cos(7\pi/6) + i \sin(7\pi/6) = -\sqrt{3}/2 - i/2, \\ a_3 = \cos(-\pi/6) + i \sin(-\pi/6) = \sqrt{3}/2 - i/2, \quad a_4 = \cos(5\pi/6) + i \sin(5\pi/6) = -\sqrt{3}/2 + i/2.$$

Of course, solving the equation  $\det(A) = 1$  with Sage is straightforward. Simply add the code `solve(det(A) == 1, a)` to the previous cell. This provides a fast way to verify the result.

Note that there is an alternative way to specify the possible values of  $a$ . For this, multiply the equation  $\det(A) = 1$ , i.e., the equation  $a^4 - a^2 + 1 = 0$  by  $a^2 + 1$ . This gives  $0 = (a^2 + 1)(a^4 - a^2 + 1) = a^6 + 1$ , and the idea is that we can easier treat the equation  $a^6 + 1$ , comparing the original equation. Indeed, recall by 1.G.17 that the equation  $a^6 = -1$  has six complex solutions, which can be presented as

$$a = \cos \varphi + i \sin \varphi, \quad \text{where } \varphi = \pi/6 + k\pi/3 = (2k + 1)\pi/6, \quad k = 0, 1, 2, 3, 4, 5.$$

Between them, we must discard the two choices  $k = 1$  and  $k = 4$ , since these choices solve  $a^2 + 1 = 0$ , and not our equation  $a^4 - a^2 + 1 = 0$ . Hence we conclude that  $a = \cos \varphi + i \sin \varphi$  with  $\varphi = (2k + 1)\pi/6$ , for  $k = 0, 2, 3$ , and  $k = 5$ .  $\square$

**2.E.20.** Establish whether the following matrix is invertible:

$$A = \begin{pmatrix} 3 & 2 & -1 & 2 \\ 4 & 1 & 2 & -4 \\ -2 & 2 & 4 & 1 \\ 2 & 3 & -4 & 8 \end{pmatrix}.$$

**Solution.** We just need to compute  $\det(A)$ . We will apply Laplace theorem (see 2.2.9) by expanding the first row of the given matrix. This gives

$$\begin{aligned} \det(A) &= 3 \cdot \begin{vmatrix} 1 & 2 & -4 \\ 2 & 4 & 1 \\ 3 & -4 & 8 \end{vmatrix} - 2 \cdot \begin{vmatrix} 4 & 2 & -4 \\ -2 & 4 & 1 \\ 2 & -4 & 8 \end{vmatrix} + (-1) \cdot \begin{vmatrix} 4 & 1 & -4 \\ -2 & 2 & 1 \\ 2 & 3 & 8 \end{vmatrix} - 2 \cdot \begin{vmatrix} 4 & 1 & 2 \\ -2 & 2 & 4 \\ 2 & 3 & -4 \end{vmatrix} \\ &= 3 \cdot 90 - 2 \cdot 180 - 1 \cdot 110 - 2 \cdot (-100) = 0. \end{aligned}$$

Thus  $\det(A) = 0$  and  $A$  cannot be invertible. As a verification by Sage, give the cell

```
A=matrix([[3, 2, -1, 2], [4, 1, 2, -4], [-2, 2, 4, 1], [2, 3, -4, 8]])
det(A)
```

Note that giving the command `A.inverse()`, Sage will return an error, since  $A$  is singular, i.e.,  $\det(A) = 0$ .  $\square$

We now present the determinant of the famous “Vandermonde matrix”. The Vandermonde matrix  $V_n = (V_{ij})$  is the square matrix of size  $n$ , with columns formed by the powers of a given vector  $x = (x_1, \dots, x_n)^T \in \mathbb{R}^n$ , i.e.,  $V_{ij} = x_i^{j-1}$  for  $i, j = 1, \dots, n$ , see below. This matrix is fundamental in both pure and applied mathematics. For example, in Chapter 5, we will explore its role in polynomial interpolation (see 5.1.5). Beyond mathematics, Vandermonde matrices are also significant in the natural sciences, particularly in economics and statistics.

**2.E.21. Vandermonde determinant.** The matrix

$$V_n := \begin{pmatrix} 1 & 1 & \dots & 1 \\ x_1 & x_2 & \dots & x_n \\ x_1^2 & x_2^2 & \dots & x_n^2 \\ \vdots & \vdots & & \vdots \\ x_1^{n-1} & x_2^{n-1} & \dots & x_n^{n-1} \end{pmatrix},$$

where  $x_1, \dots, x_n \in \mathbb{R}$ , is the so called Vandermonde matrix. Prove that  $\det(V_n) = \prod_{1 \leq i < j \leq n} (x_j - x_i)$ .

**Solution.** The determinant will be a polynomial on  $x_1, \dots, x_n$ , which we may denote by  $V_n(x_1, \dots, x_n) = \det(V_n)$ . Notice for  $n = 2$  the claim holds trivially. We will proceed by induction on  $n$ . In fact we can work with the transposed Vandermonde matrix  $V_n^T$ , which satisfies

$$\det(V_n^T) = \det(V_n) = V_n(x_1, \dots, x_n), \quad n = 1, 2, \dots$$

By subtracting the first row from all other rows and then expanding the first column we obtain

$$V_n(x_1, x_2, \dots, x_n) = \begin{vmatrix} 1 & x_1 & x_1^2 & \dots & x_1^{n-1} \\ 0 & x_2 - x_1 & x_2^2 - x_1^2 & \dots & x_2^{n-1} - x_1^{n-1} \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 0 & x_n - x_1 & x_n^2 - x_1^2 & \dots & x_n^{n-1} - x_1^{n-1} \end{vmatrix} = \begin{vmatrix} x_2 - x_1 & x_2^2 - x_1^2 & \dots & x_2^{n-1} - x_1^{n-1} \\ \vdots & \vdots & \ddots & \vdots \\ x_n - x_1 & x_n^2 - x_1^2 & \dots & x_n^{n-1} - x_1^{n-1} \end{vmatrix}.$$

Let us now take out  $x_{i+1} - x_1$  from the  $i$ -th row, for all  $i \in \{1, 2, \dots, n-1\}$ . Then we deduce that

$$V_n(x_1, x_2, \dots, x_n) = (x_2 - x_1) \cdots (x_n - x_1) \cdot \begin{vmatrix} 1 & x_2 + x_1 & \dots & \sum_{j=0}^{n-2} x_2^{n-j-2} x_1^j \\ \vdots & \vdots & \ddots & \vdots \\ 1 & x_n + x_1 & \dots & \sum_{j=0}^{n-2} x_n^{n-j-2} x_1^j \end{vmatrix}.$$

By subtracting from every column the  $x_1$ -multiple of the previous column, starting with the last and ending with the second one, we obtain

$$\begin{vmatrix} 1 & x_2 + x_1 & \cdots & \sum_{j=0}^{n-2} x_2^{n-j-2} x_1^j \\ \vdots & \vdots & \ddots & \vdots \\ 1 & x_n + x_1 & \cdots & \sum_{j=0}^{n-2} x_n^{n-j-2} x_1^j \end{vmatrix} = \begin{vmatrix} 1 & x_2 & \cdots & x_2^{n-2} \\ \vdots & \vdots & \ddots & \vdots \\ 1 & x_n & \cdots & x_n^{n-2} \end{vmatrix}.$$

Therefore, if for simplicity set  $V_n = V_n(x_1, x_2, \dots, x_n)$ , we see that  $V_n = (x_2 - x_1) \cdots (x_n - x_1) \cdot V_{n-1}(x_2, \dots, x_n)$ . Now, it is clear that  $V_2(x_{n-1}, x_n) = x_n - x_{n-1}$ , and thus by induction it follows that  $V_n(x_1, x_2, \dots, x_n) = \prod_{1 \leq i < j \leq n} (x_j - x_i)$ .

Observe that the determinant is non-zero, whenever the numbers  $x_1, \dots, x_n$  are mutually distinct. For an alternative proof of this classical result we refer to 5.1.5.  $\square$

**2.E.22. Vandermonde matrix in Sage.** Compute in Sage the determinant of a  $3 \times 3$  Vandermonde matrix  $V_3(x_1, x_2, x_3)$  using appropriately the `matrix.vandermonde` command.

**Solution.** To use the `matrix.vandermonde` command in Sage we need to specify first a vector. Since the task requires a general  $3 \times 3$  Vandermonde matrix, this vector should be of size  $3 \times 1$  and symbolic. Note also that the `matrix.vandermonde` command returns the transpose of the Vandermonde matrix. Hence, for  $n = 3$  one can use the following code block:

```
var("x1", "x2", "x3")
x=vector([x1, x2, x3])
V3=matrix.vandermonde(x, ring=None)
show(V3.T)
show("The determinant of the Vandermonde matrix is given by:", det(V3.T).factor())
```

Sage generates the desired matrix  $V_3(x_1, x_2, x_3)$ ,

$$\begin{pmatrix} 1 & 1 & 1 \\ x_1 & x_2 & x_3 \\ x_1^2 & x_2^2 & x_3^2 \end{pmatrix},$$

and also provides the result for its determinant, as shown below:

The determinant of the Vandermonde matrix is given by:  $-(x_1 - x_2)(x_1 - x_3)(x_2 - x_3)$ .

An alternative goes as follows:

```
A=matrix.vandermonde(SR.var(["x1", "x2", "x3"]))
show(A.T); show(det(A.T).factor())
```

$\square$

**2.E.23.** Use two different methods to solve the linear system

$$\begin{cases} x_1 + x_2 + x_3 + x_4 = 2, \\ x_1 + x_2 - x_3 - x_4 = 3, \\ x_1 - x_2 + x_3 - x_4 = 3, \\ x_1 - x_2 - x_3 + x_4 = 5. \end{cases}$$

Hints: Solve the system by computing the inverse of the coefficient matrix. Another method is based on the Cramer's rule.

**Solution.** In matrix notation we have  $Ax = b$ , where

$$A = \begin{pmatrix} 1 & 1 & 1 & 1 \\ 1 & 1 & -1 & -1 \\ 1 & -1 & 1 & -1 \\ 1 & -1 & -1 & 1 \end{pmatrix}, \quad x = \begin{pmatrix} x_1 \\ x_2 \\ x_3 \\ x_4 \end{pmatrix}, \quad b = \begin{pmatrix} 2 \\ 3 \\ 3 \\ 5 \end{pmatrix},$$

respectively. We compute  $\det(A) = -16$ , hence  $A$  is invertible and the linear system has a unique solution which occurs by multiplying the matrix equation  $Ax = b$  by  $A^{-1}$  from the left, i.e.,  $x = A^{-1}b$ . Thus, it suffices to compute the inverse of  $A$  and next do the matrix multiplication  $A^{-1}b$ . We see that

$$A^{-1} = \begin{pmatrix} \frac{1}{4} & \frac{1}{4} & \frac{1}{4} & \frac{1}{4} \\ \frac{1}{4} & \frac{1}{4} & -\frac{1}{4} & -\frac{1}{4} \\ \frac{1}{4} & -\frac{1}{4} & \frac{1}{4} & -\frac{1}{4} \\ \frac{1}{4} & -\frac{1}{4} & -\frac{1}{4} & \frac{1}{4} \end{pmatrix} \implies x = A^{-1}b = \begin{pmatrix} \frac{1}{4} & \frac{1}{4} & \frac{1}{4} & \frac{1}{4} \\ \frac{1}{4} & \frac{1}{4} & -\frac{1}{4} & -\frac{1}{4} \\ \frac{1}{4} & -\frac{1}{4} & \frac{1}{4} & -\frac{1}{4} \\ \frac{1}{4} & -\frac{1}{4} & -\frac{1}{4} & \frac{1}{4} \end{pmatrix} \begin{pmatrix} 2 \\ 3 \\ 3 \\ 5 \end{pmatrix} = \begin{pmatrix} \frac{13}{4} \\ -\frac{3}{4} \\ -\frac{3}{4} \\ \frac{1}{4} \end{pmatrix}.$$

Thus, the solution has the following form:

$$\left(\frac{13}{4}, -\frac{3}{4}, -\frac{3}{4}, \frac{1}{4}\right)^T \in \mathbb{R}^4.$$

In order to compute  $A^{-1}$  we applied the relation  $A^{-1} = (1/\det(A))\text{adj}(A)$ . Recall that the algebraic adjoint matrix  $\text{adj}(A)$  of  $A$  is defined by  $\text{adj}(A) = (A_{ij})^T$ , where  $A_{ij}$  is the algebraic complement of the element  $a_{ij}$  of the matrix  $A$ , that is,  $A_{ij} = (-1)^{i+j} \det(\hat{A}_{ij})$ . Here,  $\hat{A}_{ij}$  denotes the matrix obtained by  $A$  by deleting the  $i$ th row and  $j$ th column. We compute

$$\begin{array}{l}
 A_{11} = (-1)^{1+1} \det \begin{pmatrix} 1 & -1 & -1 \\ -1 & 1 & -1 \\ -1 & -1 & 1 \end{pmatrix} = -4, \\
 A_{12} = (-1)^{1+2} \det \begin{pmatrix} 1 & -1 & -1 \\ 1 & 1 & -1 \\ 1 & -1 & 1 \end{pmatrix} = -4, \\
 A_{13} = (-1)^{1+3} \det \begin{pmatrix} 1 & 1 & -1 \\ 1 & -1 & -1 \\ 1 & -1 & 1 \end{pmatrix} = -4, \\
 A_{14} = (-1)^{1+4} \det \begin{pmatrix} 1 & 1 & -1 \\ 1 & -1 & 1 \\ 1 & -1 & -1 \end{pmatrix} = -4, \\
 A_{21} = (-1)^{2+1} \det \begin{pmatrix} 1 & 1 & 1 \\ -1 & 1 & -1 \\ -1 & -1 & 1 \end{pmatrix} = -4, \\
 A_{22} = (-1)^{2+2} \det \begin{pmatrix} 1 & 1 & 1 \\ 1 & 1 & -1 \\ 1 & -1 & 1 \end{pmatrix} = -4, \\
 A_{23} = (-1)^{2+3} \det \begin{pmatrix} 1 & 1 & 1 \\ 1 & -1 & -1 \\ 1 & -1 & 1 \end{pmatrix} = 4, \\
 A_{24} = (-1)^{2+4} \det \begin{pmatrix} 1 & 1 & 1 \\ 1 & -1 & 1 \\ 1 & -1 & -1 \end{pmatrix} = 4, \\
 A_{31} = (-1)^{3+1} \det \begin{pmatrix} 1 & 1 & 1 \\ 1 & -1 & -1 \\ -1 & -1 & 1 \end{pmatrix} = -4, \\
 A_{32} = (-1)^{3+2} \det \begin{pmatrix} 1 & 1 & 1 \\ 1 & -1 & -1 \\ 1 & -1 & 1 \end{pmatrix} = 4, \\
 A_{33} = (-1)^{3+3} \det \begin{pmatrix} 1 & 1 & 1 \\ 1 & 1 & -1 \\ 1 & -1 & 1 \end{pmatrix} = -4, \\
 A_{34} = (-1)^{3+4} \det \begin{pmatrix} 1 & 1 & 1 \\ 1 & 1 & -1 \\ 1 & -1 & -1 \end{pmatrix} = 4, \\
 A_{41} = (-1)^{4+1} \det \begin{pmatrix} 1 & 1 & 1 \\ 1 & -1 & -1 \\ -1 & 1 & -1 \end{pmatrix} = -4, \\
 A_{42} = (-1)^{4+2} \det \begin{pmatrix} 1 & 1 & 1 \\ 1 & -1 & -1 \\ 1 & 1 & -1 \end{pmatrix} = 4, \\
 A_{43} = (-1)^{4+3} \det \begin{pmatrix} 1 & 1 & 1 \\ 1 & 1 & -1 \\ 1 & -1 & -1 \end{pmatrix} = 4, \\
 A_{44} = (-1)^{4+4} \det \begin{pmatrix} 1 & 1 & 1 \\ 1 & 1 & -1 \\ 1 & -1 & 1 \end{pmatrix} = -4.
 \end{array}$$

Hence by applying the rule  $A^{-1} = (1/\det(A))\text{adj}(A)$  we obtain the given expression for the inverse  $A^{-1}$  of  $A$ .  $\square$

**2.E.24.** Confirm all the computations presented in 2.E.23 via Sage.  $\circ$

**2.E.25.** Present in Sage the solution given in 2.E.23 via the Cramer's rule.  $\circ$

**2.E.26.** Explain why the matrix

$$A = \begin{pmatrix} 5 & 0 & 8 & 0 \\ 1 & 5 & 0 & 4 \\ 4 & 0 & 5 & 0 \\ 0 & 7 & 0 & 8 \end{pmatrix}$$

is invertible. Next use Sage to compute its algebraic adjoint and its inverse.

**Solution.** Computing the determinant of  $A$  we see that  $\det(A) = -84$ . Thus  $A$  has an inverse, with an inverse given by  $A^{-1} = \frac{1}{\det(A)} \cdot \text{adj}(A)$ . As we know, in order to derive the adjoint and the inverse of  $A$  in Sage, the corresponding code has the form

```
A=matrix([[5, 0, 8, 0], [1, 5, 0, 4], [4, 0, 5, 0], [0, 7, 0, 8]])
print(det(A)); show(A.adjugate()); show(A.inverse())
```

Executing this block we get the following expressions:

$$\text{adj}(A) = \begin{pmatrix} 60 & 0 & -96 & 0 \\ -40 & -56 & 64 & 28 \\ -48 & 0 & 60 & 0 \\ 35 & 49 & -56 & -35 \end{pmatrix}, \quad A^{-1} = \begin{pmatrix} -\frac{5}{7} & 0 & \frac{8}{7} & 0 \\ \frac{10}{21} & \frac{2}{3} & -\frac{16}{21} & -\frac{1}{3} \\ \frac{4}{7} & 0 & -\frac{5}{7} & 0 \\ -\frac{5}{12} & -\frac{7}{12} & \frac{2}{3} & \frac{5}{12} \end{pmatrix}.$$

**2.E.27.** For the matrix  $F = \begin{pmatrix} \alpha & \beta & 0 \\ \gamma & \delta & 0 \\ 0 & 0 & 1 \end{pmatrix}$ , where  $\alpha, \beta, \gamma, \delta \in \mathbb{R}$ , compute its algebraically adjoint matrix  $\text{adj}(F)$ . □

**2.E.28.** Calculate the algebraically adjoint matrix for the matrices

$$A = \begin{pmatrix} 3 & -2 & 0 & -1 \\ 0 & 2 & 2 & 1 \\ 1 & -2 & -3 & -2 \\ 0 & 1 & 2 & 1 \end{pmatrix}, \quad B = \begin{pmatrix} 1+i & 2i \\ 3-2i & 6 \end{pmatrix},$$

where as usual  $i$  denotes the imaginary unit. □

**2.E.29.** Show that the matrix

$$A = \begin{pmatrix} 2 & -3 & -5 \\ -1 & 4 & 5 \\ 1 & -3 & -4 \end{pmatrix} \in \text{Mat}_3(\mathbb{R})$$

is *idempotent*, i.e.,  $A^2 = A$ .<sup>13</sup> Then, based explicitly on this property of  $A$ , compute  $AB$  and  $B^2$ , where  $B = A - E$ , with  $E$  being the  $3 \times 3$  identity matrix. Moreover, compute the determinant  $\det(A)$  of  $A$ . □

**2.E.30.** Let  $A, B, P \in \text{Mat}_n(\mathbb{R})$  be invertible  $n \times n$  matrices such that  $B = PAP^{-1}$ . Can we conclude that  $\det(A) = \det(B)$  and  $\det(A^{-1}B) = 1$ ? Use the Cauchy theorem (see 2.2.7) to support your answer. □

### C) MATERIAL ON VECTOR SPACES AND LINEAR MAPPINGS

**2.E.31.** Consider the complex numbers  $\mathbb{C}$  as a real vector space. Determine the coordinates of  $z = 2 + i$  in the basis given by the roots of the polynomial  $x^2 + x + 1$ .

**Solution.** Because roots of the given polynomial are  $-\frac{1}{2} + i\frac{\sqrt{3}}{2}$  and  $-\frac{1}{2} - i\frac{\sqrt{3}}{2}$ , we have to determine the coordinates  $(a, b)$  of the vector  $z = 2 + i$  in the basis  $(-\frac{1}{2} + i\frac{\sqrt{3}}{2}, -\frac{1}{2} - i\frac{\sqrt{3}}{2})$ . These real numbers  $a, b$  are uniquely determined by the condition

$$a \cdot \left(-\frac{1}{2} + i\frac{\sqrt{3}}{2}\right) + b \cdot \left(-\frac{1}{2} - i\frac{\sqrt{3}}{2}\right) = 2 + i.$$

By equating separately the real and the imaginary parts of the equation, we obtain a system of two linear equations in two variables:

$$\left\{ \begin{array}{l} -\frac{1}{2}a - \frac{1}{2}b = 2, \\ \frac{\sqrt{3}}{2}a - \frac{\sqrt{3}}{2}b = 1 \end{array} \right\}.$$

The solution has the form  $a = -2 + \frac{\sqrt{3}}{3}$ , and  $b = -2 - \frac{\sqrt{3}}{3}$ , respectively, hence the required coordinates are given by  $(-2 + \frac{1}{\sqrt{3}}, -2 - \frac{1}{\sqrt{3}})$ . □

**2.E.32.** Consider the complex numbers  $\mathbb{C}$  as a real vector space. Determine the coordinates of the number  $2 + i$  in the basis given by the roots of the polynomial  $x^2 - x + 1$ . □

**2.E.33.** Express the vector  $(5, 1, 11)^T \in \mathbb{R}^3$ , as a linear combination of the vectors  $(3, 2, 2)^T$ ,  $(2, 3, 1)^T$ , and  $(1, 1, 3)^T$ . □

**2.E.34.** Given the vectors  $u_1 = (1, 1, a, 1)^T$ ,  $u_2 = (1, b, 1, 1)^T$ ,  $u_3 = (c, 1, 1, 1)^T$  in  $\mathbb{R}^4$ , specify the values of the parameters  $a, b, c \in \mathbb{R}$ , such that  $u_1, u_2, u_3$  are linearly dependent. □

**2.E.35.** Let  $V$  be vector space with a basis formed by the vectors  $u, v, w, z$ . Determine whether or not the following vectors of  $V$  are linearly independent:  $u - 3v + z$ ,  $v - 5w - z$ ,  $3w - 7z$  and  $u - w + z$ . □

**2.E.36.** Complete the vectors  $1 - x^2 + x^3$ ,  $1 + x^2 + x^3$ ,  $1 - x - x^3$  to a basis of the vector space  $\mathbb{R}_3[x]$  of polynomials over  $\mathbb{R}$  of degree at most 3. □

**2.E.37.** Depending on the parameter  $t \in \mathbb{R}$ , determine the dimension of the subspace  $U \subset \mathbb{R}^3$  for the following two cases:

(a) The subspace  $U$  is generated by the vectors  $u_1 = (1, 1, 1)^T$ ,  $u_2 = (1, t, 1)^T$ , and  $u_3 = (2, 2, t)^T$ ;

(b) The subspace  $U$  is generated by the vectors  $u_1 = (t, t, t)^T$ ,  $u_2 = (-4t, -4t, 4t)^T$ , and  $u_3 = (-2, -2, -2)^T$ . □

<sup>13</sup>More general, a  $n \times n$  matrix  $A$  is called *idempotent* if  $A^2 = A$ . Idempotent matrices are also called *projectors* (or *projections*), see also the exercise 2.E.61 below.

**2.E.38.** (a) Using a similar approach to the proof shown in 2.C.31, prove that the linear mapping

$$\begin{pmatrix} a & b \\ c & d \\ e & f \end{pmatrix} \mapsto (a, b, c, d, e, f)^T,$$

is a linear isomorphism between the vector spaces  $\text{Mat}_{3,2}(\mathbb{R})$  and  $\mathbb{R}^6$ . Next find a basis of  $\text{Mat}_{3,2}(\mathbb{R})$ .

(b) Determine a basis of the subspace

$$U = \text{span}_{\mathbb{R}} \left\{ U_1 = \begin{pmatrix} 1 & 2 \\ 3 & 4 \\ 5 & 6 \end{pmatrix}, U_2 = \begin{pmatrix} 0 & 1 \\ 2 & 3 \\ 4 & 5 \end{pmatrix}, U_3 = \begin{pmatrix} -1 & 0 \\ 1 & 2 \\ 3 & 4 \end{pmatrix}, U_4 = \begin{pmatrix} -2 & -1 \\ 0 & 1 \\ 2 & 3 \end{pmatrix} \right\} \subset \text{Mat}_{3,2}(\mathbb{R}).$$

Extend this basis to a basis of the whole space  $\text{Mat}_{3,2}(\mathbb{R})$  of real  $3 \times 2$  matrices.

**Solution.** (a) An explicit proof here is very similar to 2.C.31, so you can easily complete the necessary steps alone. As for a basis, verify (also in Sage, with the same method described in 2.C.31) that the following matrices

$$E_1 = \begin{pmatrix} 1 & 0 \\ 0 & 0 \\ 0 & 0 \end{pmatrix}, \quad E_2 = \begin{pmatrix} 0 & 1 \\ 0 & 0 \\ 0 & 0 \end{pmatrix}, \quad E_3 = \begin{pmatrix} 0 & 0 \\ 1 & 0 \\ 0 & 0 \end{pmatrix}, \quad E_4 = \begin{pmatrix} 0 & 0 \\ 0 & 1 \\ 0 & 0 \end{pmatrix}, \quad E_5 = \begin{pmatrix} 0 & 0 \\ 0 & 0 \\ 1 & 0 \end{pmatrix}, \quad E_6 = \begin{pmatrix} 0 & 0 \\ 0 & 0 \\ 0 & 1 \end{pmatrix},$$

are linearly independent, and hence they form a basis of the vector space  $\text{Mat}_{3,2}(\mathbb{R})$  of all real  $3 \times 2$  matrices.

(b) Let us use the indicated isomorphism and consider real  $3 \times 2$  matrices as vectors in  $\mathbb{R}^6$ . In this way, the four given matrices can be identified with the rows of the following matrix:

$$A = \begin{pmatrix} 1 & 2 & 3 & 4 & 5 & 6 \\ 0 & 1 & 2 & 3 & 4 & 5 \\ -1 & 0 & 1 & 2 & 3 & 4 \\ -2 & -1 & 0 & 1 & 2 & 3 \end{pmatrix}.$$

It is easy to show that  $A$  has rank 2. This implies that the subspace  $U$  is generated just by the first two matrices  $U_1, U_2$ , which consequently form a basis for  $U$ . Hence in fact the rest two matrices  $U_3, U_4 \in U$  should be linear combinations of  $U_1, U_2$ , and indeed you should be able to verify that  $U_3 = -U_1 + 2U_2$ , and  $U_4 = -2U_1 + 3U_2$ , respectively.

Now, there are many options for extending this basis to a basis of the whole space. For instance, we may choose the first two of the given matrices above, together with the matrices  $E_3, E_4, E_5, E_6$  of the basis mentioned in (a). In order to prove the linear independence we may first apply the isomorphism established in (a), and then compute the determinant of the matrix induced by  $U_1, U_2, E_3, E_4, E_5, E_6$ . We see that

$$\begin{vmatrix} 1 & 2 & 3 & 4 & 5 & 6 \\ 0 & 1 & 2 & 3 & 4 & 5 \\ 0 & 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 \end{vmatrix} = 1 \neq 0.$$

Clearly, the dimension is 6, so the linear spanning is automatic and we have obtained a basis. Prove that the choice of the matrices  $E_3, E_4, E_5, E_6$  is not so crucial, in the sense that we could fix any four matrices between  $E_1, \dots, E_6$ .  $\square$

**2.E.39.** Consider the linear subspaces  $U$  and  $V$  of  $\mathbb{R}^3$ , generated by the vectors  $u_1 = (1, 1, -3)^T$ ,  $u_2 = (1, 2, 2)^T$ , and  $v_1 = (1, 1, -1)^T$ ,  $v_2 = (1, 2, 1)^T$ ,  $v_3 = (1, 3, 3)^T$ , respectively. Determine the intersection  $U \cap V$ .  $\circ$

**2.E.40.** In the vector space  $\mathbb{R}^3$ , determine the matrix of the orthogonal projection onto the plane  $x + y - 2z = 0$ .  $\circ$

**2.E.41.** In the vector space  $\mathbb{R}^3$ , determine the matrix of the orthogonal projection on the plane  $2x - y + 2z = 0$ .  $\circ$

**2.E.42.** Consider the following subspaces of  $\mathbb{R}^4$ :

$$U = \text{span}_{\mathbb{R}} \{(2, 1, 2, 2)^T\}, \quad W = \text{span}_{\mathbb{R}} \{(-1, 0, -1, 2)^T, (-1, 0, 1, 0)^T, (0, 0, 1, -1)^T\}.$$

(a) Is it true that  $U \perp W$  with respect to the dot product on  $\mathbb{R}^4$ ?

(b) Is it true that  $U^\perp = W$ , and hence  $\mathbb{R}^4 = U \oplus W$ ?  $\circ$

**2.E.43.** Let  $W$  be the subspace of the Euclidean space  $(\mathbb{R}^4, \langle \cdot, \cdot \rangle)$  spanned by the vectors  $E_1 = (1, 0, 0, 1)^T$ ,  $E_2 = (0, 1, 0, 1)^T$  and  $E_3 = (1, 2, 1, 0)^T$ . Present an orthonormal basis of  $W$ . Next deduce that its orthogonal complement  $W^\perp$  with respect to the standard Euclidean product  $\langle \cdot, \cdot \rangle$  is one-dimensional and find a generator.  $\circ$

**2.E.44.** Consider the linear mapping  $F : \mathbb{R}^4 \rightarrow \mathbb{R}^2$  given by

$$\mathbb{R}^4 \ni u = (x_1, x_2, x_3, x_4)^T \mapsto F(u) = \begin{pmatrix} x_1 + 2x_3 + 3x_4 \\ x_2 + 4x_3 + 5x_4 \end{pmatrix} \in \mathbb{R}^2.$$

- Find the matrix  $A$  of  $F$  with respect to the standard bases on  $\mathbb{R}^4$  and  $\mathbb{R}^2$ .
- Find the column space, row space, kernel and cokernel of the matrix of  $F$ , and next use Sage to confirm your answers by applying the commands presented in 2.C.20.
- Deduce that the transpose operator of  $F$  is injective.
- Prove the orthogonal decompositions

$$\mathbb{R}^4 = C(A^T) \oplus \text{Ker}(A), \quad \mathbb{R}^2 = C(A) \oplus \text{Ker}(A^T) = C(A) \oplus \{0\} \cong C(A).$$

**Solution.** (i) Let us denote the vectors of the standard bases of  $\mathbb{R}^4$  and  $\mathbb{R}^2$  by  $e_1 = (1, 0, 0, 0)^T$ ,  $e_2 = (0, 1, 0, 0)^T$ ,  $e_3 = (0, 0, 1, 0)^T$ ,  $e_4 = (0, 0, 0, 1)^T$  and  $\alpha_1 = (1, 0)^T$ ,  $\alpha_2 = (0, 1)^T$ , respectively. Then, we see that

$$\begin{aligned} F(e_1) &= (1, 0)^T = \alpha_1, \\ F(e_2) &= (0, 1)^T = \alpha_2, \\ F(e_3) &= (2, 4)^T = 2\alpha_1 + 4\alpha_2, \\ F(e_4) &= (3, 5)^T = 3\alpha_1 + 5\alpha_2. \end{aligned}$$

Thus, the matrix of  $F$  with respect to the standard bases is given by  $A = \begin{pmatrix} 1 & 0 & 2 & 3 \\ 0 & 1 & 4 & 5 \end{pmatrix}$ . We may verify this result in Sage, by applying the method described in 2.C.28, for example:

```
V=RR^4
W=RR^2;
var("x1, x2, x3, x4")
f(x1, x2, x3, x4)=[x1+2*x3+3*x4, x2+4*x3+5*x4]
T=linear_transformation(V, W, f)
A=T.matrix(side="right");
show(A)
```

(ii) The matrix  $A$  is already in RREF, and hence its rank equals two,  $\text{rank}(A) = 2$ . Here is a confirmation via Sage:

```
A=matrix([[1, 0, 2, 3], [0, 1, 4, 5]])
print(A==A.rref()); print(rank(A))
```

In particular, the rows of  $A$  are linearly independent. Hence, the row space of  $A$  is a 2-dimensional subspace of  $\mathbb{R}^4$  given by  $C(A^T) = \text{span}_{\mathbb{R}} \{(1, 0, 2, 3)^T, (0, 1, 4, 5)^T\}$ . Let us denote by

$$\alpha_1 = \begin{pmatrix} 1 \\ 0 \end{pmatrix}, \quad \alpha_2 = \begin{pmatrix} 0 \\ 1 \end{pmatrix}, \quad \alpha_3 = \begin{pmatrix} 2 \\ 4 \end{pmatrix}, \quad \alpha_4 = \begin{pmatrix} 3 \\ 5 \end{pmatrix}$$

the column vectors of  $A$ . Then, we see that  $\alpha_3 = 2\alpha_1 + 4\alpha_2$ ,  $\alpha_4 = 3\alpha_1 + 5\alpha_2$ , while  $\alpha_1, \alpha_2$  are linearly independent. Therefore,  $C(A)$  is a 2-dimensional subspace of  $\mathbb{R}^2$  generated by the vectors of the standard basis of  $\mathbb{R}^2$ , i.e.,  $C(A) = \text{span}_{\mathbb{R}} \{(1, 0)^T, (0, 1)^T\}$ .

The kernel of  $A$  corresponds to solutions of the homogeneous system  $Au = 0$ , i.e.,

$$\begin{pmatrix} 1 & 0 & 2 & 3 \\ 0 & 1 & 4 & 5 \end{pmatrix} \begin{pmatrix} x_1 \\ x_2 \\ x_3 \\ x_4 \end{pmatrix} = \begin{pmatrix} 0 \\ 0 \end{pmatrix}.$$

This corresponds to the system  $\{x_1 + 2x_3 + 3x_4 = 0, x_2 + 4x_3 + 5x_4 = 0\}$  and we deduce that  $\text{Ker}(A)$  is a 2-dimensional subspace of  $\mathbb{R}^4$  given by

$$\text{Ker}(A) = \left\{ \begin{pmatrix} -2t - 3s \\ -4t - 5s \\ t \\ s \end{pmatrix} : t, s \in \mathbb{R} \right\} = \text{span}_{\mathbb{R}} \left\{ \begin{pmatrix} -2 \\ -4 \\ 1 \\ 0 \end{pmatrix}, \begin{pmatrix} -3 \\ -5 \\ 0 \\ 1 \end{pmatrix} \right\}.$$

The left null space of  $A$  corresponds to solutions of the homogeneous system  $A^T w = 0$  for some  $w = (y_1, y_2)^T \in \mathbb{R}^2$ , i.e.,

$$\begin{pmatrix} 1 & 0 \\ 0 & 1 \\ 2 & 4 \\ 3 & 5 \end{pmatrix} \begin{pmatrix} y_1 \\ y_2 \end{pmatrix} = \begin{pmatrix} 0 \\ 0 \\ 0 \\ 0 \end{pmatrix}.$$

This system has a unique solution given by  $y_1 = y_2 = 0$ . Thus, the cokernel  $\text{Ker}(A^T)$  is trivial.

To verify these results in Sage, one may proceed as in 2.C.20:

```
A=matrix([[1, 0, 2, 3], [0, 1, 4, 5]])
print("\nThe column space of A is given by:", A.column_space())
print("\nThe row space of A is given by:", A.row_space())
print("\nThe kernel of A is given by:", A.right_kernel())
print("\nThe cokernel of A is given by:", A.left_kernel())
```

For your convenience here is the output of Sage:

The column space of A is given by: Free module of degree 2 and rank 2 over Integer Ring  
Echelon basis matrix:

```
[1 0]
[0 1]
```

The row space of A is given by: Free module of degree 4 and rank 2 over Integer Ring  
Echelon basis matrix:

```
[1 0 2 3]
[0 1 4 5]
```

The kernel of A is given by: Free module of degree 4 and rank 2 over Integer Ring  
Echelon basis matrix:

```
[ 1  1  1 -1]
[ 0  2 -3  2]
```

The cokernel of A is given by: Free module of degree 2 and rank 0 over Integer Ring  
Echelon basis matrix:

```
[]
```

(iii) The transpose of  $F$  is the linear operator  $\hat{F}: \mathbb{R}^2 \rightarrow \mathbb{R}^4$  whose matrix presentation (with respect to the standard bases of  $\mathbb{R}^2$  and  $\mathbb{R}^4$ ) is given by the transpose of  $A$ . Thus  $\hat{F}(w) = A^T w$  for any  $w \in \mathbb{R}^2$  and  $\hat{F}$  is injective since  $\text{Ker}(A^T) = \{0\}$ .

(iv) Above we saw that  $C(A^T) = \text{span}_{\mathbb{R}}\{(1, 0, 2, 3)^T, (0, 1, 4, 5)^T\}$  and  $\text{Ker}(A) = \text{span}_{\mathbb{R}}\{(-2, -4, 1, 0)^T, (-3, -5, 0, 1)^T\}$ .

Suppose that  $v$  is a vector in  $C(A^T) \cap \text{Ker}(A)$ . Then we can think  $v$  as a linear combination of the vectors  $E_1 = (1, 0, 2, 3)^T$  and  $E_2 = (0, 1, 4, 5)^T$ , satisfying the additional condition  $Av = 0$ . This gives the homogeneous system

$$Av = \begin{pmatrix} 1 & 0 & 2 & 3 \\ 0 & 1 & 4 & 5 \end{pmatrix} \begin{pmatrix} \alpha \\ \beta \\ 2\alpha + 4\beta \\ 3\alpha + 5\beta \end{pmatrix} = \begin{pmatrix} 0 \\ 0 \end{pmatrix} \iff \begin{pmatrix} 14\alpha + 23\beta \\ 23\alpha + 42\beta \end{pmatrix} = \begin{pmatrix} 0 \\ 0 \end{pmatrix},$$

which has the zero solution  $\alpha = \beta = 0$  as unique. Thus,  $v = 0$  and  $C(A^T) \cap \text{Ker}(A) = \{0\}$ . This, along with the relation  $\dim C(A^T) + \dim \text{Ker}(A) = 2 + 2 = 4 = \dim \mathbb{R}^4$  proved above, precisely defines the conditions for a direct sum, i.e.,  $\mathbb{R}^4 = C(A^T) \oplus \text{Ker}(A)$ . The orthogonality condition  $C(A^T) \perp \text{Ker}(A)$  follows by 2.C.56. For a direct verification, observe that for any  $u \in C(A^T)$  and  $w \in \text{Ker}(A)$  we have

$$u = aE_1 + vE_2, \quad w = cE_3 + dE_4$$

for some scalars  $a, b, c, d \in \mathbb{R}$ , where  $E_3 = (-2, -4, 1, 0)^T$ ,  $E_4 = (-3, -5, 0, 1)^T$  and the vectors  $E_1, E_2$  are as above. Thus, we only need prove that  $\langle E_1, E_3 \rangle = 0 = \langle E_1, E_4 \rangle$  and  $\langle E_2, E_3 \rangle = 0 = \langle E_2, E_4 \rangle$ , which is straightforward:

$$E_3^T E_1 = -2 + 2 = 0, \quad E_4^T E_1 = -3 + 3 = 0, \quad E_3^T E_2 = -4 + 4 = 0, \quad E_4^T E_2 = -5 + 5 = 0.$$

Recall that in Sage these scalar products can be computed using the `dot_product` command:

```
E1=vector([1, 0, 2, 3])
E2=vector([0, 1, 4, 5])
E3=vector([-2, -4, 1, 0])
E4=vector([-3, -5, 0, 1])
print(E1.dot_product(E3)==0)
print(E2.dot_product(E3)==0)
```

```
print (E1.dot_product (E4)==0)
print (E2.dot_product (E4)==0)
```

The second decomposition  $\mathbb{R}^2 = C(A) \oplus \text{Ker}(A^T)$  can be verified in an analogous way, but it is much easier and reduces to  $\mathbb{R}^2 \cong C(A)$ , as  $\text{Ker}(A^T)$  is trivial.  $\square$

**2.E.45. Remark.** Recall from the theoretical task 2.C.56 that any  $m \times n$  matrix  $A$  over  $\mathbb{R}$  satisfies

$$C(A) \perp \text{Ker}(A^T), \quad \text{and} \quad C(A^T) \perp \text{Ker}(A),$$

with respect to the corresponding dot products. In fact, it is not so difficult to prove that

$$C(A) \cap \text{Ker}(A^T) = \{0\}, \quad C(A^T) \cap \text{Ker}(A) = \{0\}, \quad \dim \text{Ker}(A^T) = m - \text{rank}(A), \quad \dim \text{Ker}(A) = n - \text{rank}(A),$$

for any such matrix  $A$ , and all these properties together lead to the following orthogonal direct sum decompositions:

$$\mathbb{R}^m = C(A) \oplus \text{Ker}(A^T), \quad \mathbb{R}^n = C(A^T) \oplus \text{Ker}(A).$$

Note that this result extends to complex matrices with appropriate adjustments (for instance one should use the standard Hermitian inner product on  $\mathbb{C}^m$  and  $\mathbb{C}^n$ , and replace  $A^T$  by the conjugate transpose of the complex matrix  $A$ , which we will mainly explore in Chapter 3, see also below).

**2.E.46.** Consider the linear mapping  $F : \mathbb{R}^4 \rightarrow \mathbb{R}^2$  presented in 2.E.44 and the sets

$$\begin{aligned} \underline{u} &= \{u_1 = (1, 0, 0, 0)^T, u_2 = (0, 1, 0, 0)^T, u_3 = (0, 0, 1, 0)^T, u_4 = (1, 1, 1, 1)^T\}, \\ \underline{v} &= \{v_1 = (1, 1)^T, v_2 = (2, -1)^T\}. \end{aligned}$$

- i) Use Sage to prove that  $\underline{u}$  and  $\underline{v}$  are bases of  $\mathbb{R}^4$  and  $\mathbb{R}^2$ , respectively.
- ii) Find the new coordinates  $w_{\underline{u}}$  of the vector  $w = (1, 2, 3, 4)^T \in \mathbb{R}^4$  with respect to  $\underline{u}$ .
- iii) Find the new matrix presentation of  $F$  with respect the new bases  $\underline{u}$  and  $\underline{v}$  presented above.
- iv) Verify that the image of  $w$  by  $F$  remains invariant across the two different matrix representations of  $F$  (this is true for any vector  $w \in \mathbb{R}^4$ ). In particular, demonstrate that  $F(w) = Q F(w)_{\underline{v}}$ , where  $F(w)_{\underline{v}}$  is the image of  $w$  in the new coordinates on  $\mathbb{R}^2$ , and  $Q$  is the transition matrix from the new basis  $\underline{v}$  to the standard basis of  $\mathbb{R}^2$ .

**Solution.** (i) We can use Sage via the method described in 2.C.10 to verify the linear independence of  $u_1, \dots, u_4$

```
u1=vector(QQ, [1, 0, 0, 0])
u2=vector(QQ, [0, 1, 0, 0])
u3=vector(QQ, [0, 0, 1, 0])
u4=vector(QQ, [1, 1, 1, 1])
U=RR^4; L=[v1, v2, v3, v4]
U.linear_dependence(L)==[]
```

Similarly one can check the linear independence of  $v_1, v_2$ . Since for both cases the vectors are linearly independent we have  $\text{span}\{u_1, \dots, u_4\} \cong \mathbb{R}^4$  and  $\text{span}\{v_1, v_2\} \cong \mathbb{R}^2$ , respectively, and the claim for the bases follows.

(ii) The transition matrix from the basis  $\underline{u}$  to the standard basis  $\underline{e}$  of  $\mathbb{R}^4$ , is given by the matrix  $T$  having as columns vectors the vectors  $u_1, \dots, u_4$ . The transition matrix from  $\underline{e}$  to  $\underline{u}$  is the inverse matrix  $T^{-1}$ , given here: (compute  $T^{-1}$  on your own)

$$T = \begin{pmatrix} 1 & 0 & 0 & 1 \\ 0 & 1 & 0 & 1 \\ 0 & 0 & 1 & 1 \\ 0 & 0 & 0 & 1 \end{pmatrix}, \quad T^{-1} = \begin{pmatrix} 1 & 0 & 0 & -1 \\ 0 & 1 & 0 & -1 \\ 0 & 0 & 1 & -1 \\ 0 & 0 & 0 & 1 \end{pmatrix}.$$

Thus, the new coordinates of the vector  $w$  in terms of  $\underline{u}$  are given by  $w_{\underline{u}} = T^{-1}w = (-3, -2, -1, 4)^T$ . In Sage this task can be solved as in 2.C.42, hence we leave the verification to the reader.

(iii) Here one should apply the method we learned in 2.C.44. In particular, by 2.E.44 we know that the matrix of the mapping  $F : \mathbb{R}^4 \rightarrow \mathbb{R}^2$  with respect to the standard bases is given by  $A = \begin{pmatrix} 1 & 0 & 2 & 3 \\ 0 & 1 & 4 & 5 \end{pmatrix}$ . Therefore, the new matrix of  $F$  with respect to the bases  $\underline{u}$  and  $\underline{v}$  is given by  $A' = [F]_{\underline{u}, \underline{v}} = Q^{-1}AT$ , where  $Q^{-1}$  is the inverse of the transition matrix  $Q$  from the new basis  $\underline{v}$  to the standard basis of  $\mathbb{R}^2$ , and  $T$  is as above. Since  $Q = \begin{pmatrix} 1 & 2 \\ 1 & -1 \end{pmatrix}$ , we compute  $Q^{-1} = -\frac{1}{3} \begin{pmatrix} -1 & -2 \\ -1 & 1 \end{pmatrix} = \begin{pmatrix} 1/3 & 2/3 \\ 1/3 & -1/3 \end{pmatrix}$ , and

$$A' = \begin{pmatrix} 1/3 & 2/3 \\ 1/3 & -1/3 \end{pmatrix} \begin{pmatrix} 1 & 0 & 2 & 3 \\ 0 & 1 & 4 & 5 \end{pmatrix} \begin{pmatrix} 1 & 0 & 0 & 1 \\ 0 & 1 & 0 & 1 \\ 0 & 0 & 1 & 1 \\ 0 & 0 & 0 & 1 \end{pmatrix} = \begin{pmatrix} 1/3 & 2/3 & 10/3 & 26/3 \\ 1/3 & -1/3 & -2/3 & -4/3 \end{pmatrix}.$$

Here is a verification of these computations by Sage:

```
A=matrix([[1, 0, 2, 3], [0, 1, 4, 5]])
T=matrix([[1, 0, 0, 1], [0, 1, 0, 1], [0, 0, 1, 1], [0, 0, 0, 1]])
Q=matrix([[1, 2], [1, -1]])
Qinv=Q.inverse(); show(Qinv*A*T)
(iv)
```

In Sage one can find the matrix of the linear mapping  $F$  with respect to the new bases  $\underline{u}$  and  $\underline{v}$ , by combining the functions  $T = \text{linear\_transformation}(U, V, F)$  and  $T.\text{restrict\_domain}(U1).\text{restrict\_codomain}(V1)$ . Within the program, we should define the spaces spanned by the bases  $\underline{u}$  and  $\underline{v}$ , which we may denote by  $U1$  and  $V1$ , respectively (of course, these spaces are isomorphic to  $\mathbb{R}^4$  and  $\mathbb{R}^2$ ). This can be done by the command  $U1 = U.\text{subspace\_with\_basis}(u)$ , for example, where  $U$  is the domain of  $F$ . Additionally, to simplify the matrix displays we can instruct Sage to work within the vectors space  $\mathbb{Q}^4$  and  $\mathbb{Q}^2$ , instead of  $\mathbb{R}^4$  and  $\mathbb{R}^2$ . This adjustment does not affect the final result. The implementation of these concepts is as follows:

```
U=QQ^4; u1=vector([1, 0, 0, 0]); u2=vector([0, 1, 0, 0])
u3=vector([0, 0, 1, 0]); u4=vector([1, 1, 1, 1]); u=[u1, u2, u3, u4]
U1=U.subspace_with_basis(u)
V=QQ^2; v1=vector([1, 1]); v2=vector([2, -1]); v=[v1, v2]
V1=V.subspace_with_basis(v)
var("x1, x2, x3, x4")
F(x1, x2, x3, x4)=[x1+2*x3+3*x4, x2+4*x3+5*x4]
T=linear_transformation(U, V, F)
S=T.restrict_domain(U1).restrict_codomain(V1)
Ahat=S.matrix(side="right")
show(Ahat)
```

Check on your own that executing this code block Sage returns the matrix  $\begin{pmatrix} 1/3 & 2/3 & 10/3 & 26/3 \\ 1/3 & -1/3 & -2/3 & -4/3 \end{pmatrix}$ .

(iv) Above we have seen that the new coordinates of  $w \in \mathbb{R}^4$  in the basis  $\underline{u}$  are given by  $w_{\underline{u}} = T^{-1}w$ . On the other hand the matrix  $A' = [F]_{\underline{u}, \underline{v}}$  in the new bases is given by  $A' = Q^{-1}AT$ . The image  $F(w)$  in the new coordinates and in terms of matrices is the following vector:

$$F(w)_{\underline{v}} = A'w_{\underline{u}} = (Q^{-1}AT)(T^{-1}w) = Q^{-1}ATT^{-1}w = Q^{-1}Aw \in \mathbb{R}^2.$$

To bring this vector back to the original coordinates in  $\mathbb{R}^2$  we need to apply the transition matrix  $Q$ , which gives the result:  $QF(w)_{\underline{v}} = QQ^{-1}Aw = Aw = F(w)$ . Use the explicit expressions of  $w_{\underline{u}}$ ,  $A'$  and  $Q$  to confirm the claim, as well.  $\square$

**2.E.47.** Construct an orthogonal basis of the subspace  $W = \text{span}_{\mathbb{R}} \{(1, 1, 1, 1)^T, (1, 1, 1, -1)^T, (-1, 1, 1, 1)^T\} \subset \mathbb{R}^4$ .  $\circ$

**2.E.48.** In  $\mathbb{R}^4$ , find an orthogonal basis of the subspace of all linear combinations of the vectors  $(1, 0, 1, 0)^T$ ,  $(0, 1, 0, -7)^T$ , and  $(4, -2, 4, 14)^T$ . Moreover, find an orthogonal basis of the subspace generated by the vectors  $(1, 2, 2, -1)^T$ ,  $(1, 1, -5, 3)^T$  and  $(3, 2, 8, -7)^T$ .  $\circ$

**2.E.49.** Consider the following vectors of  $\mathbb{R}^5$ :  $u_1 = (1, 1, 2, 0, 0)^T$ ,  $u_2 = (1, -1, 0, 1, a)^T$  and  $u_3 = (1, b, 2, 3, -2)^T$ . Specify the values of the parameters  $a, b \in \mathbb{R}$  such that these vectors are pairwise orthogonal.  $\circ$

**2.E.50.** Let  $V$  the linear subspace of  $\mathbb{R}^4$  generated by the vectors  $(-1, 2, 0, 1)^T$ ,  $(3, 1, -2, 4)^T$ ,  $(-4, 1, 2, -4)^T$ , and  $(2, 3, -2, 5)^T$ . Determine the orthogonal complement of  $V$  with respect to the standard dot product in  $\mathbb{R}^4$ .  $\circ$

**2.E.51.** Consider the following two vectors  $u_1 = (1, -2, 2, 1)^T$  and  $u_2 = (1, 3, 2, 1)^T$  of  $\mathbb{R}^4$ . Extend their set into an orthogonal basis of the whole  $\mathbb{R}^4$ , with respect to the usual dot product.  $\circ$

**2.E.52.** Let  $V \subset \mathbb{R}^5$  the linear subspace generated by the vectors  $(1, 1, -1, -1, 0)^T$ ,  $(1, -1, -1, 0, -1)^T$ ,  $(1, 1, 0, 1, 1)^T$ , and  $(-1, 0, -1, 1, 1)^T$ . Find a basis for its orthogonal complement  $V^\perp$  with respect to the usual dot product.  $\circ$

**2.E.53.** In the Euclidean space  $\mathbb{R}^5$ , determine the orthogonal complement  $W^\perp$  of the subspace  $W$ , if

(a)  $W = \{(r + s + t, -r + t, r + s, -t, s + t); r, s, t \in \mathbb{R}\}$ ;

(b)  $W$  is the set of the solutions of the following system of linear equations  $\{x_1 - x_3 = 0, x_1 - x_2 + x_3 - x_4 + x_5 = 0\}$ .  $\circ$

So far we have primarily focused on real matrices, though manipulating complex matrices is quite similar. When dealing with complex matrices, a key operation is the complex conjugation. For a complex matrix  $A = (a_{ij}) \in \text{Mat}_{m,n}(\mathbb{C})$ , the complex conjugate  $\bar{A}$  is defined by  $\bar{A} = (\bar{a}_{ij})$ , where  $\bar{z}$  denotes the complex conjugate of  $z \in \mathbb{C}$ . Note that the matrix  $\bar{A}$  belongs to  $\text{Mat}_{m,n}(\mathbb{C})$ , as well. Another important operation is the conjugate transpose of a complex matrix, denoted by  $A^* = \overline{A^T} = \bar{A}^T$ . This results in a matrix in  $\text{Mat}_{n,m}(\mathbb{C})$ , provided that  $A \in \text{Mat}_{m,n}(\mathbb{C})$ . Any real matrix  $A$  can be viewed as a complex matrix with zero imaginary part, and hence such a matrix satisfies  $A^* = A^T$ . In Chapter 3 we will examine these concepts in greater detail. Hence you may consider the rest of this section as preparatory groundwork.

**2.E.54.** Recall that real matrix  $A \in \text{Mat}_n(\mathbb{R})$  is called symmetric if  $A = A^T$ , and skew-symmetric (or antisymmetric) if  $A = -A^T$ . Using the identity  $(A^T)^T = A$ , show that any square matrix  $A$  can be expressed as the sum of a symmetric and a skew-symmetric matrix. Then illustrate the statement using the matrix  $A$  given below and verify your answer in Sage:

$$A = \begin{pmatrix} 1 & 0 & 2 \\ 6 & 3 & 0 \\ 2 & 2 & 4 \end{pmatrix}.$$

**2.E.55.** (a) Given a squared matrix  $A \in \text{Mat}_n(\mathbb{R})$ , show that  $A + A^T$  is symmetric, and that  $A - A^T$  is skew-symmetric.

(b) Given a  $n \times n$  skew-symmetric matrix  $A$  with  $n$  odd, show that  $\det(A) = 0$ .

(c) Prove that the trace of any skew-symmetric matrix  $A$  is zero.

**2.E.56.** (a) Find  $A^*$  if  $A = \begin{pmatrix} 1+i & \sqrt{2} & 2-3i \\ 4i & 1-2i & 7 \end{pmatrix}$ . Confirm your answer by Sage.

(b) This is a theoretical task: Show that

- $(zA)^* = \bar{z}A^*$ , for any  $A \in \text{Mat}_{m,n}(\mathbb{C})$  and  $z \in \mathbb{C}$ .
- $(A+B)^* = A^* + B^*$ , for any  $A, B \in \text{Mat}_{m,n}(\mathbb{C})$ .
- $(AB)^* = B^*A^*$ , for any  $A \in \text{Mat}_{m,n}(\mathbb{C})$  and  $B \in \text{Mat}_{n,r}(\mathbb{C})$ .
- $(A^*)^* = A$ , for any  $A \in \text{Mat}_{m,n}(\mathbb{C})$ .
- If  $A \in \text{Mat}_{m,n}(\mathbb{C})$  is invertible, then  $A^*$  is invertible and  $(A^*)^{-1} = (A^{-1})^*$ .
- $\text{tr}(A^*) = \text{tr}(A)$ , for any  $A \in \text{Mat}_m(\mathbb{K})$ , where  $\mathbb{K}$  is one of  $\mathbb{R}$  or  $\mathbb{C}$ . In particular, any  $A \in \text{Mat}_m(\mathbb{R})$  satisfies  $\text{tr}(A^T) = \text{tr}(A)$ .

**Solution.** (a)  $A^*$  is an element of  $\text{Mat}_{3,2}(\mathbb{C})$ , given by  $\begin{pmatrix} 1-i & -4i \\ \sqrt{2} & 1+2i \\ 2+3i & 7 \end{pmatrix}$ . In Sage to compute  $A^*$  use the following cell:

```
A=matrix(CDF, [[1+i, sqrt(2), 2-3*i], [4*i, 1-2*i, 7]])
A_Herm=(A.conjugate()).T
show(A_Herm); bool(A_Herm==A.H)
```

Notice that `A.H` is a shortcut that Sage provides to derive directly the complex conjugate of a complex matrix, analogous to the command `A.T` that we use for the transpose of a matrix (cf. ??). The last line in the previous block verifies that our definition of  $\bar{A}^T$  that we introduced in Sage is consistent with the `A.H` command.

(b) Let  $A \in \text{Mat}_{m,n}(\mathbb{C})$ , with  $A = (a_{ij})$  and  $1 \leq i \leq m$  and  $1 \leq j \leq n$ , respectively. If  $A^* = (a_{k\ell}^*)$ , then  $a_{k\ell}^* = \bar{a}_{\ell k}$  with  $1 \leq k \leq n$  and  $1 \leq \ell \leq m$ , respectively. Consider some  $z \in \mathbb{C}$  and suppose that  $(zA)^* = ((za)_{k\ell}^*)$  and  $\bar{z}A^* = (\bar{z}a_{k\ell}^*)$ , respectively. Then  $(za)_{k\ell}^* = \overline{z\bar{a}_{\ell k}} = \bar{z}\bar{a}_{\ell k} = \bar{z}a_{k\ell}^*$ , which proves that  $(zA)^* = \bar{z}A^*$ . Directly

$$(zA)^* = \overline{zA^T} = (\bar{z}\bar{A})^T = \bar{z}\bar{A}^T = \bar{z}A^*.$$

Next, if  $(A+B)^* = ((a+b)_{k\ell}^*)$ , then  $(a+b)_{k\ell}^* = \overline{(a+b)_{\ell k}} = \bar{a}_{\ell k} + \bar{b}_{\ell k} = a_{k\ell}^* + b_{k\ell}^*$ . This proves the second relation. For the third one, first notice that since  $AB$  is a  $m \times r$  matrix,  $(AB)^*$  is a  $r \times m$  matrix, as the matrix  $B^*A^*$  in the r.h.s. Thus, for any  $k, \ell$  with  $1 \leq k \leq r$  and  $1 \leq \ell \leq m$  we get

$$(ab)_{k\ell}^* = \overline{(ab)_{\ell k}} = \sum_s \overline{a_{\ell s} b_{sk}} = \sum_s \bar{a}_{\ell s} \bar{b}_{sk} = \sum_s \bar{b}_{sk} \bar{a}_{\ell s} = \sum_s b_{ks}^* a_{s\ell}^* = (ba)_{k\ell}^*.$$

Directly  $(AB)^* = \overline{(AB)^T} = \overline{(A\bar{B})^T} = \overline{B^T \bar{A}^T} = B^* A^*$ . For the fourth relation, let  $(A^*)^* = ((a^*)_{k\ell}^*)$  for some  $1 \leq k \leq m$  and  $1 \leq \ell \leq n$ . Then we have  $(a^*)_{k\ell}^* = \overline{a_{k\ell}^*} = \overline{\bar{a}_{\ell k}} = a_{k\ell}$ . Thus  $(A^*)^* = A$ . Now, an application of the conjugate transpose to the identity  $AA^{-1} = E = A^{-1}A$  gives  $(A^{-1})^* A^* = E^* = E = A^*(A^{-1})^*$  and the claim for the inverse follows ( $E$  is

the identity  $n \times n$  matrix).

For the final claim first observe that

$$\operatorname{tr}(A^*) = \sum_{i=1}^m a_{ii}^* = \sum_{i=1}^m \overline{a_{ii}} = \overline{\sum_{i=1}^m a_{ii}} = \overline{\operatorname{tr}(A)}.$$

The result for the real case now follows. □

#### D) MATERIAL ON THE PROPERTIES OF LINEAR MAPPINGS

**2.E.57.** Verify the results of eigenvalues and eigenvectors presented in the following table.

linear transformation	matrix form	eigenvalues	algebraic multiplicity	eigenvectors
identity	$\begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}$	1	2	$\begin{pmatrix} 1 \\ 0 \end{pmatrix}, (V_1 \cong \mathbb{R}^2)$
homothety	$\begin{pmatrix} c & 0 \\ 0 & c \end{pmatrix}, c \in \mathbb{R} \setminus \{0, 1\}$	$c$	2	$\begin{pmatrix} 1 \\ 0 \end{pmatrix}, (V_c \cong \mathbb{R}^2)$
rotation	$\begin{pmatrix} \cos(\theta) & \sin(\theta) \\ -\sin(\theta) & \cos(\theta) \end{pmatrix}, \theta \neq k\pi, k \in \mathbb{Z}$	$\cos(\theta) \pm i \sin(\theta) = e^{\pm i\theta}$	1, 1	$\begin{pmatrix} 1 \\ i \end{pmatrix}, \begin{pmatrix} 1 \\ -i \end{pmatrix}$
stretching	$\begin{pmatrix} c & 0 \\ 0 & 1 \end{pmatrix}, c \in \mathbb{R} \setminus \{1\}$	$c, 1$	1, 1	$\begin{pmatrix} 1 \\ 0 \end{pmatrix}, \begin{pmatrix} 0 \\ 1 \end{pmatrix}$
hor. shear	$\begin{pmatrix} 1 & a \\ 0 & 1 \end{pmatrix}, a \in \mathbb{R} \setminus \{0\}$	1	2	$\begin{pmatrix} x \\ 0 \end{pmatrix}, x \in \mathbb{R}$
ver. shear	$\begin{pmatrix} 1 & 0 \\ a & 1 \end{pmatrix}, a \in \mathbb{R} \setminus \{0\}$	1	2	$\begin{pmatrix} 0 \\ y \end{pmatrix}, y \in \mathbb{R}$
reflection (about $y$ -axis)	$\begin{pmatrix} -1 & 0 \\ 0 & 1 \end{pmatrix}$	$\pm 1$	1, 1	$\begin{pmatrix} 0 \\ 1 \end{pmatrix}, \begin{pmatrix} 1 \\ 0 \end{pmatrix}$
reflection (about $x$ -axis)	$\begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}$	$\pm 1$	1, 1	$\begin{pmatrix} 1 \\ 0 \end{pmatrix}, \begin{pmatrix} 0 \\ 1 \end{pmatrix}$

**Solution.** We have explored these transformations and their matrices in detail in 1.E.17, but we will now leave the detailed calculations as an exercise. Note that among the linear transformations in this table, only the vertical or horizontal shears are *not* diagonalizable. The rotation  $R(\theta)$  is diagonalizable over  $\mathbb{C}$  for any  $\theta$ , but it is diagonalizable over  $\mathbb{R}$  only when  $\theta$  is a multiple of  $\pi$ , which we have excluded. □

Consider a  $n \times n$  matrix  $A$  with characteristic polynomial  $\chi_A(\lambda) = \det(A - \lambda E)$ . As described in 2.4.2, this polynomial  $r$  is of degree  $n$ , and can be expressed as

$$\chi_A(\lambda) = c_n \lambda^n + c_{n-1} \lambda^{n-1} + \cdots + c_1 \lambda + c_0,$$

where  $c_n = (-1)^n$ ,  $c_0 = \det(A)$ , and  $c_{n-1} = (-1)^{n-1} \operatorname{tr}(A)$ . For a  $2 \times 2$  matrix this expression simplifies to

$$\chi_A(\lambda) = \lambda^2 - \operatorname{tr}(A) \lambda + \det(A).$$

On the other hand, for a  $3 \times 3$  matrix  $A$  the polynomial reduces to

$$\chi_A(\lambda) = -\lambda^3 + \operatorname{tr}(A) \lambda^2 + c_1 \lambda + \det(A). \quad (*)$$

To use this expression we first need to determine  $c_1$ . An expression of  $c_1$  is provided below.

**2.E.58.** For a  $3 \times 3$  matrix  $A$ , use the relation  $(*)$  to prove that

$$\chi_A(\lambda) = -\lambda^3 + \operatorname{tr}(A) \cdot \lambda^2 + (\det(A - E) + 1 - \operatorname{tr}(A) - \det(A)) \cdot \lambda + \det(A). \quad {}^{14}$$

Next, based on this relation compute the characteristic polynomial and the eigenvalues of the matrix

$$A = \begin{pmatrix} 32 & -67 & 47 \\ 7 & -14 & 13 \\ -7 & 15 & -6 \end{pmatrix}.$$

Can you verify your result in Sage? ○

**2.E.59.** Determine the  $4 \times 4$  real matrix  $A$  whose eigenvalues are given by  $\lambda_1 = 6$  and  $\lambda_2 = 7$  and satisfy one the following conditions:

<sup>14</sup>This method is not the fastest way to compute  $\chi_A$  for a  $3 \times 3$  matrix  $A$ . However, it offers an alternative approach that can be conveniently used to verify our direct computation.

- i)  $\lambda_2$  has algebraic multiplicity three, and geometric multiplicity three;
- ii)  $\lambda_2$  has algebraic multiplicity three, and geometric multiplicity two;
- iii)  $\lambda_2$  has algebraic multiplicity three, and geometric multiplicity one.

**2.E.60.** Find the eigenvalues and the eigenvectors of the matrix  $A = \begin{pmatrix} -1 & -\frac{5}{6} & \frac{5}{3} \\ 0 & -\frac{2}{3} & -\frac{2}{3} \\ 0 & \frac{1}{6} & -\frac{4}{3} \end{pmatrix}$ .

**2.E.61.** In this exercise let  $\mathbb{K} \in \{\mathbb{R}, \mathbb{C}\}$  and consider an idempotent matrix  $A \in \text{Mat}_n(\mathbb{K})$ , i.e.,  $A^2 = A$ . Prove the following statements (see also 2.3.19).

- (a)  $E - A$  is also idempotent, where  $E$  is the identity matrix;
- (b)  $\text{Ker}(A) = \text{Im}(E - A)$  and  $\text{Im}(A) = \text{Ker}(E - A)$ ;
- (c)  $\text{Ker}(A) \oplus \text{Im}(A) = \mathbb{K}^n$ ;
- (d) If  $\mathbb{K}^n = V \oplus W$  for some subspaces  $V, W \subset \mathbb{K}^n$ , then there exists a unique idempotent matrix  $A \in \text{Mat}_n(\mathbb{K})$  such that  $V = \text{Ker}(A)$  and  $W = \text{Im}(A)$ ;
- (e) The eigenvalues of  $A$  are 0 and 1;
- (f)  $\det(A) = 0$  and  $\text{tr}(A) = \text{rank}(A)$ .

**Solution.** (a) We have

$$(E - A)^2 = E - 2A + A^2 = E - 2A + A = E - A.$$

This proves (a).

(b) Suppose that  $y \in \text{Ker}(A)$ , that is,  $Ay = 0$ . Then  $(E - A)y = Ey = y$ , and so  $y \in \text{Im}(E - A)$ . Conversely, if  $y \in \text{Im}(E - A)$ , then we have  $y = (E - A)x$  for some  $x \in \mathbb{K}^n$ . Therefore,  $Ay = A(E - A)x = (A - A^2)x = 0$ , i.e.,  $y \in \text{Ker}(A)$ . This proves that  $\text{Ker}(A) = \text{Im}(E - A)$  and similarly is treated the second relation in (b).

(c) Any  $x \in \mathbb{K}^n$  can be expressed as

$$x = (E - A)x + Ax = v + w, \quad \text{where } v := (E - A)x, \quad w := Ax,$$

respectively. Obviously,  $w \in \text{Im}(A)$  and by (b) we have  $v \in \text{Ker}(A)$ . This shows that  $\mathbb{K}^n = \text{Ker}(A) + \text{Im}(A)$ . Let us now prove that this sum is direct (see 2.3.6). Consider some  $u \in \text{Ker}(A) \cap \text{Im}(A)$ . Because  $u \in \text{Ker}(A)$  means that  $Au = 0$ , and by (b) the relation  $u \in \text{Im}(A)$  implies that  $(E - A)u = 0$ , we get  $u = 0$ , and hence  $\text{Ker}(A) \cap \text{Im}(A) = \{0\}$ . Thus  $\mathbb{K}^n = \text{Ker}(A) \oplus \text{Im}(A)$ .

(d) By assumption  $\mathbb{K}^n = V \oplus W$ , hence any  $x$  is uniquely expressed as  $x = v + w$ , with  $v \in V$  and  $w \in W$ . Consider the mapping  $F : \mathbb{K}^n \rightarrow \mathbb{K}^n$  with  $F(x) = w \in W$ . Clearly,  $F$  is linear and satisfies  $F \circ F = F^2 = F$ . Moreover,  $\text{Im}(F) = W$  and  $\text{Ker}(F) = V$ . Hence, taking as  $A$  the matrix presentation of  $F$  in the standard basis of  $\mathbb{K}^n$ , we are done (the uniqueness follows from the definition of  $F$ ).

(e) Suppose that  $\lambda$  is an eigenvalue of  $A$  with eigenvector  $x$ , i.e.,  $Ax = \lambda x$ . Then

$$A^2x = A(Ax) = A(\lambda x) = \lambda(Ax) = \lambda^2 x,$$

and this shows that  $\lambda^2$  is an eigenvalue of  $A^2$ . However,  $A$  is idempotent and thus we get the relation  $\lambda x = Ax = A^2x = \lambda^2 x$ , that is,  $\lambda(\lambda - 1)x = 0$ . The claim now follows.

(f) Recall that  $\det(A)$  coincides with product of the eigenvalues of  $A$ , hence we get  $\det(A) = 0$  since 0 is an eigenvalue of  $A$ . On the other hand, all eigenvectors of  $A$  belong either to the subspace  $\text{Im}(A)$  (for  $\lambda = 1$ ) or to the subspace  $\text{Ker}(A)$  (for  $\lambda = 0$ ). But since by (c) we have  $\mathbb{K}^n = \text{Ker}(A) \oplus \text{Im}(A)$ , the eigenvectors of  $A$  must span  $\mathbb{K}^n$  and hence  $A$  is diagonalizable. It follows that the multiplicity of  $\lambda = 1$  is precisely the rank of  $A$ . Therefore, the relation  $\text{tr}(A) = \text{rank}(A)$  is now immediate, since the trace coincides with the sum of the eigenvalues  $A$  and the only eigenvalues are 0, 1.

In Chapter 3 we will meet further examples of matrices  $A$  satisfying the decomposition  $\mathbb{K}^n = \text{Ker}(A) \oplus \text{Im}(A)$ , as Hermitian matrices. □

**2.E.62. Eigenface for facial recognition – An application via Sage.** In facial recognition, a prominent technique is the so called *eigenface method*. This technique involves analyzing a set of grayscale images, each represented as a column vector, to identify the *principal component*, which is the eigenvector associated with the largest eigenvalue, also known as the *eigenface*. This eigenface captures the most significant variance among the images.

For an illustration, consider two grayscale images, each with pixel values ranging from 0 to 255, represented by the following  $2 \times 2$  matrices:

$$I_1 = \begin{pmatrix} 50 & 60 \\ 55 & 58 \end{pmatrix}, \quad I_2 = \begin{pmatrix} 70 & 80 \\ 72 & 78 \end{pmatrix}.$$

Using Sage, compute the eigenface by applying the following steps:

- i) Convert the grayscale image into column vectors  $I_1, I_2$  (this is known as “flattening of the image”).
- ii) Construct the data matrix  $D$ : Stack the column vectors  $I_1, I_2$  to create a data matrix.
- iii) Compute the mean image:  $(I_1 + I_2)/2$ .
- iv) Center the data: Subtract the mean image from each column of the data matrix to center the data. Denote this matrix by  $\text{cen}(D)$ .
- v) Calculate the covariance matrix from the centered data:  $\text{cov}_{\text{matrix}} = (\text{cen}(D))^T \text{cen}(D)$ .

**Solution.** Here is a possible solution:

```
# Given images - vectorize the values
I1 = Matrix([[50], [60], [55], [58]])
I2 = Matrix([[70], [80], [72], [78]])
# Construct the data matrix
D = I1.augment(I2)
# Compute the mean image
mean_image = (I1 + I2) / 2
# Subtract the mean from each image in the data matrix
centered_D = D - mean_image * Matrix([1, 1])
# Compute the covariance matrix
cov_matrix = centered_D.transpose() * centered_D
# Find the eigenvalues and eigenvectors
eigenvalues, eigenvectors = cov_matrix.eigenmatrix_right()
# The Eigenface
eigenface_vector = eigenvectors.column(0).normalized()
show(eigenface_vector)
```

Note that the principal component is presented as the primary **Eigenface**, and we have normalized it. Sage’s answer is  $(\frac{1}{2}\sqrt{2}, -\frac{1}{2}\sqrt{2})$ . This is the eigenvector corresponding to the largest eigenvalue of the covariance matrix. It represents the direction of maximum variance in the data, or in other words, the direction along which the variation among the images is the greatest.<sup>15</sup>  $\square$

**2.E.63.** Based on the eigenvalues and eigenvectors of a given  $3 \times 3$  matrix  $A$ , we can often interpret the induced linear transformations on  $\mathbb{R}^3$  geometrically. With this in mind, prove that the following statements are true:

- i) If the matrix has the eigenvalues 0 and 1, the latter with geometric multiplicity 2, then it is a projection in the direction of the eigenvector associated with the eigenvalue 0 onto the plane given by the eigenspace of the eigenvalue 1.
- ii) If the matrix has the eigenvalues 0 and 1, the latter with geometric multiplicity 2, and the eigenvector associated with 0 is perpendicular to the plane generated by the eigenvectors associated with the eigenvalue 1, then the mapping is an orthogonal projection.
- iii) If the matrix has eigenvalue  $-1$  with the eigenvector perpendicular to the plane generated by the eigenvectors associated with the eigenvalue 1, then it is a mirror symmetry through the plane of the eigenvectors associated with 1.
- iv) If the matrix has eigenvalue 1 with an eigenvector perpendicular to the plane generated by the eigenvectors associated with the eigenvalue  $-1$ , then it is an axial symmetry in  $\mathbb{R}^3$  through the axis given by the eigenvector associated with 1.

**Solution.** We will prove the first three statements and leave the last one as an exercise.

(i) Since 1 has algebraic multiplicity 2 there are two linearly independent vectors  $\{v_1, v_2\}$  corresponding to this eigenvalue. Since the algebraic multiplicity of 0 is 1, the geometric multiplicity of 0 should be also 1. This means that the corresponding eigenspace (nullspace)  $V_0$  generated by a unique vector  $v_0$ , and we get a direct sum decomposition  $\mathbb{R}^3 = V_0 \oplus V_1$ , with  $\dim V_0 = 1$  and  $\dim V_1 = 2$ , respectively. Thus, any vector on  $u \in \mathbb{R}^3$  can be expressed as  $u = \sum_{i=0}^2 c_i v_i$ , for some scalars  $c_0, c_1, c_2$ . By applying the  $3 \times 3$  matrix  $A$  to  $x$  we get

$$Au = A(c_0 v_0 + c_1 v_1 + c_2 v_2) = c_0 A v_0 + c_1 A v_1 + c_2 A v_2 = c_1 v_1 + c_2 v_2.$$

It is now easy to prove that  $A^2 = A$ :

$$A^2(u) = A(Au) = A(c_1 v_1 + c_2 v_2) = c_1 A v_1 + c_2 A v_2 = c_1 v_1 + c_2 v_2 = Au, \quad u \in \mathbb{R}^3.$$

<sup>15</sup>Principal Component Analysis (PCA) is a statistical method used to identify patterns in data and reduce dimensionality by projecting the data onto a set of orthogonal axes. In the context of PCA and the eigenface method, the *maximum variance* in the data is the direction in which the data varies the most.

Thus,  $A$  is a projection matrix mapping any vector  $u \in \mathbb{R}^3$  onto the plane  $V_1$  along the direction defined by the line  $V_0$  in  $\mathbb{R}^3$ .  
 (ii) Let us use the notation from (i) and assume that the eigenvector  $v_0$  associated with 0 is perpendicular to  $V_1$ . Without loss of generality, we may assume that the eigenvectors  $v_1, v_2$  that span  $V_1$  are orthonormal, i.e.,

$$\langle v_1, v_1 \rangle = v_1^T v_1 = 1 = v_2^T v_2 = \langle v_2, v_2 \rangle, \quad \langle v_1, v_2 \rangle = v_2^T v_1 = 0 = v_1^T v_2 = \langle v_2, v_1 \rangle.$$

Since  $v_1 v_1^T$  and  $v_2 v_2^T$  are the projection matrices onto the lines spanned by  $v_1, v_2$ , respectively, the projection matrix  $A$  onto the plane  $V_1$  has the form  $A = v_1 v_1^T + v_2 v_2^T$ . It is now a direct computation to prove that  $A$  is an orthogonal projection, i.e.,  $A^2 = A$  and  $A = A^T$ .

(iii) By assumption, the matrix  $A$  has the eigenvalues  $-1$  and  $1$ , the second one with geometric multiplicity 2. Thus, there are two linearly independent vectors  $u_1, u_2$  which generate the eigenspace  $V_1$ . Consequently, any vector  $x \in V_1$  can be written as a linear combination of  $u_1, u_2$ . Also,  $V_{-1}$  is 1-dimensional, generated by the eigenvector corresponding to the eigenvalue  $-1$ , which we may denote by  $v_0$ . This eigenvector is perpendicular to  $V_1$  and hence we have  $\langle v_1, v_0 \rangle = \langle v_2, v_0 \rangle = 0$ . Let  $x = a_1 u_1 + a_2 u_2$  be some arbitrary vector of  $V_1$ . Then we see that

$$Ax = A(a_1 u_1 + a_2 u_2) = a_1 A u_1 + a_2 A u_2 = a_1 u_1 + a_2 u_2 = x,$$

i.e.,  $A$  preserves  $V_1$ . Moreover, since  $A v_0 = -v_0$  we deduce that  $v_0$  is reflected through the plane  $V_1$ . Since  $A$  reflects vectors that are perpendicular to the plane  $V_1$ , while leaving vectors in  $V_1$  unchanged, we deduce that  $A$  represents a mirror symmetry through the plane  $V_1$  in  $\mathbb{R}^3$ .  $\square$

**2.E.64.** (a) Determine the eigenvalues and eigenvectors of the matrix

$$A = \begin{pmatrix} 1 & 1 & 0 \\ 1 & 2 & 1 \\ 1 & 2 & 1 \end{pmatrix}.$$

(b) Describe the geometric interpretation of the corresponding linear mapping, and write down its matrix in the basis  $\underline{u} = \{u_1 = (1, -1, 1)^T, u_2 = (1, 2, 0)^T, u_3 = (0, 1, 1)^T\}$ .

**Solution.** (a) The characteristic polynomial  $\chi_A(\lambda) = \det(A - \lambda E)$  of  $A$  is of degree three, so over  $\mathbb{C}$  we expect to find three roots. We compute

$$\begin{vmatrix} 1-\lambda & 1 & 0 \\ 1 & 2-\lambda & 1 \\ 1 & 2 & 1-\lambda \end{vmatrix} = -\lambda^3 + 4\lambda^2 - 2\lambda = -\lambda(\lambda^2 - 4\lambda + 2)$$

and hence the equation  ${}_A P(\lambda) = 0$  has only real solutions, given by  $\lambda_1 = 0$ ,  $\lambda_{\pm} = 2 \pm \sqrt{2}$ . These are the three eigenvalues of  $A$ . To verify these claims we can use Sage and apply the rules from 2.D.2. Thus, let us type

```
A=matrix(SR, [[1, 1, 0], [1, 2, 1], [1, 2, 1]])
show(A)
p(x) = A.characteristic_polynomial(x)
show(p(x)); show(p.roots())
```

Sage prints out the characteristic polynomial of  $A$  (up to a sign), and the triple

$$\left[ \left( -\sqrt{2} + 2, 1 \right), \left( \sqrt{2} + 2, 1 \right), (0, 1) \right],$$

where we can read the three eigenvalues together with the multiplicities. Alternatively, we can use the command `A.eigenvalues()`. Next we should compute the corresponding eigenvectors:

• For  $\lambda_1 = 0$  we get the kernel of  $A$ , which is of course determined by solving the matrix equation  $Ax = 0$ , i.e.,

$$\begin{pmatrix} 1 & 1 & 0 \\ 1 & 2 & 1 \\ 1 & 2 & 1 \end{pmatrix} \begin{pmatrix} x_1 \\ x_2 \\ x_3 \end{pmatrix} = \begin{pmatrix} 0 \\ 0 \\ 0 \end{pmatrix}.$$

The result is  $V_0 = \text{Ker}(A) = \text{span}_{\mathbb{R}}\{E_0 := (1, -1, 1)^T\}$ , and hence the eigenspace  $V_0$  is 1-dimensional.

• For  $\lambda_+ = 2 + \sqrt{2}$  we get the matrix equation

$$\begin{pmatrix} -(1 + \sqrt{2}) & 1 & 0 \\ 1 & -\sqrt{2} & 1 \\ 1 & 2 & -(1 + \sqrt{2}) \end{pmatrix} \begin{pmatrix} x_1 \\ x_2 \\ x_3 \end{pmatrix} = \begin{pmatrix} 0 \\ 0 \\ 0 \end{pmatrix}.$$

Again the solution forms a one-dimensional space,  $V_{\lambda_+} = \text{span}_{\mathbb{R}}\{E_+ := (1, 1 + \sqrt{2}, 1 + \sqrt{2})^T\}$ .

• For  $\lambda_- = 2 - \sqrt{2}$  we solve the matrix equation

$$\begin{pmatrix} (\sqrt{2}-1) & 1 & 0 \\ 1 & \sqrt{2} & 1 \\ 1 & 2 & (\sqrt{2}-1) \end{pmatrix} \begin{pmatrix} x_1 \\ x_2 \\ x_3 \end{pmatrix} = \begin{pmatrix} 0 \\ 0 \\ 0 \end{pmatrix}.$$

Solving the corresponding homogeneous linear system we see that  $V_{\lambda_-} = \text{span}_{\mathbb{R}}\{E_- := (1, 1 - \sqrt{2}, 1 - \sqrt{2})^T\}$ . To verify the results for the eigenvectors using Sage, just add the code `A.eigenvectors_right()`. Of course, the case of the zero-eigenvalue which corresponds to the null space of  $A$  can be treated by the command `A.right_kernel()`, as well.

(b) Let us first express the induced linear transformation in the given basis  $\underline{u}$ , which is easier and relies on  $A$ . For this, we need to determine the matrix  $T$  for moving from the standard basis  $\underline{e}$  to the new basis  $\underline{u}$ . But let us apply the tip from 2.C.41, and first obtain the matrix for changing the basis from  $\underline{u}$  to the standard one, that is, the matrix  $T^{-1}$ , whose columns consist just of the vectors  $u_1, u_2, u_3$ :

$$T^{-1} = \begin{pmatrix} 1 & 1 & 0 \\ -1 & 2 & 1 \\ 1 & 0 & 1 \end{pmatrix} \Rightarrow T = (T^{-1})^{-1} = \begin{pmatrix} 0 & 0 & 1 \\ 1 & 0 & -1 \\ -2 & 1 & 3 \end{pmatrix}.$$

Hence, the matrix of the linear transformation under the new basis is given by

$$TAT^{-1} = \begin{pmatrix} 0 & 5 & 2 \\ 0 & -2 & -1 \\ 0 & 14 & 6 \end{pmatrix}.$$

To determine geometrically the mapping induced by the given matrix  $A$ , we can combine our results about the eigenvectors of  $A$  with the statements in 2.E.63. The induced map can be interpreted as a projection along the eigenvector  $E_0 \in V_0 = \text{Ker}(A)$  into the plane generated by the eigenvectors  $E_+ \in V_+$  and  $E_- \in V_-$ , composed with the linear mapping given by stretching in the directions of these eigenvectors by the factor corresponding to the eigenvalues.  $\square$

**2.E.65.** Given the matrix

$$M = \begin{pmatrix} -\frac{2}{3} & -\frac{1}{3} & -\frac{2}{3} \\ \frac{4}{3} & -\frac{7}{3} & -\frac{8}{3} \\ -1 & 1 & -1 \end{pmatrix}$$

determine geometrically the induced linear mapping (in a similar way we did in task 2.E.64).  $\circ$

**2.E.66. (Pauli matrices)** In physics, the state of a particle with spin  $\frac{1}{2}$  is described by the so called *Pauli matrices*. They are the following  $2 \times 2$  matrices over  $\mathbb{C}$ :

$$\sigma_1 = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}, \quad \sigma_2 = \begin{pmatrix} 0 & -i \\ i & 0 \end{pmatrix}, \quad \sigma_3 = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix},$$

where as usual  $i = \sqrt{-1}$ . For square matrices we define their *commutator* (denoted by square brackets  $[ , ]$ ) as  $[\sigma_1, \sigma_2] := \sigma_1\sigma_2 - \sigma_2\sigma_1$ .

i) Show that  $[\sigma_1, \sigma_2] = 2i\sigma_3$ ,  $[\sigma_1, \sigma_3] = -2i\sigma_2$ , and  $[\sigma_2, \sigma_3] = 2i\sigma_1$ , respectively.

ii) Prove that  $\sigma_1^2 = \sigma_2^2 = \sigma_3^2 = 1$  and that the eigenvalues of the matrices  $\sigma_1, \sigma_2, \sigma_3$  are  $\pm 1$ .

iii) It is known that the matrices describing the state of the particle with spin 1 are the following  $3 \times 3$  matrices over  $\mathbb{C}$ :

$$\sigma_x = \frac{1}{\sqrt{2}} \begin{pmatrix} 0 & 1 & 0 \\ 1 & 0 & 1 \\ 0 & 1 & 0 \end{pmatrix}, \quad \sigma_y = \frac{1}{\sqrt{2}} \begin{pmatrix} 0 & -i & 0 \\ i & 0 & -i \\ 0 & i & 0 \end{pmatrix}, \quad \sigma_z = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & -1 \end{pmatrix}.$$

Show that these matrices satisfy the same commuting relations as the Pauli matrices.  $\circ$

**2.E.67. (Quaternionic relations)** Using the Pauli matrices  $\sigma_1, \sigma_2, \sigma_3$  introduced in 2.E.66, set

$$I := E = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}, \quad J := i\sigma_3, \quad K := i\sigma_2, \quad L := i\sigma_1.$$

Prove the following relations, known as the *quaternionic relations*:

$$I^2 = J^2 = K^2 = -1, \quad IJ = -JI = K, \quad JK = -KJ = I, \quad KI = -IK = J.$$

**2.E.68. Remark.** The quaternionic relations impose on the 4-dimensional space spanned by  $1, I, J, K$  the structure of a 4-dimensional *algebra* over  $\mathbb{R}$ . This algebra was invented by W. R. Hamilton in 1843, and is known as the *algebra of quaternions*, denoted by  $\mathbb{H}$ , that is,

$$\mathbb{H} = \text{span}_{\mathbb{R}}\{1, I, J, K\}.$$

Roughly speaking, an “algebra” is a vector space endowed with a binary bilinear operation for multiplication. For the algebra of quaternions, the multiplication is given by the matrix multiplication, hence observe that  $\mathbb{H}$  is associative and non-commutative. A *quaternion* is simply an element in  $\mathbb{H}$ , and hence a linear combination of  $\{1, I, J, K\}$ . On the other hand, the algebra generated by the matrices  $\sigma_1, \sigma_2, \sigma_3$  is isomorphic (as algebra) to the so called *Clifford algebra* of  $\mathbb{R}^3$ . This Clifford algebra is strongly related with developments in geometric algebra, which is an advanced topic with beautiful applications in robotics.

## Solutions to the problems

2.A.2. 1) We have  $(A-E)(A+E) = A^2 + AE - EA - E^2 = A^2 - E$ , since  $AE = EA = A$  for any square matrix  $A$  and the identity matrix satisfies  $E^n = E$  for all  $n$ . We compute  $A^2 = \begin{pmatrix} 1 & 1 + \sqrt{2} \\ 0 & 2 \end{pmatrix}$ , and hence  $(A-E)(A+E) = \begin{pmatrix} 0 & 1 + \sqrt{2} \\ 0 & 1 \end{pmatrix}$ .

2) Here we get  $AB = \begin{pmatrix} 5 & 4 \\ 4\sqrt{2} & 0 \end{pmatrix}$ , thus  $A(Bu) = (AB)u = \begin{pmatrix} 5 & 4 \\ 4\sqrt{2} & 0 \end{pmatrix} \begin{pmatrix} 0 \\ \sqrt{2} \end{pmatrix} = \begin{pmatrix} 4\sqrt{2} \\ 0 \end{pmatrix}$ . Alternatively, we could first compute  $Bu$ , that is,

$$Bu = \begin{pmatrix} 1 & 4 \\ 4 & 0 \end{pmatrix} \begin{pmatrix} 0 \\ \sqrt{2} \end{pmatrix} = \begin{pmatrix} 4\sqrt{2} \\ 0 \end{pmatrix} \implies A(Bu) = \begin{pmatrix} 1 & 1 \\ 0 & \sqrt{2} \end{pmatrix} \begin{pmatrix} 4\sqrt{2} \\ 0 \end{pmatrix} = \begin{pmatrix} 4\sqrt{2} \\ 0 \end{pmatrix}.$$

3) In this case we compute

$$(A-B)(A+B) = \begin{pmatrix} 0 & -3 \\ -4 & \sqrt{2} \end{pmatrix} \begin{pmatrix} 2 & 5 \\ 4 & \sqrt{2} \end{pmatrix} = \begin{pmatrix} -12 & -3\sqrt{2} \\ 4\sqrt{2}-8 & -18 \end{pmatrix}.$$

Thus  $(A-B)(A+B)u = \begin{pmatrix} -12 & -3\sqrt{2} \\ 4\sqrt{2}-8 & -18 \end{pmatrix} \begin{pmatrix} 0 \\ \sqrt{2} \end{pmatrix} = -\begin{pmatrix} 6 \\ 18\sqrt{2} \end{pmatrix} = -6 \begin{pmatrix} 1 \\ 3\sqrt{2} \end{pmatrix}$ .

4) Obviously

$$aA^2 + aB^2 = a(A^2 + B^2) = a \begin{pmatrix} 18 & \sqrt{2} + 5 \\ 4 & 18 \end{pmatrix}.$$

5) The inner product of  $u, v$  is given by

$$u \cdot v = \begin{pmatrix} 0 \\ \sqrt{2} \end{pmatrix} \cdot \begin{pmatrix} 1 \\ 4 \end{pmatrix} = 0 \cdot 1 + \sqrt{2} \cdot 4 = 4\sqrt{2},$$

hence the given quantity equals to zero.

6) This is also easy. We compute  $A^3 = AA^2 = \begin{pmatrix} 1 & 1 \\ 0 & \sqrt{2} \end{pmatrix} \begin{pmatrix} 1 & 1 + \sqrt{2} \\ 0 & 2 \end{pmatrix} = \begin{pmatrix} 1 & 3 + \sqrt{2} \\ 0 & 2\sqrt{2} \end{pmatrix}$ , and thus

$$4A^3 - B^2 = \begin{pmatrix} 4 & 12 + 4\sqrt{2} \\ 0 & 8\sqrt{2} \end{pmatrix} - \begin{pmatrix} 17 & 4 \\ 4 & 16 \end{pmatrix} = \begin{pmatrix} -13 & 8 + 4\sqrt{2} \\ -4 & -16 + 8\sqrt{2} \end{pmatrix}.$$

7) In this case we obtain  $\sqrt{2}u - \frac{1}{2}v = \begin{pmatrix} 0 \\ 2 \end{pmatrix} - \begin{pmatrix} 1/2 \\ 2 \end{pmatrix} = \begin{pmatrix} -1/2 \\ 0 \end{pmatrix}$ .

8) Above we computed  $A(Bu) = \begin{pmatrix} 4\sqrt{2} \\ 0 \end{pmatrix}$ . Hence

$$\frac{\sqrt{2}}{2}u - ABu + 2v = \begin{pmatrix} 0 \\ 1 \end{pmatrix} - \begin{pmatrix} 4\sqrt{2} \\ 0 \end{pmatrix} + \begin{pmatrix} 2 \\ 8 \end{pmatrix} = \begin{pmatrix} 2 - 4\sqrt{2} \\ 9 \end{pmatrix}.$$

9) In this case we have

$$A^2u - B^2v = \begin{pmatrix} 1 & 1 + \sqrt{2} \\ 0 & 2 \end{pmatrix} \begin{pmatrix} 0 \\ \sqrt{2} \end{pmatrix} - \begin{pmatrix} 17 & 4 \\ 4 & 16 \end{pmatrix} \begin{pmatrix} 1 \\ 4 \end{pmatrix} = \begin{pmatrix} 2 + \sqrt{2} \\ 2\sqrt{2} \end{pmatrix} - \begin{pmatrix} 33 \\ 68 \end{pmatrix} = \begin{pmatrix} \sqrt{2} - 31 \\ 2\sqrt{2} - 68 \end{pmatrix}.$$

10) Notice that  $B^2u = \begin{pmatrix} 17 & 4 \\ 4 & 16 \end{pmatrix} \begin{pmatrix} 0 \\ \sqrt{2} \end{pmatrix} = \begin{pmatrix} 4\sqrt{2} \\ 16\sqrt{2} \end{pmatrix} = 4\sqrt{2}v$ . Hence the vector  $w := B^2u$  is a non-zero multiple of the vector  $v$ , and since  $\|v\|^2 = v \cdot v$ , we see that the given expression is a multiple of the square of the norm of  $v$ . Indeed, we have  $v \cdot v = 17$  and a direct computation gives

$$(B^2u) \cdot (4v) = w \cdot (4v) = (4\sqrt{2}v) \cdot (4v) = 16\sqrt{2}v \cdot v = 16\sqrt{2}\|v\|^2 = 272\sqrt{2}.$$

2.A.4. Notice that one could follow alternative computations to obtain the same results. Now, for a verification of the results in Sage, we use the cell

```
A=matrix([[1, sqrt(2), pi], [0, 1, 1], [-pi, 0, 2]])
B=matrix([[0, 1, 1], [-1, 0, pi], [-1, 0, 1]])
u=vector([pi, 0, sqrt(2)]); E=matrix.identity(3)
show(A-E); show((A-E)^2)
C=(A-E)^2*(4*B); show(C); show(C*u)
show(B^2); show((A-E).transpose())
D=(A-E).transpose()*B^2; show(D); show(D*u)
show(A*B*u); show(B*A*u)
```

**2.A.16.** (a) The linear systems whose extended matrix is  $B_{\pm}$ , are overdetermined, i.e., we have more equations than unknowns:

$$\underbrace{\begin{pmatrix} 1 & 1 \\ 3 & 2 \\ 2 & \pm 1 \end{pmatrix}}_{3 \times 2} \underbrace{\begin{pmatrix} x_1 \\ x_2 \end{pmatrix}}_{2 \times 1} = \underbrace{\begin{pmatrix} -2 \\ 0 \\ 2 \end{pmatrix}}_{3 \times 1},$$

or in other words

$$\begin{cases} x_1 + x_2 = -2, \\ 3x_1 + 2x_2 = 0, \\ 2x_1 + x_2 = 2, \end{cases} \quad \text{and} \quad \begin{cases} x_1 + x_2 = -2, \\ 3x_1 + 2x_2 = 0, \\ 2x_1 - x_2 = 2, \end{cases}$$

respectively. Such systems are inconsistent, unless some of the equations are linearly dependent. For the matrix  $B_+$ , the cell

```
Bp=matrix(QQ, [[1, 1, -2], [3, 2, 0], [2, 1, 2]])
rec=Bp.rref();show(rec)
print(Bp.pivots())
```

returns the matrix  $\begin{pmatrix} 1 & 0 & 4 \\ 0 & 1 & -6 \\ 0 & 0 & 0 \end{pmatrix}$ , and the pair  $(0, 1)$ , respectively. Thus, the pivots are on the first and second column and the system admits a unique solution, given by  $\{x_1 = 4, x_2 = -6\}$ . This also follows by using the backslash operator:

```
Ap=matrix(QQ, [[1, 1], [3, 2], [2, 1]])
b=vector([-2, 0, 2])
x=Ap\b; show(x)
```

Theoretically, this unique solution is explained by the fact that the second equation in the corresponding linear system is a linear combination of the first and the third:

$$3x_1 + 2x_2 = (x_1 + x_2) + (2x_1 + x_2) = -2 + 2 = 0.$$

On the other side for the matrix  $B_-$  Sage gives as reduced row echelon form the identity  $3 \times 3$  matrix, and so as pivot columns all the three columns, i.e., the pivot command for  $B_-$  returns  $(0, 1, 2)$ . The existence of a pivot in the last column implies that the corresponding linear system is inconsistent, a claim that you can easily prove also by hand.

(b) For the matrix  $C$  the cell

```
C=matrix(QQ, [[2, 1, 7, 0], [-1, 4, 10, 5], [3, 2, 12, 10], [0, 0, 0, 10]])
show(C.rref())
print(C.pivots())
```

returns

$$\begin{pmatrix} 1 & 0 & 2 & 0 \\ 0 & 1 & 3 & 0 \\ 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & 0 \end{pmatrix} \quad \text{and} \quad (0, 1, 3),$$

respectively. Thus, the pivots are located in the first, second, and fourth columns. Moreover, the presence of the last row containing only zeros alerts the possibility of an infinite number of solutions. Indeed, because there is no pivot in the 3rd column,  $x_3$  is a free variable. In particular, the homogeneous system  $Cx = 0$  has infinite solutions given by  $x_1 = -2x_3 = -2t$ ,  $x_2 = -3x_3 = -3t$ ,  $x_4 = 0$ , with  $x_3 = t \in \mathbb{R}$ .

**2.A.17.** Clearly the unknowns  $X_1$  and  $X_2$  must be  $2 \times 2$  matrices, so we may set  $X_1 = \begin{pmatrix} a_1 & b_1 \\ c_1 & d_1 \end{pmatrix}$  and  $X_2 = \begin{pmatrix} a_2 & b_2 \\ c_2 & d_2 \end{pmatrix}$ , respectively, for some  $a_i, b_i, c_i, d_i \in \mathbb{R}$ , for all  $i = 1, 2$ . Then, for the first case an easy computation gives that

$$\begin{pmatrix} a_1 + 3c_1 & b_1 + 3d_1 \\ 3a_1 + 8c_1 & 3b_1 + 8d_1 \end{pmatrix} = \begin{pmatrix} 1 & 2 \\ 3 & 4 \end{pmatrix}.$$

This implies the following system of equations  $\{a_1 + 3c_1 = 1, b_1 + 3d_1 = 2, 3a_1 + 8c_1 = 3, 3b_1 + 8d_1 = 4\}$ , which has a unique solution given by  $a_1 = 1, b_1 = -4, c_1 = 0$  and  $d_1 = 2$ . Thus  $X_1 = \begin{pmatrix} 1 & -4 \\ 0 & 2 \end{pmatrix}$ .

Let apply a more elegant method for the second case, which is based on the inverse of a  $2 \times 2$  matrix  $A$ . Recall that the inverse of a  $n \times n$  matrix is the square matrix of the same order as  $A$ , uniquely determined by the equation  $AA^{-1} = A^{-1}A = E$ , where as usual  $E$  is the identity matrix. Notice that  $A^{-1}$  may not always exist. By the discussion in 2.2.11 we know the following nice expression of the inverse of a  $2 \times 2$  matrix  $A = \begin{pmatrix} a & b \\ c & d \end{pmatrix}$ , where  $a, b, c, d \in \mathbb{R}$  and  $\det(A) = ad - bc \neq 0$ :

$$A^{-1} = \frac{1}{(ad-bc)} \cdot \begin{pmatrix} d & -b \\ -c & a \end{pmatrix}.$$

An application gives  $A^{-1} = \begin{pmatrix} -8 & 3 \\ 3 & -1 \end{pmatrix}$ , and then by multiplying both sides of the given equation from the right by  $A^{-1}$ , we deduce that

$$X_2 = \begin{pmatrix} 1 & 2 \\ 3 & 4 \end{pmatrix} A^{-1} = \begin{pmatrix} -2 & 1 \\ -12 & 5 \end{pmatrix}$$

(since  $X_2 A A^{-1} = X_2 I = X_2$ ). Of course, this method applies for solving also the first matrix equation (here one should multiply both sides of the given equation by the corresponding  $A^{-1}$  from the left, so that  $A^{-1} A X_1 = I X_1 = X_1$ ).

**2.A.19.** We obtain

$$A^{-1} = \begin{pmatrix} 1 & 10 & -4 \\ 1 & 12 & -5 \\ 0 & 5 & -2 \end{pmatrix}, B^{-1} = \begin{pmatrix} 2 & -3 & 0 & 0 & 0 \\ -5 & 8 & 0 & 0 & 0 \\ 0 & 0 & -1 & 0 & 0 \\ 0 & 0 & 0 & -5 & 2 \\ 0 & 0 & 0 & 3 & -1 \end{pmatrix}, C^{-1} = \frac{1}{2} \cdot \begin{pmatrix} 0 & 1 & 1 & 0 \\ 0 & 1 & 0 & -1 \\ 1 & -1 & 0 & 0 \\ 1 & -1 & -1 & 1 \end{pmatrix}, D^{-1} = \frac{1}{2} \cdot \begin{pmatrix} 3 & -i \\ i & 1 \end{pmatrix}.$$

**2.A.20.** Of course, we may use Sage to transform the given matrix  $A$  to a row-echelon form.

```
A=matrix([[1, -3, 0, 1], [1, -2, 2, -4], [1, -1, 0, 1], [-2, -1, 1, -2]])
show(A.echelon_form())
```

Sage returns the matrix

$$\begin{pmatrix} 1 & 0 & 0 & 6 \\ 0 & 1 & 0 & 5 \\ 0 & 0 & 1 & 5 \\ 0 & 0 & 0 & 10 \end{pmatrix},$$

hence the rank of  $A$  equals to four. In fact, Sage allows us to directly compute the rank of a given matrix  $A$ , by the command `A.rank()`.

Let us move to the remaining questions. The extended matrix of the first linear system has the form

$$\left( \begin{array}{cccc|c} 1 & 1 & 1 & -2 & 4 \\ -3 & -2 & -1 & -1 & 5 \\ 0 & 2 & 0 & 1 & 1 \\ 1 & -4 & 1 & -2 & 3 \end{array} \right).$$

But the left-hand side of this extended matrix is exactly  $A^T$ , thus we can get the column-echelon form the same way as before. In particular, the columns of the matrix are linearly independent and the rank is maximal, i.e., four again. Therefore, there exists the inverse of  $A^T$ , i.e., the matrix  $(A^T)^{-1}$ , and it turns out that the system has a unique solution given by

$$(x_1, x_2, x_3, x_4)^T = (A^T)^{-1} \cdot (4, 5, 1, 3)^T.$$

Next, the homogenous system has the same left-hand side (given by the matrix  $A^T$ ), as the first. Because the numbers on the right-hand side of the equations in the system do not influence the number of solutions and because every homogeneous system has a zero solution, the only solution of the second system is the zero one,  $(x_1, x_2, x_3, x_4)^T = (0, 0, 0, 0)^T$ .

The extended matrix of the 3rd system coincides with  $A$ :

$$\left( \begin{array}{ccc|c} 1 & -3 & 0 & 1 \\ 1 & -2 & 2 & -4 \\ 1 & -1 & 0 & 1 \\ -2 & -1 & 1 & -2 \end{array} \right).$$

Sage revealed to us that the transformation of the matrix into the row echelon form, yields a row of the form

$$(0 \ 0 \ 0 \ | \ a), \quad \text{where } a \neq 0.$$

However, the column on the right-hand side is not a linear combination of the columns on the left-hand side (the rank of the matrix is four). It follows that this system has no solution. We may verify this claim easily in Sage, e.g. via the `solve` command.

```
var("x1, x2, x3")
eq1=x1-3*x2-1;eq2=x1-2*x2+2*x3+4
eq3=x1-x2-1;eq4=-2*x1-x2+x3+2
solve([eq1==0,eq2==0,eq3==0,eq4==0],x1,x2,x3)
```

Sage's output is `[]`, indicating that the system has no solutions (the output `[]` is a common way for Sage to represent an empty solution set).

**2.B.2.** First we treat  $\sigma$ , where observe that after the integer 3 in the second row, there are the small integers 1 and 2, so in the required sum we add 2. Next, after 1 there is no smaller number and we add 0. In the sequel, after the integer 6 there are the smaller numbers five, four and two, thus we add 3, similarly for seven, eight and nine, while for five we add 2, for four we add 1 and for two nothing. Thus we have  $2 + 3 + 3 + 3 + 3 + 2 + 1 = 17$  inversions in total, which implies that  $\sigma$  is an odd permutation. Its parity is  $(-1)^{17} = -1$ . Applying the alternative method (using the theorem given in 2.2.2), we obtain the expression  $\sigma = (1, 3)(3, 6)(6, 9)(9, 2)(4, 7)(7, 5)(5, 8)$ . Thus, there are seven transpositions in the decomposition, and the permutation is indeed odd.

Similarly we can treat the second permutation  $\tau$ , which decomposes into a product of three transpositions (using the cycle decomposition):  $\tau = (1, 2, 4)(3, 6) = (1, 2)(2, 4)(3, 6)$ . Or one can count the number of inversions in  $\tau$ . The latter is given by  $1 + 2 + 3 + 0 + 1 = 7$ , and thus both ways imply that  $\tau$  is an odd permutation, i.e.,  $\text{sign}(\tau) = -1$ .

**2.B.7.** According to Laplace theorem given 2.2.9 we can compute the determinant via expansion along the fifth row (or the second column, which each contains four zeros). We obtain:

$$\begin{vmatrix} 1 & 0 & 1 & 0 & 1 \\ 0 & 2 & 0 & 2 & 0 \\ 0 & 0 & 3 & 0 & 3 \\ 4 & 0 & 0 & 4 & 4 \\ 0 & 0 & 0 & 0 & 5 \end{vmatrix} = 0 \cdot \begin{vmatrix} 0 & 1 & 0 & 1 \\ 2 & 0 & 2 & 0 \\ 0 & 3 & 0 & 3 \\ 0 & 0 & 4 & 4 \end{vmatrix} - 0 \cdot \begin{vmatrix} 1 & 1 & 0 & 1 \\ 0 & 0 & 2 & 0 \\ 0 & 3 & 0 & 3 \\ 4 & 0 & 4 & 4 \end{vmatrix} + 0 \cdot \begin{vmatrix} 1 & 0 & 0 & 1 \\ 0 & 2 & 2 & 0 \\ 0 & 0 & 0 & 3 \\ 4 & 0 & 4 & 4 \end{vmatrix} - 0 \cdot \begin{vmatrix} 1 & 0 & 1 & 1 \\ 0 & 2 & 0 & 0 \\ 0 & 0 & 3 & 3 \\ 4 & 0 & 0 & 4 \end{vmatrix} + 5 \cdot \begin{vmatrix} 1 & 0 & 1 & 0 \\ 0 & 2 & 0 & 2 \\ 0 & 0 & 3 & 0 \\ 4 & 0 & 0 & 4 \end{vmatrix}$$

$$= 5 \cdot \begin{vmatrix} 1 & 0 & 1 & 0 \\ 0 & 2 & 0 & 2 \\ 0 & 0 & 3 & 0 \\ 4 & 0 & 0 & 4 \end{vmatrix} = 5 \cdot 2 \cdot \begin{vmatrix} 1 & 1 & 0 \\ 0 & 3 & 0 \\ 4 & 0 & 4 \end{vmatrix} = 120.$$

The determinant of the last  $3 \times 3$  matrix was computed by the Sarrus rule. The check in Sage is most simple:

```
D=matrix([[1, 0, 1, 0, 1],[0, 2, 0, 2, 0],[0, 0, 3, 0, 3],[4, 0, 0, 4, 4],[0, 0, 0, 0, 5]])
det(D)
```

**2.B.8.** (a) This is a direct consequence of the Cauchy theorem, that is,  $\det(AB) = \det(A) \det(B)$ , see 2.2.7.

(b) This identity is in fact a consequence of the following: The determinant of a  $n \times n$  matrix  $A$  is a *multilinear mapping* in the columns (or rows) of  $A$ . Hence for example if  $c \in \mathbb{R}$  and  $A^j$  denotes the  $j$ th column of  $A$  such that  $A = (A^1 \ A^2 \ \dots \ A^n)$ , then we have

$$\det(cA) = \det((cA^1 \ cA^2 \ \dots \ cA^n)) = c^n \det((A^1 \ A^2 \ \dots \ A^n)) = c^n \det(A).$$

It remains to prove our statement for the multi-linearity of  $\det$ , which we leave as an exercise on multilinear mappings, see also 2.3.23.

(c) On can present many examples. For instance, based on the identity presented in part (b) for  $A = B$  and  $n > 1$  we see that  $\det(A + B) = \det(2A) = 2^n \det(A) > 2 \det(A) = \det(A) + \det(B)$ .

**2.B.10.** (a) We present the solutions mainly via Sage, and leave to the reader the description of formal proofs. To find the null space of the matrix  $A$ , give the cell

```
A=matrix([[1, -1, pi, 0],[0, pi, -1, 0], [1, 0, -1, pi]])
show(A.right_kernel())
```

The output has the form

$$\text{RowSpan}_{\text{SR}} \left( 1 \quad -\frac{1}{\pi(\pi-\frac{1}{\pi})} \quad -\frac{1}{\pi-\frac{1}{\pi}} \quad -\frac{\pi-\frac{1}{\pi}+1}{\pi(\pi-\frac{1}{\pi})} \right).$$

Therefore,  $\text{Ker}(A)$  is 1-dimensional. In a similar way we compute  $\text{Ker}(B) = \text{span}\{(1, -1, -1, 1)^T\}$ . We will learn for vector subspaces and the notion of “dimension” of a vector (sub)space very soon, in Section C.

(b) Obviously, the required submatrix has the form  $\begin{pmatrix} \pi & 0 \\ 0 & \pi \end{pmatrix}$ , which is diagonal. In Sage there are many ways to determine submatrices. For the specific case, where we should cancel both rows and columns, an appropriate command is `A.matrix_from_rows_and_columns()`:

```
d=A.matrix_from_rows_and_columns([1, 2],[1,3]); show(d)
#verify that d is diagonal
print(bool(d==diagonal_matrix([pi, pi])))
```

In this command the brackets  $[1, 2]$  and  $[1, 3]$  specify the rows and columns that are retained in the submatrix.

Another method relies on the bracket operation that we shortly mentioned above. Hence for example, add the cell

```
suba=A[1:3, 1:4:2]; show(suba)
```

We mention that in the expression  $A[1 : 3, 1 : 4 : 2]$  the final index 2 is the slice step between the columns.

(c) The submatrix obtained by  $B$  after canceling the first and last row, and the fourth column has the form  $\begin{pmatrix} 2 & 1 & 4 \\ 3 & 4 & 1 \end{pmatrix}$ . In Sage use the block

```
B=matrix([[1, 2, 3, 4],[2, 1, 4, 3], [3, 4, 1, 2], [4, 3, 2, 1]])
show(B.matrix_from_rows_and_columns([1, 2],[0, 1,2]))
```

or, as an alternative, you may type

```
B=matrix([[1, 3, 4],[2, 1, 4, 3], [3, 4, 1, 2], [4, 3, 2, 1]])
show(B[1:3, 0:-1])
```

In fact, one can replace the final line by the command `show(B[1 : 3, 0 : 3])`.

(d) In this case the required submatrix has the form  $\begin{pmatrix} 2 & 4 \\ 4 & 2 \end{pmatrix}$ , which is obviously symmetric. In Sage add in the previous block the code

```
subb=B.matrix_from_rows_and_columns([1,3], [0, 2])
bool(subb==subb.transpose())
```

**2.C.2.** The set of real polynomials of degree exactly  $m$  is *not* a real vector space, because it fails to satisfy one of the key properties of a vector space: closure under addition. This is because the sum of two polynomials of degree  $m$  does not necessarily have the same degree. Can you provide an explicit example?

**2.C.4.** One can use the following block:

```
v1=vector(QQ, [1/2, 2/3, 1, 0])
v2=vector(QQ, [2, 0, 1/7, 0])
v3=vector(QQ, [0, 1/5, 2/5, 1])
v4=vector(QQ, [-1, 2, 0, 3])
show(3*v1+2*v2+5*v3+v4)
```

Another approach involves placing the vectors and their coefficients into two separate lists and then manipulating these lists as follows:

```
vectors=[v1, v2, v3, v4]
scalars=[3, 2, 5, 1]
lin_comb=sum([scalars[i]*vectors[i] for i in range(len(vectors))])
show(lin_comb)
```

In this block we used the `len()` function to determine the number of elements in the list with vectors, which can be very useful when working with large lists. Check yourselves that both cells print out the following answer:  $(\frac{9}{2}, 5, \frac{37}{7}, 8)$ . There are further methods to describe the linear combination (span) of vectors via Sage, presented in [2.C.12](#).

**2.C.5.** A solution goes as follows:

```
A=matrix(QQ, [[3, -9, 9, 0],[9, -3, 6, 0],[9, -6, 0,-6],[-9, 12, 6, 6]])
b = vector(QQ, [-1, -1, 2, 0])
cols=A.columns(); show(cols)
soln = [-2/15, 1/5, 2/15, -11/15]
bool(sum([soln[i]*cols[i] for i in range(len(cols))])==b)
```

In this block we used the function `.columns()` to access the columns of  $A$ . Note also that the final line verifies that linear combination of the columns of  $A$  with coefficients from `soln` (this represents the given solution), equals the vector  $b$ . Executing this block we obtain `True`. In fact, in our solution we could replace the final line by

```
show(sum([soln[i]*cols[i] for i in range(len(cols))]))
```

so that we can directly compare this expression with the constant vector  $b$ .

**2.C.6.** The finite field  $\mathbb{Z}_5$  is an important mathematical structure used in various areas (such as algebra, cryptography, and computer science). It consists of the integers from 0 to 4,  $\mathbb{Z}_5 = \{0, 1, 2, 3, 4\}$ , with arithmetic operations performed modulo 5. For your convenience we present the addition and multiplication table for  $\mathbb{Z}_5$ :

+	0	1	2	3	4
0	0	1	2	3	4
1	1	2	3	4	0
2	2	3	4	0	1
3	3	4	0	1	2
4	4	0	1	2	3

·	0	1	2	3	4
0	0	0	0	0	0
1	0	1	2	3	4
2	0	2	4	1	3
3	0	3	1	4	2
4	0	4	3	2	1

For instance,  $3 + 4 = 7 = 2(\text{mod}5)$  and  $2 \cdot 3 = 6 = 1(\text{mod}5)$ . The vector space  $\mathbb{Z}_5^3 = \mathbb{Z}_5 \times \mathbb{Z}_5 \times \mathbb{Z}_5$  consists of vectors  $(a, b, c)^T$ , where each entry  $a, b, c$  is an element of the finite field  $\mathbb{Z}_5$ . Hence,  $\mathbb{Z}_5^3$  is 3-dimensional over  $\mathbb{Z}_5$ . The addition and scalar multiplication are respectively defined by

$$u + v = \begin{pmatrix} (u_1 + v_1) \text{ mod } 5 \\ (u_2 + v_2) \text{ mod } 5 \\ (u_3 + v_3) \text{ mod } 5 \end{pmatrix}, \quad cu = \begin{pmatrix} (cu_1) \text{ mod } 5 \\ (cu_2) \text{ mod } 5 \\ (cu_3) \text{ mod } 5 \end{pmatrix},$$

for any two vectors  $u = (u_1, u_2, u_3)^T, v = (v_1, v_2, v_3)^T$  and scalar  $c \in \mathbb{Z}_5$ . For instance:

$$\begin{pmatrix} 3 \\ 4 \\ 2 \end{pmatrix} + \begin{pmatrix} 2 \\ 3 \\ 4 \end{pmatrix} = \begin{pmatrix} (3+2) \text{ mod } 5 \\ (4+3) \text{ mod } 5 \\ (2+4) \text{ mod } 5 \end{pmatrix} = \begin{pmatrix} 0 \\ 2 \\ 1 \end{pmatrix}, \quad 3 \begin{pmatrix} 1 \\ 4 \\ 2 \end{pmatrix} = \begin{pmatrix} 3 \text{ mod } 5 \\ 12 \text{ mod } 5 \\ 6 \text{ mod } 5 \end{pmatrix} = \begin{pmatrix} 3 \\ 2 \\ 1 \end{pmatrix}.$$

The zero vector is the additive identity in  $\mathbb{Z}_5^3$ . Can you derive the expression of the additive inverse of some vector  $u = (u_1, u_2, u_3)^T \in \mathbb{Z}_5^3$ ? About the total number of vectors in  $\mathbb{Z}_5^3$  we see that each entry of a vector in  $\mathbb{Z}_5^3$  can independently take one of 5 possible values:  $\{0, 1, 2, 3, 4\}$ . Thus, the total number of vectors in this space is  $5^3 = 125$ . Here is a verification via Sage (to create the finite field  $\mathbb{Z}_5$  we will use the function GF)

```
# Define the finite field Z_5
F = GF(5)
# Define the 3-dimensional vector space over Z_5
V = VectorSpace(F, 3)
# Calculate the total number of vectors in the vector space
total_vectors = V.cardinality()
# Output the result
total_vectors
```

**2.C.8.** Here is a block that we can use to answer the task:

```
V=QQ^3
e1=vector([1, 0, 0])
e2=vector([0, 1, 0])
e3=vector([0, 0, 1])
Vxy=V.span([e1, e2]); print(Vxy)
Vxz=V.span([e1, e3]); print(Vxz)
Vyz=V.span([e2, e3]); print(Vyz)
```

Let us also present what Sage prints out:

```
Vector space of degree 3 and dimension 2 over Rational Field
Basis matrix:
[1 0 0]
[0 1 0]
Vector space of degree 3 and dimension 2 over Rational Field
Basis matrix:
[1 0 0]
[0 0 1]
Vector space of degree 3 and dimension 2 over Rational Field
Basis matrix:
[0 1 0]
[0 0 1]
```

**2.C.9.** For a matrix  $A$  of size  $m \times n$  the column space is defined by  $C(A) = \{Ax : x \in \mathbb{R}^n\}$ . Hence, obviously,  $C(A)$  is a subset of  $\mathbb{F}^m$ . Note that  $C(A)$  contains the zero vector, since  $A0 = 0$ . To prove that is a linear subspace of  $\mathbb{F}^m$  we should prove that  $C(A)$  is closed under vector addition and scalar multiplication. Let  $u, v \in C(A)$ . Then, there exist vectors  $x, y \in \mathbb{F}^n$  such that  $u = Ax$  and  $v = Ay$ , respectively. Thus, considering the linear combination  $\alpha u + \beta v$  of  $u, v$  for some scalars  $\alpha, \beta \in \mathbb{F}$ , we see that  $\alpha u + \beta v = \alpha(Ax) + \beta(Ay) = A(\alpha x + \beta y)$ . This shows that  $\alpha u + \beta v \in C(A)$ , and hence  $C(A)$  is a subspace of  $\mathbb{F}^m$ . Recall that the rank of  $A$  equals the number of (nonzero) pivots in elimination, hence it coincides with the maximum number of linearly independent columns (or linearly independent rows). The relation now between the dimension of  $C(A)$  and the rank of  $A$  follows. A similar analysis applies for the row space and the left null space, which we leave for practice.

**2.C.11.** The given vectors are linearly independent: The equation  $a \cdot v_1 + b \cdot v_2 = 0$  for some  $a, b \in \mathbb{R}$ , can be equivalently written in matrix form as  $(a, 0, a, 2a)^T + (0, b, 0, 0)^T = (0, 0, 0, 0)^T$ , from where we immediately get  $a = 0 = b$ . We can verify the independence of  $v_1, v_2$  in Sage as in [2.C.10](#):

```
V=QQ^4;v1=vector(QQ, [1, 0, 1, 2]); v2=vector(QQ, [0, 1, 0, 0])
V.linear_dependence([v1, v2]) ==[]
```

It follows that the linear span  $W = \text{span}_{\mathbb{Q}}\{v_1, v_2\}$  is a 2-dimensional linear subspace of  $\mathbb{Q}^4$ . As we said an alternative is given by using the command `span`. For example, adding in the previous cell the syntax

```
W=V.span([v1, v2]); W
```

verifies that  $W$  is 2-dimensional subspace of  $\mathbb{Q}^4$ . In Sage we can directly find a basis of a vector space  $V$  by the command `W.basis()`. Hence for example we can type

```
V=QQ^4
v1=vector(QQ, [1, 0, 1, 2])
v2=vector(QQ, [0, 1, 0, 0])
W=V.subspace([v1, v2])
B=W.basis();show(B)
```

By this block Sage will directly print the basis vectors  $v_1$  and  $v_2$ . Other techniques to create subspaces rely on the creation of row or column spaces of matrices, a situation that we will encounter a bit later.

**2.C.12.** (a) It is easy to see the vector equation  $av_1 + bv_2 = 0$  for some scalars  $a, b$ , implies that  $a = b = 0$ . Thus, the vectors  $v_1, v_2$  are linearly independent and automatically form a basis of  $W = \text{span}_{\mathbb{Q}}\{v_1, v_2\}$ . Therefore,  $W$  is 2-dimensional, see also the discussion in [2.3.7-2.3.10](#) for the concept of dimension of a vector space. A general element of  $W$  has the form  $w = c_1v_1 + c_2v_2 = (2c_1 + 4c_2, -c_1, 3c_1 + c_2)^T$  with  $c_1, c_2 \in \mathbb{Q}$ .

There are many ways to program Sage to verify the linear independence of  $v_1, v_2$ . Here, we present a method that uses the rank of the matrix  $A$ , which has  $v_1, v_2$  as its columns. For a built-in method in Sage to check linear independence we refer to [2.C.10](#).

```
A = matrix(QQ, [[2, 4], [-1, 0], [3, 1]])
rank_of_A = A.rank()
print(f"The rank of matrix A is: {rank_of_A}")
if rank_of_A == 2:
    print("The vectors are linearly independent.")
else:
    print("The vectors are linearly dependent.")
```

Sage's output has the form

```
The rank of matrix A is: 2
The vectors are linearly independent.
```

To introduce  $W$  in Sage we can type

```
V = VectorSpace(QQ, 3); v1 = V([2, -1, 3]); v2 = V([4, 0, 1])
W = V.subspace([v1, v2])
print("\nSubspace W spanned by v1 and v2:")
print(W)
```

An alternative to create  $W$  is to use the `span` command, as in [2.C.8](#):

```
W.span([v1, v2]); print(W)
```

For both cases Sage's output has the form

```

Subspace W spanned by v1 and v2:
Vector space of degree 3 and dimension 2 over Rational Field
Basis matrix:
[ 1  0  1/4]
[ 0  1 -5/2]

```

We will analyze the terms used in this answer in more detail soon. For now, keep only that  $W$  is a 2-dimensional subspace of  $\mathbb{Q}^3$ , over the rationals.

To illustrate  $W$  we can leverage Sage's 3D-graphics functions, because we are working within a three-dimensional space. We want to generate a figure displaying  $v_1$  in red,  $v_2$  in green and  $W$  as the shaded area. With this goal in mind one can execute the following block:

```

# Define the vectors
v1 = vector(QQ, [2, -1, 3])
v2 = vector(QQ, [4, 0, 1])
# Create a meshgrid for the plane using linear combinations of v1 and v2
u, v = var("u v")
plane = u*v1 + v*v2
# Define the plot range for u and v
plot_range = (-1, 1)
# Plot the plane
plane_plot = parametric_plot3d(plane,
                                (u, *plot_range),
                                (v, *plot_range),
                                color="lightblue",
                                opacity=0.5)
# Plot the vectors v1 and v2 starting from the origin
v1_plot = arrow3d((0, 0, 0), v1, color="red", thickness=0.05)
v2_plot = arrow3d((0, 0, 0), v2, color="green", thickness=0.05)
# Combine the plots
show(plane_plot + v1_plot + v2_plot, figsize=8)

```

This produces the following illustration of  $W$ :

We will meet further applications of the Sage function `parametric_plot3d` in Chapter 4.

Finally, if  $v_2$  is a multiple of  $v_1$ , then  $W$  will be reduced to a line (dimension 1).

(b) This task is a bit more challenging compared to part (a). By assumption,

$$W = \text{span}_{\mathbb{Q}}\{u_1 = (1, 1, 0, 0)^T, u_2 = (0, 1, 1, 0)^T\} = \{au_1 + bu_2 : a, b \in \mathbb{Q}\} = \{(a, a + b, b, 0)^T : a, b \in \mathbb{Q}\} \subset \mathbb{Q}^4.$$

It is easy to see that  $u_1, u_2$  are linearly independent, hence  $\dim_{\mathbb{Q}} W = 2$ , with a basis given by these vectors. For instance,

the rank of the matrix  $A = \begin{pmatrix} 1 & 0 \\ 1 & 1 \\ 0 & 1 \\ 0 & 0 \end{pmatrix}$  formed by  $u_1, u_2$  is 2. This is because by row reducing  $A$  we get

$$\begin{pmatrix} 1 & 0 \\ 1 & 1 \\ 0 & 1 \\ 0 & 0 \end{pmatrix} \rightarrow \begin{pmatrix} 1 & 0 \\ 0 & 1 \\ 0 & 1 \\ 0 & 0 \end{pmatrix} \rightarrow \begin{pmatrix} 1 & 0 \\ 0 & 1 \\ 0 & 0 \\ 0 & 0 \end{pmatrix},$$

and the final matrix has 2 pivot columns. Thus  $\text{rank}(A) = 2$  and  $u_1, u_2$  are linearly independent.

The *quotient space*  $V/W$  is the set of equivalence classes of vectors in  $V$ , under the equivalence relation  $\sim$  defined by the subspace  $W \subset V$ , i.e.,  $v_1 \sim v_2$  if and only if  $v_1 - v_2 \in W$ , where  $v_1, v_2 \in V$ . Thus, we can view  $V/W$  as  $V/W = \{[u] : u \in V\}$ , where the equivalence class of  $u \in V$  is denoted by  $[u] = \{u + w : w \in W\}$ , see 3.4.13 in Chapter 3.

The quotient space  $V/W$  inherits a vector space structure from  $V$ , with operations defined by  $[u] + [v] = [u + v]$  and  $a[u] = [au]$ , for any two vectors  $u, v$  and scalar  $a$ , try to verify this claim yourselves. It is also easy to prove that the dimension of  $V/W$  is given by  $\dim(V/W) = \dim(V) - \dim(W)$ .

For our case,  $V = \mathbb{Q}^4$  and  $\dim_{\mathbb{Q}} W = 2$ , thus  $\dim_{\mathbb{Q}} V/W = 4 - 2 = 2$ . Since  $W$  is a 2-dimensional plane in  $\mathbb{Q}^4$ , geometrically the quotient space  $V/W$  represents the remaining “directions”, after factoring out the influence of  $W$ . To introduce the quotient space  $V/W$  in Sage we can use the command `V.quotient(W)`, as follows:

```
V = VectorSpace(QQ, 4)
u1 = vector(QQ, [1, 1, 0, 0])
u2 = vector(QQ, [0, 1, 1, 0])
W = V.subspace([u1, u2])
print(V.quotient(W))
```

Let us present Sage’s output:

```
Vector space quotient V/W of dimension 2 over Rational Field where
V: Vector space of dimension 4 over Rational Field
W: Vector space of degree 4 and dimension 2 over Rational Field
Basis matrix:
[ 1  0 -1  0]
[ 0  1  1  0]
```

Notice in this answer the basis matrix refers to  $W$ . For a basis of  $V/W$  see 2.C.13.

**2.C.13.** The quotient space  $V/W$  is a 2-dimensional vector space over  $\mathbb{Q}$ , as shown in 2.C.12. Thus, a basis of  $V/W$  will consist of two vectors. These vectors can be chosen to extend the basis of  $W$  to a basis of  $V = \mathbb{Q}^4$ . For example, consider the vector  $e_3 = (0, 0, 1, 0)^T$  of the standard basis of  $\mathbb{Q}^4$ , and suppose that  $e_3 = au_1 + bu_2$  for some  $a, b \in \mathbb{Q}$ . Then we get the following system of equations  $\{a = 0, a + b = 0, b = 1\}$ , which does not admit a consistent solution for  $a, b \in \mathbb{Q}$ . This means that  $e_3 \notin W$ . Similarly we can show that  $e_4 = (0, 0, 0, 1)^T \notin W$ . Thus a basis of  $V/W$  is given by  $\underline{u} = \{e_3, e_4\}$ .

To verify with Sage that  $\underline{u}$  forms a basis of  $V/W$  we will use the `vector in subspace` command, which provides a convenient way to check if a given vector is an element of a specified subspace. Our program has the following form:

```
# Define the vectors
u1 = vector(QQ, [1, 1, 0, 0])
u2 = vector(QQ, [0, 1, 1, 0])
e3 = vector(QQ, [0, 0, 1, 0])
e4 = vector(QQ, [0, 0, 0, 1])
# Define the space W spanned by u1 and u2
V = VectorSpace(QQ, 4)
W = V.span([u1, u2])
# Check if e3 and e4 are in the span of W
def is_in_subspace(vector, subspace):
    return vector in subspace
is_e3_in_W = is_in_subspace(e3, W)
is_e4_in_W = is_in_subspace(e4, W)
# Check linear independence of e3 and e4
```

```
# Construct the matrix with e3 and e4 as rows
matrix_e3_e4 = Matrix(QQ, [e3, e4])
is_independent = matrix_e3_e4.rank() == 2
# Construct the span of e3 and e4
span_V = V.span([e3, e4])
span_check = span_V.dimension() == 2
# Display results
is_e3_in_W, is_e4_in_W, is_independent, span_check
```

Confirm yourselves that Sage's output appears as  $(\text{False}, \text{False}, \text{True}, \text{True})$ , verifying that  $e_3, e_4$  do *not* lie on  $W$  and that  $\underline{u}$  is indeed a basis of  $V/W$ . Try exploring additional examples by presenting an alternative basis.

**2.C.14.** (a) Taking  $a = b = 0$  we see that  $U$  contains the zero vector  $(0, 0, 0)^T$ . Thus, to show that  $U$  is a subspace of  $\mathbb{Z}_5^3$ , we need to prove closure under addition and scalar multiplication. Let  $u = (a_1, 2b_1, 3a_1 + 4b_1)^T$  and  $v = (a_2, 2b_2, 3a_2 + 4b_2)^T$  be arbitrary vectors of  $U$ , where  $a_i, b_i \in \mathbb{Z}_5$  for all  $i = 1, 2$ . Then, we see that

$$u + v = (a_1 + a_2, 2(b_1 + b_2), 3(a_1 + a_2) + 4(b_1 + b_2))^T \in U, \quad cu = (ca_1, 2cb_1, c(3a_1 + 4b_1)) \in U,$$

with  $c \in \mathbb{Z}_5$ . Therefore,  $U$  is a vector subspace of  $\mathbb{Z}_5^3$ .

(b) Notice that

$$\begin{pmatrix} a \\ 2b \\ 3a + 4b \end{pmatrix} = a \begin{pmatrix} 1 \\ 0 \\ 3 \end{pmatrix} + b \begin{pmatrix} 0 \\ 2 \\ 4 \end{pmatrix} = au_1 + bu_2, \quad \text{where } u_1 = \begin{pmatrix} 1 \\ 0 \\ 3 \end{pmatrix}, \quad u_2 = \begin{pmatrix} 0 \\ 2 \\ 4 \end{pmatrix}.$$

Thus the vectors  $u_1, u_2$  span  $U$ , i.e.,  $U = \text{span}_{\mathbb{Z}_5}\{u_1, u_2\}$ , and to obtain a basis it remains to prove linear independence.

Let  $A = \begin{pmatrix} 1 & 0 \\ 0 & 2 \\ 3 & 4 \end{pmatrix}$  be the matrix having as columns the vectors  $u_1, u_2$ . To find the RREF of  $A$  we mention that in  $\mathbb{Z}_5$  the

inverse of 2 equals 3 and the inverse of 4 equals 4 itself. For example, for the case of 2 one needs to find an integer  $y$  such that  $2 \cdot y = 1 \pmod{5}$ . Since  $6 = 1 \pmod{5}$  our claim follows. Similarly for 4, we have  $4 \cdot 4 = 16 = 1 \pmod{5}$ . Performing elementary row operations with respect to the arithmetic in  $\mathbb{Z}_5$  (see the tables in 2.C.6), we obtain the following reduced row

echelon form:  $\begin{pmatrix} 1 & 0 \\ 0 & 1 \\ 0 & 0 \end{pmatrix}$ . For a confirmation of this matrix in Sage, add the cell

```
F = GF(5)
A=matrix(F, [[1, 0], [0, 2], [3, 4]]); A.rref()
```

It is now immediate that  $\text{rank}(A) = 2$ . Hence the vectors  $u_1, u_2$  are linearly independent. and so they form a basis of  $U$ . This implies that  $\dim_{\mathbb{Z}_5} U = 2$ . To confirm the linear independence of  $u_1, u_2$  in Sage, we use the following cell:

```
F = GF(5); V = VectorSpace(F, 3)
u1=vector(F, [1, 0, 3]); u2=vector(F, [0, 2, 4])
V.linear_dependence([u1, u2]) == []
```

By adding

```
U=span([u1, u2]); U.dimension()
```

we also get a direct verification of the dimension of  $U$ .

**2.C.16.** Considered vectors are linearly independent if and only if the vectors  $(1, -2, 0, 0)^T$ ,  $(3, 0, 1, -1)^T$ ,  $(1, -4, 1, 2)^T$ , and  $(0, 4, 8, 4)^T$  are linearly independent in  $\mathbb{R}^4$ . We see that

$$\begin{vmatrix} 1 & -2 & 0 & 0 \\ 3 & 0 & 1 & -1 \\ 1 & -4 & 1 & 2 \\ 0 & 4 & 8 & 4 \end{vmatrix} = -36 \neq 0,$$

thus the vectors are linearly independent.

**2.C.19.** In this task, first check that the given vectors  $v_1, v_2$  are linearly independent. Next, if  $A$  is the matrix having as columns these two vectors, construct the extended matrix  $(A \mid I_4)$ , where  $I_4$  is the  $4 \times 4$  identity matrix. Then compute its reduced row echelon form. From this matrix, the columns with the pivots will form the desired basis. All these in Sage can be done as follows:

```
V=QQ^4; v1=vector(QQ, [2, 0, 1, 0]); v2=vector(QQ, [1, 0, 1, 0]); L=[v1,v2]
V.linear_dependence(L)==[]
I4=identity_matrix(4); A=column_matrix(L); A1=A.augment(I4)
M=A1.rref()
[A1.column(p) for p in A1.pivots()]
```

Sage's output is here:

```
[(2, 0, 1, 0), (1, 0, 1, 0), (0, 1, 0, 0), (0, 0, 0, 1)]
```

Thus the vectors  $\{v_1, v_2, v_3 = (0, 1, 0, 0)^T, v_4 = (0, 0, 0, 1)^T\}$  form the desired basis of  $\mathbb{Q}^4$ . The linear independence of these vectors can be confirmed by adding in the previous cell the next few lines of code:

```
v3=vector(QQ, [0, 1, 0, 0]); v4=vector(QQ, [0, 0, 0, 1]); Lext=[v1,v2,v3,v4]
V.linear_dependence(Lext)==[]
```

**2.C.23.** (i) This is the projection to the  $yz$ -plane and a short computation ensures its linearity.

(ii) We see that  $F((0, 0, 0)) = (0, -3, 0) \neq (0, 0, 0)$ . However, any linear mapping maps the zero vector of its domain to the zero vector of the target space. Hence, this  $F$  is not linear.

(iii) By assumption  $a \neq 0$ . Hence, for two vector  $u = (x_1, y_1)$  and  $v = (x_2, y_2)$  lying on  $\mathbb{R}^2$ , we see that

$$F(u + v) = (x_1 + x_2 + a, y_1 + y_2) \neq F(u) + F(v) = (x_1 + a, y_1) + (x_2 + a, y_2) = (x_1 + x_2 + 2a, y_1 + y_2).$$

This shows that  $F$  is not linear.

(iv) When  $a = 0$  this is the identity map, which is obviously a linear mapping. For  $a \neq 0$  the mapping  $F(x) = x + a$  is an affine mapping. This is because the mapping  $G : \mathbb{R} \rightarrow \mathbb{R}$  defined by  $G(x) := F(x) - F(0)$  is linear, for all  $x \in \mathbb{R}$ .

(v) The mapping  $F((x, y)) = (x^2, y)$  is not linear. This is because  $F(c(x, y)) = F((cx, cy)) = (c^2x^2, cy)$  and  $cF((x, y)) = (cx^2, cy)$ . Hence in general we have  $F(c(x, y)) \neq cF((x, y))$ , except if  $c = 0$  or  $c = 1$ . Since the relation  $F(c(x, y)) = cF((x, y))$  must hold for any  $c \in \mathbb{R}$  and  $u = (x, y) \in \mathbb{R}^2$  we conclude.

(vi) The mapping  $F : \mathbb{R}^2 \rightarrow \mathbb{R}_1[t]$  with  $F((x, y)) = y + xt$  is linear. Indeed, consider two arbitrary vectors  $u = (x_1, y_1)$  and  $v = (x_2, y_2)$  on  $\mathbb{R}^2$ . Then for any two scalars  $a, b \in \mathbb{R}$  we have

$$\begin{aligned} F(au + bv) &= F((ax_1, ay_1) + (bx_2, by_2)) = F((ax_1 + bx_2, ay_1 + by_2)) = (ay_1 + by_2) + (ax_1 + bx_2)t \\ &= a(y_1 + x_1t) + b(y_2 + x_2t) = aF((x_1, y_1)) + bF((x_2, y_2)). \end{aligned}$$

(vii) Fix some  $B \in \text{Mat}_n(\mathbb{R})$ . The mapping  $F(A) = AB - BA$  is also linear, and hence an endomorphism of  $\text{Mat}_n(\mathbb{R})$ . In order to prove its linearity, consider some  $\lambda, \mu \in \mathbb{R}$  and  $A_1, A_2 \in \text{Mat}_n(\mathbb{R})$ . Then we have

$$\begin{aligned} F(\lambda A_1 + \mu A_2) &= (\lambda A_1 + \mu A_2)B - B(\lambda A_1 + \mu A_2) = \lambda A_1B + \mu A_2B - \lambda BA_1 - \mu BA_2 \\ &= \lambda(A_1B - BA_1) + \mu(A_2B - BA_2) = \lambda F(A_1) + \mu F(A_2). \end{aligned}$$

(viii) The mapping  $F(A) = A^T$  is another linear endomorphism of  $\text{Mat}_n(\mathbb{R})$ . Perform the brief computation yourselves.

(ix) Let  $u = (x_1, y_1)$  and  $v = (x_2, y_2)$  two vectors on  $\mathbb{Z}_3^2 = \mathbb{Z}_3 \times \mathbb{Z}_3$ . Then we have

$$F(u + v) = F((x_1 + x_2, y_1 + y_2)) = \begin{pmatrix} (x_1 + x_2) + (y_1 + y_2) \\ 2(x_1 + x_2) + (y_1 + y_2) \\ x_1 + x_2 \end{pmatrix} = \begin{pmatrix} x_1 + y_1 \\ 2x_1 + y_1 \\ x_1 \end{pmatrix} + \begin{pmatrix} x_2 + y_2 \\ 2x_2 + y_2 \\ x_2 \end{pmatrix} = F(u) + F(v),$$

and

$$F(cu) = F((cx_1, cy_1)) = \begin{pmatrix} cx_1 + cy_1 \\ 2cx_1 + cy_1 \\ cx_1 \end{pmatrix} = c \begin{pmatrix} x_1 + y_1 \\ 2x_1 + y_1 \\ x_1 \end{pmatrix} = cF(u),$$

for all  $c \in \mathbb{Z}_3$ . Thus,  $F$  is linear.

(x) The exponential map is, of course, *not* linear because, as we will see in Chapter 5,  $e^{t_1+t_2} = e^{t_1} \cdot e^{t_2} \neq e^{t_1} + e^{t_2}$ .

**2.C.26.** Let  $\underline{e} = \{e_1 = (1, 0, 0)^T, e_2 = (0, 1, 0)^T, e_3 = (0, 0, 1)^T\}$  be the standard basis of  $\mathbb{R}^3$ . We see that

$$T(e_1) = (1, 1, 1)^T = e_1 + e_2 + e_3, \quad T(e_2) = (1, 1, 1)^T = e_1 + e_2 + e_3, \quad T(e_3) = (1, 2, 3)^T = e_1 + 2e_2 + 3e_3.$$

The columns of the matrix  $A$  corresponding to  $T$  are given by the images of the basis vectors. Thus we get

$$A = \begin{pmatrix} 1 & 1 & 1 \\ 1 & 1 & 2 \\ 1 & 1 & 3 \end{pmatrix}.$$

To work with this example in Sage, use the following code block:

```

# Define the variables and vector space
x, y, z = var("x y z")
V = W = RR^3
# Define the linear transformation
f(x, y, z) = [x + y + z, x + y + 2*z, x + y + 3*z]
T = linear_transformation(V, W, f)
# Get the matrix representation of the transformation
A = T.matrix(side="right")
# Display the matrix
show(A)

```

Verify that this confirms the matrix  $A$  obtained above.

**2.C.29.** The matrix of  $T$  with respect to the standard basis is given by  $A = \begin{pmatrix} 1 & 0 & i \\ 0 & 1 & 1 \\ i & 1 & 0 \end{pmatrix}$ . The endomorphism  $T$  will be invertible if and only if  $A$  is invertible. However,  $A$  is not of full rank, in particular,  $\text{rank}(A) = 2$  and hence  $A$  is not invertible. Alternatively, we may compute the determinant of  $A$ , which is zero,  $\det(A) = 0$ . Hence  $A$  is singular and  $T^{-1}$  does not exist. A verification is Sage is given in the usual way:

```

v1=vector([1, 0, i]); v2=vector([0, 1, 1]); v3=vector([i, 1, 0])
A=column_matrix([v1, v2, v3])
print(rank(A)); print(det(A))

```

**2.C.30.** (a) We begin with the conjugation. This maps  $1 \mapsto 1$ , and  $i \mapsto -i$ , written in the coordinates as  $(1, 0) \mapsto (1, 0)$  and  $(0, 1) \mapsto (0, -1)$ , respectively. By writing the images into the columns we obtain the matrix  $\begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}$ .

For the second map, using the basis  $\underline{u} = \{1, i\}$  we obtain  $1 \mapsto 2 + i$ ,  $i \mapsto 2i - 1$ , that is,  $(1, 0) \mapsto (2, 1)$ ,  $(0, 1) \mapsto (2, -1)$ .

Thus, the matrix of multiplication by the number  $2 + i$  under the basis  $\underline{u}$  has the form  $\begin{pmatrix} 2 & -1 \\ 1 & 2 \end{pmatrix}$ .

(b) We will only determine the matrix of the second linear map in the basis  $\underline{f}$ , and leave the first case for practice. Multiplication by  $(2 + i)$  gives us:  $(1 - i) \mapsto (1 - i)(2 + i) = 3 - i$ ,  $(1 + i) \mapsto (1 + 3i)$ . Coordinates  $(a, b)_{\underline{f}}$  of the vector  $3 - i$  in the basis  $\underline{f}$  are given, as we know, by the equation  $a \cdot (1 - i) + b \cdot (1 + i) = 3 + i$ , that is,  $(3 + i)_{\underline{f}} = (2, 1)$ . Analogously  $(1 + 3i)_{\underline{f}} = (-1, 2)$ . Altogether, we obtain the matrix  $\begin{pmatrix} 2 & -1 \\ 1 & 2 \end{pmatrix}$ . Observe that the matrices for multiplication by  $2 + i$  are the same in both bases. Why does this happen? Would the matrices be identical in both bases for multiplication by any complex number? <sup>16</sup>

**2.C.31.** To simplify the explanation, we will prove the statement for a low-dimensional case, as the idea extends easily to the general case. For example, let us consider proving that the space  $\text{Mat}_{2,3}(\mathbb{K})$  of  $2 \times 3$  matrices over  $\mathbb{K}$  is isomorphic to  $\mathbb{K}^{2 \cdot 3} = \mathbb{K}^6$ . Any element of  $\text{Mat}_{2,3}(\mathbb{K})$  has the form

$$\begin{pmatrix} a & b & c \\ d & e & f \end{pmatrix}, \quad \text{for some } a, b, c, d, e, f \in \mathbb{K}.$$

From this expression we see that the matrices

$$E_1 = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix}, E_2 = \begin{pmatrix} 0 & 1 & 0 \\ 0 & 0 & 0 \end{pmatrix}, E_3 = \begin{pmatrix} 0 & 0 & 1 \\ 0 & 0 & 0 \end{pmatrix}, E_4 = \begin{pmatrix} 0 & 0 & 0 \\ 1 & 0 & 0 \end{pmatrix}, E_5 = \begin{pmatrix} 0 & 0 & 0 \\ 0 & 1 & 0 \end{pmatrix}, E_6 = \begin{pmatrix} 0 & 0 & 0 \\ 0 & 0 & 1 \end{pmatrix}$$

generate  $\text{Mat}_{2,3}(\mathbb{K})$ . It is also easy to see that these matrices are linearly independent, and hence they form a basis of  $\text{Mat}_{2,3}(\mathbb{K})$ . This implies that  $\dim_{\mathbb{K}} \text{Mat}_{2,3}(\mathbb{K}) = 6$ . For a verification, use Sage and its command `MatrixSpace`, as follows:

```

MS = MatrixSpace(SR, 2, 3)
MS.dimension()

```

Sage print out the number 6, which is the dimension of  $\text{Mat}_{2,3}(\mathbb{K})$  over  $\mathbb{K}$ . Adding the following command, one can also obtain the basis mentioned above:

<sup>16</sup>This similarity arises because multiplication by a complex number  $c$ , corresponds to a linear transformation that is invariant under basis changes. Essentially,  $c$  acts as a scalar multiplication on the vector space, and scalar multiplication is invariant to the choice of a basis.

```
B = MS.basis(); list(B)
```

Consider finally the mapping  $\varphi$  defined by

$$\varphi : \text{Mat}_{2,3}(\mathbb{K}) \rightarrow \mathbb{K}^6, \quad \begin{pmatrix} a & b & c \\ d & e & f \end{pmatrix} \mapsto (a, b, c, d, e, f)^T.$$

This is linear and maps the basis  $E_1, \dots, E_6$  to the standard basis  $e_1 = (1, 0, \dots, 0)^T, \dots, e_6 = (0, \dots, 0, 1)^T$  of  $\mathbb{K}^6$ . Hence  $\varphi$  is a linear isomorphism (you should be able to prove that a linear mapping having this property is always an isomorphism).

**2.C.32.** An isomorphism  $f : \mathbb{R}_n[x] \rightarrow \mathbb{R}^{n+1}$  is given by  $a_0 + a_1x + a_2x^2 + \dots + a_nx^n \mapsto (a_0, a_1, \dots, a_n)$ . We leave to the reader to prove that  $f$  is a well defined linear bijection. Can you specify the inverse  $f^{-1} : \mathbb{R}^{n+1} \rightarrow \mathbb{R}_n[x]$ ?

**2.C.33.** To prove the claim it is sufficient to show that  $U = \text{span}_{\mathbb{R}}\{u_1, u_2, u_3\}$  is a 3-dimensional subspace of  $\mathbb{R}^4$ , and hence that the vectors  $u_1, u_2, u_3$  are linearly independent. Indeed for some  $a, b, c \in \mathbb{R}$  we see that the matrix equation  $au_1 + bu_2 + cu_3 = 0$  is equivalent to the system  $\{a + c = 0, 2a + b = 0, b = 0\}$  having the unique solution  $a = b = c = 0$ . Or in Sage we can type

```
u1=vector([1, 2, 0, 0]); u2=vector([0, 1, 0, 1]); u3=vector([1, 0, 0, 0]); L=[u1, u2, u3]
V=RR**4; V.linear_dependence(L)==[]
```

Let  $\underline{e} = \{e_1, e_2, e_3\}$  be the standard basis of  $\mathbb{R}^3$ . Check yourselves that a linear isomorphism  $f : \mathbb{R}^3 \rightarrow U$  is defined by

$$f(e_1) = u_1, \quad f(e_2) = u_2, \quad f(e_3) = u_3.$$

**2.C.34.** A subspace of  $\mathbb{R}^3$  can be 0, 1, 2 or 3-dimensional. Thus, up to linear isomorphisms, such a subspace should be isomorphic to

- (a) the origin of  $\mathbb{R}^3$  (the single zero vector), or, (c) a plane passing through the origin of  $\mathbb{R}^3$ , or,  
 (b) a line passing through the origin of  $\mathbb{R}^3$ , or, (d)  $\mathbb{R}^3$  itself.

**2.C.36.** We can easily see that  $\underline{u}$  is a basis of  $\mathbb{C}^3$ , e.g., via Sage. To find its dual, we need to specify linear forms  $\varphi_i : \mathbb{C}^3 \rightarrow \mathbb{C}$  for  $i = 1, 2, 3$ , satisfying the relations

$\varphi_1(u_1) = 1, \varphi_1(u_2) = 0 = \varphi_1(u_3), \quad \varphi_2(u_1) = 0, \varphi_2(u_2) = 1, \varphi_2(u_3) = 0, \quad \varphi_3(u_1) = 0 = \varphi_3(u_2), \varphi_3(u_3) = 1,$   
 respectively. We may suppose that

$$\varphi_1(z_1, z_2, z_3) = \sum_{i=1}^3 a_i z_i, \quad \varphi_2(z_1, z_2, z_3) = \sum_{i=1}^3 b_i z_i, \quad \varphi_3(z_1, z_2, z_3) = \sum_{i=1}^3 c_i z_i,$$

for some complex numbers  $a_i, b_i, c_i, (i = 1, 2, 3)$ . From the first set of equations we get  $a_1 = 1, a_2 = 0$  and  $a_3 = i$ , thus  $\varphi_1(z_1, z_2, z_3) = z_1 + iz_3$ . From the second set of equations we get  $b_1 = 0, b_2 = -i$  and  $b_3 = 1$ , thus  $\varphi_2(z_1, z_2, z_3) = -iz_2 + z_3$ . Finally for  $\varphi_3$  we get  $c_1 = 0 = c_2$  and  $c_3 = -i$ , that is,  $\varphi_3(z_1, z_2, z_3) = -iz_3$ . You may try to verify alone that  $\{\varphi_1, \varphi_2, \varphi_3\}$  is indeed a basis of  $(\mathbb{C}^3)^*$ .

**2.C.37.** (a) Suppose that  $u = \sum_{i=1}^n c_i u_i$  for some real numbers  $c_i$ , for all  $i = 1, \dots, n$ . Then, by linearity, we see that

$$\varphi_1(u) = \varphi_1\left(\sum_i c_i u_i\right) = \sum_i c_i \varphi_1(u_i) = c_1 \varphi_1(u_1) + c_2 \varphi_1(u_2) + \dots + c_n \varphi_1(u_n) = c_1 \cdot 1 + c_2 \cdot 0 + \dots + c_n \cdot 0 = c_1,$$

and in an analogous way we can show that  $\varphi_i(u) = c_i$ , for all  $i = 1, \dots, n$ . Based on this remark we obtain the first relation:  $u = \sum_{i=1}^n c_i u_i = \sum_{i=1}^n \varphi_i(u) u_i$ .

(b) To prove the second relation let us apply  $\xi$  in both sides of the relation in (a). Since  $\varphi_i(u)$  are scalars for all  $i$ , i.e.,  $\varphi_i(u) \in \mathbb{K}$ , this gives

$$\xi(u) = \xi\left(\sum_i \varphi_i(u) u_i\right) = \sum_i \varphi_i(u) \xi(u_i) = \left(\sum_i \xi(u_i) \varphi_i\right)(u).$$

This relation holds for all  $u \in V$  and hence the result follows, i.e.,  $\xi = \sum_i \xi(u_i) \varphi_i$ .

**2.C.38.** If  $A = (a_{ij}), B = (b_{ij}) \in \text{Mat}_m(\mathbb{K})$  and  $c \in \mathbb{K}$ , then we have  $\text{tr}(A+B) = (a_{11} + b_{11}) + \dots + (a_{mm} + b_{mm}) = (a_{11} + \dots + a_{mm}) + (b_{11} + \dots + b_{mm}) = \text{tr}(A) + \text{tr}(B)$  and  $\text{tr}(cA) = ca_{11} + \dots + ca_{mm} = c(a_{11} + \dots + a_{mm}) = c \text{tr}(A)$ . Thus  $\text{tr}$  is a linear transformation, and since the output is a scalar, i.e.,  $\text{tr}(A) \in \mathbb{K}$ , it is a linear form of  $\text{Mat}_m(\mathbb{K})$ .

Now, for  $A, B \in \text{Mat}_m(\mathbb{K})$  we have  $AB = ((ab)_{ij})$  and  $BA = ((ba)_{ij})$ . Thus,

$$\text{tr}(AB) = \sum_{i=1}^m (ab)_{ii} = \sum_{i=1}^m \sum_{k=1}^m a_{ik} b_{ki} = \sum_{k=1}^m \sum_{i=1}^m b_{ki} a_{ik} = \sum_{k=1}^m (ba)_{kk} = \text{tr}(BA).$$

As a counterexample of the relation  $\text{tr}(AB) = \text{tr}(A)\text{tr}(B)$ , consider any non-zero matrix  $A \in \text{Mat}_m(\mathbb{R})$  and the identity matrix  $E \in \text{Mat}_m(\mathbb{R})$ . Then we see that  $\text{tr}(AE) = \text{tr}(A)$ , but  $\text{tr}(E)\text{tr}(A) = m\text{tr}(A)$ . Hence, except of the trivial case  $m = 1$  where the relation actually holds, this provides an answer.

**2.C.39.** Consider for example the endomorphism  $f : \mathbb{R}^2 \rightarrow \mathbb{R}^2$  represented by the matrix  $A = \begin{pmatrix} 3 & 1 \\ 0 & 2 \end{pmatrix}$  with respect to the standard basis  $\underline{e}$  of  $\mathbb{R}^2$ . Obviously,  $\text{tr}(A) = 3 + 2 = 5$ . Another basis of  $\mathbb{R}^2$  is given by  $\underline{u} = \{(1, 1)^T, (1, -1)^T\}$  (use Sage, as indicated below, to verify that these two vectors are linearly independent).

```
V=RR^2;
v1=vector(RR, [1,1])
v2=vector(RR, [1, -1])
V.linear_dependence([v1, v2]) ==[]
```

The matrix that changes from the new basis  $\underline{u}$  to the standard one  $\underline{e}$  is formed by placing the new basis vectors as columns, see also below. Let us denote this matrix by  $P = \begin{pmatrix} 1 & 1 \\ 1 & -1 \end{pmatrix}$ . The matrix presentation of  $f$  in the new basis is given by  $A' = P^{-1}AP = \begin{pmatrix} 3 & 0 \\ 1 & 2 \end{pmatrix}$ , see the discussion in the end of 2.3.16. We see that  $\text{tr}(A') = 5 = \text{tr}(A)$ , hence the trace is invariant under a change of basis. You may like to confirm this result in Sage (and the expression of  $A'$ ). This can be done by the usual methods, see the cell given here:

```
# Define the matrix A in the standard basis
A = Matrix(RR, [[3, 1], [0, 2]])
# Define the change of basis matrix P
P = Matrix(RR, [[1, 1], [1, -1]])
# Compute the inverse of P
P_inv = P.inverse()
# Compute the matrix representation of the endomorphism in the new basis
A_prime = P_inv * A * P
show(A_prime)
# Compute the traces
bool(A.trace() == A_prime.trace())
```

**2.C.40.** In 2.C.38 we proved the relation  $\text{tr}(AB) = \text{tr}(BA)$ . Hence, for any invertible  $m \times m$  matrix  $P$  over  $\mathbb{K}$  we obtain

$$\text{tr}(P^{-1}AP) = \text{tr}(P^{-1}(AP)) = \text{tr}((AP)P^{-1}) = \text{tr}(APP^{-1}) = \text{tr}(AE) = \text{tr}(A).$$

Thus,  $A$  and  $P^{-1}AP$  have the same trace and our claim follows. For the determinant observe that

$$\det(B) = \det(P^{-1}AP) = \det(P^{-1})\det(A)\det(P) = \det(A)\frac{\det(P)}{\det(P)} = \det(A).$$

Here, we utilized the fact that the determinant of the product of matrices equals the product of their determinants, and that for any invertible matrix  $P$ , the determinant of its inverse is given by  $\det(P^{-1}) = 1/\det(P)$ .

Now, in (a) the given matrices  $A, B$  are such that  $\text{tr}(A) = \text{tr}(B) = 4$  but  $\det(A) = 7 \neq 6 = \det(B)$ . Thus, according to our result above, the matrices  $A, B$  cannot be similar.

For the matrices  $A, B$  given in (b), we have  $\text{tr}(A) = \text{tr}(B) = 0$  and  $\det(A) = \det(B) = 0$ , hence we cannot conclude by applying our criterium. However, let  $M = \begin{pmatrix} \alpha & \beta \\ \gamma & \delta \end{pmatrix}$  be an invertible  $2 \times 2$  real matrix. Thus we assume that  $\det(M) = \alpha\delta - \beta\gamma \neq 0$ , so that  $M^{-1} = \frac{1}{\alpha\delta - \beta\gamma} \begin{pmatrix} \delta & -\beta \\ -\gamma & \alpha \end{pmatrix}$ . For simplicity, we may fix  $\alpha, \beta$  so that  $\det(M) = 1$ . Then we see that

$$M^{-1}AM = \begin{pmatrix} \delta & -\beta \\ -\gamma & \alpha \end{pmatrix} \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix} \begin{pmatrix} \alpha & \beta \\ \gamma & \delta \end{pmatrix} = \begin{pmatrix} 0 & \delta \\ 0 & -\gamma \end{pmatrix} \begin{pmatrix} \alpha & \beta \\ \gamma & \delta \end{pmatrix} = \begin{pmatrix} \gamma\delta & \delta^2 \\ -\gamma^2 & -\gamma\delta \end{pmatrix}.$$

Therefore, in this case the matrices  $A, B$  are similar. Notice that for  $\gamma = \delta = 0$ , we have  $\det(M) = 0$ , hence we should exclude these values.

The matrices  $A, B$  given in (c) are also similar: Let us verify this in Sage via the command `B.is_similar(A)`, as follows:

```
A = matrix([[2, 1], [1, 2]])
B = matrix([[3, 0], [0, 1]])
b, P = B.is_similar(A, transformation=True)
b; show(P)
```

The output here is True, which means that  $A, B$  are indeed similar, while `show(P)` prints the matrix  $P$ , satisfying  $P^{-1}AP = B$ . A verification of this relation can be done by adding the code

```
bool(P.inverse()*A*P==B)
```

In fact, later we will explain that the diagonal matrix  $B$  in (c) consists of the eigenvalues of  $A$ , and so the similarity of  $A, B$  is related with the study of the eigenvectors of  $A$ , see also below.

**2.C.42.** To solve in Sage the task given in 2.C.41, we first introduce the vector space  $V = \mathbb{R}^3$  and confirm the linear independence of the vectors  $u_1, u_2$  and  $u_3$ . Next, we use these vectors to form the transition matrix  $T$ , which can be done easily via the `column_matrix` command. Finally, we compute the inverse of  $T$ , and display the new coordinates of  $w$  by applying the rule  $T^{-1}w$ . Here is the corresponding code:

```
V=RR^3;u1=vector([1, 1, 3])
u2=vector([1, -1, 1]);u3=vector([3, 1,5])
V.linear_dependence([u1, u2, u3])==[]
T=column_matrix([v1, v2, v3])
Tinv=T.inverse()
w=vector([1, 2, 3]); wcor=Tinv*w
show(wcor)
```

**2.C.43.** Suppose that  $u_2$  consists of the vectors  $V_1, V_2, V_3$ . By the given expression of  $T$  we have

$$V_1 = E_1 + E_2 - E_3 = (2, 0, 0)^T, \quad V_2 = E_1 + 2E_2 + E_3 = (3, 3, 2)^T, \quad V_3 = E_1 + E_2 + 2E_3 = (2, 3, 3)^T.$$

Thus  $u_2 = \{(2, 0, 0)^T, (3, 3, 2)^T, (2, 3, 3)^T\}$ . As a verification in Sage, you may type

```
V = RR**3; V1 = vector(RR, [2, 0, 0]);
V2 = vector(RR, [3, 3, 2]); V3 = vector(RR, [2, 3, 3])
V.linear_dependence([V1, V2, V3]) == [ ]
```

**2.C.44.** Again the transition matrix  $T$  for changing the basis from the basis  $\underline{f} = \{f_1, f_2, f_3\}$  to the standard basis  $\underline{e}$  can be obtained by expressing the coordinates of the vectors  $f_1, f_2, f_3$  in the standard basis as the columns of the matrix  $T$ . On the other hand, the transition matrix for changing the basis from  $\underline{e}$  to  $\underline{f}$  is the inverse of  $T$ . We compute

$$T = \begin{pmatrix} 1 & -1 & 2 \\ 1 & 1 & 0 \\ 0 & 1 & 1 \end{pmatrix}, \quad T^{-1} = \begin{pmatrix} \frac{1}{4} & \frac{3}{4} & -\frac{1}{2} \\ -\frac{1}{4} & \frac{1}{4} & \frac{1}{2} \\ \frac{1}{4} & -\frac{1}{4} & \frac{1}{2} \end{pmatrix}.$$

Now we can derive the matrix of the mapping in the basis  $\underline{f}$ , which is given by (see also 2.2.11)

$$T^{-1}AT = \begin{pmatrix} -\frac{1}{4} & 2 & -\frac{3}{4} \\ \frac{5}{4} & 0 & \frac{7}{4} \\ \frac{3}{4} & -2 & \frac{9}{4} \end{pmatrix}.$$

A method in Sage that can be used to derive the matrix of  $F: \mathbb{R}^3 \rightarrow \mathbb{R}^3$  using built-in functions, is described in 2.E.46.

**2.C.46.** (i) As always, the expressions of the given vectors  $u_1, u_2$  are with respect to the standard basis of  $\mathbb{R}^3$ . To compute their (standard) scalar product we have

$$u_1 \cdot u_2 = \langle u_1, u_2 \rangle = u_2^T u_1 = (-1 \quad 1 \quad -\sqrt{2}) \begin{pmatrix} 1 \\ 3 \\ \sqrt{2} \end{pmatrix} = -1 + 3 - 2 = 0.$$

And the same gives the computation

$$u_2 \cdot u_1 = \langle u_2, u_1 \rangle = u_1^T u_2 = (1 \quad 3 \quad \sqrt{2}) \begin{pmatrix} -1 \\ 1 \\ -\sqrt{2} \end{pmatrix} = -1 + 3 - 2 = 0.$$

This verifies that  $\langle \cdot, \cdot \rangle$  is symmetric. Having  $u_1 \cdot u_2 = 0$  means that the vectors  $u_1, u_2$  are orthogonal each other,  $u_1 \perp u_2$ . Moreover,  $\|u_1\| = \sqrt{u_1 \cdot u_1} = \sqrt{1 + 9 + 2} = \sqrt{12} = 2\sqrt{3}$  and  $\|u_2\| = \sqrt{u_2 \cdot u_2} = \sqrt{1 + 1 + 2} = \sqrt{4} = 2$ , respectively. A verification of these computations In Sage relies on the block

```
u1 = vector([1, 3, sqrt(2)])
u2 = vector([-1, 1, -sqrt(2)])
sp1=u1.dot_product(u2);
sp2=u2.dot_product(u1); bool(sp1==sp2)
```

```
print(sp1); print(sp2)
print(norm(u1)); print(norm(u2))
```

(ii) Let us present the solution in Sage:

```
v1=vector([0, 1, 2])
v2=vector([-1, 2, 3])
spr1=v1.dot_product(v2)
print(spr1); print(norm(v1))
print(norm(v2))
```

In order to compute the angle between  $v_1, v_2$ , add the code

```
theangle = spr1/(norm(v1) * norm(v2))
arccos(theangle).n()
```

Notice the answer printed out by Sage is in radians.

**2.C.51.** It is straightforward to verify the orthonormal basis expression obtained in 2.C.48, using the function  $\text{proj}(v, u)$  developed in 2.C.48. The corresponding code block is as follows:

```
E1 = vector( [1, 1, 1, 1])
E2 = vector( [1, 1, 1, 0])
E3 = vector( [1, 1, 0, 0])
def proj (v,u):
    p = v. dot_product (u)/(norm (u)^2)*u
    return(p)
w1 = E1; w2 = E2 - proj(E2, w1)
w3 = E3 - proj(E3, w2)-proj(E3, w1)
g = [w1, w2, w3]; g
W1 = w1/norm(w1); W2 = w2/norm(w2)
W3 = w3/norm(w3); G = [W1, W2, W3]; G
```

Verify on your own that running this block, Sage will print the basis  $\{w_1, w_2, w_3\}$ , denoted by  $g$ , and the orthonormal basis  $\{\hat{w}_1, \hat{w}_2, \hat{w}_3\}$ , denoted by  $G$ .

**2.C.52.** The set of solutions of the given homogeneous linear equation is always a vector spaces. For our case, a computation shows that a basis of this vector space consists of the vectors

$$u_1 = (-1, 1, 0, 0)^T, \quad u_2 = (-1, 0, 1, 0)^T, \quad u_3 = (-1, 0, 0, 1)^T.$$

Let us now denote by  $\{v_1, v_2, v_3\}$  the orthogonal basis obtained using the Gram-Schmidt orthogonalisation process. We have  $v_1 = u_1$  and for the rest two vectors we respectively compute

$$v_2 = u_2 - \frac{u_2^T \cdot v_1}{\|v_1\|^2} v_1 = u_2 - \frac{1}{2} v_1 = \left(-\frac{1}{2}, -\frac{1}{2}, 1, 0\right)^T,$$

$$v_3 = u_3 - \frac{u_3^T \cdot v_1}{\|v_1\|^2} v_1 - \frac{u_3^T \cdot v_2}{\|v_2\|^2} v_2 = u_3 - \frac{1}{2} v_1 - \frac{1}{6} v_2 = \left(-\frac{1}{3}, -\frac{1}{3}, -\frac{1}{3}, 1\right)^T.$$

**2.C.53.** The kernel  $\text{Ker}(\varphi)$  of  $\varphi$  is a linear subspace of  $\mathbb{R}^4$ . To specify  $\text{Ker}(\varphi)$  we need to solve the matrix equation  $Ax = 0$ , for some arbitrary vector  $x = (x_1, x_2, x_3, x_4)^T \in \mathbb{R}^4$ . Let us use Sage to quickly perform this task:

```
A = matrix(SR, 4, 4, [[1/2, 2, -1/2, -1/2], [1, 1/2, 1, 3/2],
[2, 9/2, 0, 1/2], [2, 2, 0, 0]])
A.right_kernel()
```

Sage's output has the form

```
Vector space of degree 4 and dimension 1 over Symbolic Ring
Basis matrix: [ 1, -1, -8, 5]
```

This means that  $\text{Ker}(\varphi)$  is 1-dimensional subspace of  $\mathbb{R}^4$ , spanned by the vector  $E_1 = (1, -1, -8, 5)^T \in \mathbb{R}^4$ . For the norm of this vector we compute  $\|E_1\| = \sqrt{91}$ , hence an orthonormal basis of  $V$  consists of the vector  $\frac{1}{\sqrt{91}}E_1$ .

**2.C.54.** (i) Let  $x = (x_1, x_2, x_3, x_4)^T$  be a vector orthogonal to  $u$ , with respect to the dot product on  $\mathbb{R}^4$ . Then  $x \cdot u = x_1 + x_2 + x_3 + x_4 = 0$ . Thus, if  $U$  is the subspace of vectors orthogonal to  $u$ , then

$$U = \{(x_1, x_2, x_3, x_4)^T \in \mathbb{R}^4 : x_4 = -(x_1 + x_2 + x_3)\} = \{(x_1, x_2, x_3, -(x_1 + x_2 + x_3)^T) : x_1, x_2, x_3 \in \mathbb{R}\}.$$

It follows that  $U$  is 3-dimensional. In particular, vectors of  $U$  can be expressed as

$$(x_1, x_2, x_3, -(x_1 + x_2 + x_3))^T = x_1 E_1 + x_2 E_2 + x_3 E_3,$$

where  $E_1, E_2, E_3$  are the vectors defined by  $E_1 = (1, 0, 0, -1)^T$ ,  $E_2 = (0, 1, 0, -1)^T$ , and  $E_3 = (0, 0, 1, -1)^T$ , respectively. We easily check that these are linearly independent, and hence they provide a basis of  $U$ .

(ii) For the second task we get two conditions from orthogonality, namely:

$$x \cdot w = x_1 - x_4 = 0, \quad x \cdot z = -x_1 + x_3 = 0.$$

This means that the vector  $x = (x_1, x_2, x_3, x_4)^T$  is orthogonal both to the vectors  $w$  and  $z$  if and only if  $x_1 = x_4$  and  $x_1 = x_3$ . Therefore, if  $V$  denotes the subspace of vectors orthogonal to  $w$  and  $z$ , then we see that  $V = \{(x_1, x_2, x_1, x_1)^T : x_1, x_2 \in \mathbb{R}\}$ . It turns out that  $V$  is 2-dimensional, with a basis given by the vectors  $v_1 = (1, 0, 1, 1)^T$  and  $v_2 = (0, 1, 0, 0)^T$ .

**2.C.56.** We will prove that  $C(A)$  is orthogonal to the cokernel  $\text{Ker}(A^T)$  and leave the second case for practice. Recall that for a  $m \times n$  matrix  $A$ , both  $C(A)$  and  $\text{Ker}(A^T)$  are subspaces of  $\mathbb{R}^m$  given by  $C(A) = \{Ax : x \in \mathbb{R}^n\}$  and  $\text{Ker}(A^T) = \{y \in \mathbb{R}^m : A^T y = 0\}$ , respectively. Hence, for  $u \in C(A)$  and  $w \in \text{Ker}(A^T)$  we see that

$$\langle u, w \rangle = w^T u = w^T Ax = (A^T w)^T x = 0x = 0,$$

where the first equality is the definition of the dot product, the second occurs by replacing  $u \in C(A)$  by  $Ax$  and the third relies on the relation  $(AB)^T = B^T A^T$ . Thus  $w^T u = 0$  and  $C(A) \perp \text{Ker}(A^T)$  with respect to the dot product on  $\mathbb{R}^m$ .

Recall now from 2.C.20 that for the matrix  $A = \begin{pmatrix} 2 & 4 \\ 1 & 3 \\ 0 & 5 \end{pmatrix}$  the column space  $C(A)$  is spanned by the vectors  $u_1 = (2, 1, 0)^T$  and  $u_2 = (4, 3, 5)^T$ , while the left null space  $\text{Ker}(A^T)$  is spanned by the vector  $u_3 = (5, -10, 2)^T$ . Hence, we see that

$$\langle u_1, u_3 \rangle = u_3^T u_1 = \begin{pmatrix} 5 & -10 & 2 \end{pmatrix} \begin{pmatrix} 2 \\ 1 \\ 0 \end{pmatrix} = 10 - 10 = 0, \quad \langle u_2, u_3 \rangle = u_3^T u_2 = \begin{pmatrix} 5 & -10 & 2 \end{pmatrix} \begin{pmatrix} 4 \\ 3 \\ 5 \end{pmatrix} = 20 - 30 + 10 = 0.$$

Similarly, we saw that the row space  $C(A^T)$  is the subspace  $\text{span}\{(2, 4)^T, (1, 3)^T\}$ , while  $\text{Ker}(A)$  is trivial,  $\text{Ker}(A) = \{0\}$ . Hence it is also trivial to prove that  $C(A^T) \perp \text{Ker}(A)$ .

**2.D.5.** Observe that this matrix differs from the one in 2.D.1 by just a single sign. However, in this case the characteristic polynomial of  $A$  has the form  $\lambda^3 - 6\lambda^2 + 12\lambda - 8$ , or in other words  $\chi_A(\lambda) = (\lambda - 2)^3$ . Therefore, the unique eigenvalue of  $A$  is given by  $\lambda = 2$ , with algebraic multiplicity three. The geometric multiplicity of  $\lambda$  is either one, two or three. Let us determine the eigenvectors associated to  $\lambda$ . They are the solutions of the matrix equation  $(A - 2E)x = 0$ , and a direct computation shows that the eigenspace  $V_2$  has the form  $V_2 = \text{span}_{\mathbb{R}}\{(1, -1, 0)^T, (0, 0, 1)^T\}$ . Thus, the geometric multiplicity of the unique eigenvalue  $\lambda$  of  $A$  equals to two.

**2.D.7.** Let us prove the statement for  $n = 3$  and when  $A$  is upper triangular, and similarly is treated the more general case. Thus we assume that  $A$  has the form

$$A = \begin{pmatrix} a_{11} & a_{12} & a_{13} \\ 0 & a_{22} & a_{23} \\ 0 & 0 & a_{33} \end{pmatrix},$$

with  $a_{ij} \in \mathbb{K}$  for all  $i, j$ . Then it is easy to see that the characteristic polynomial has the form  $\chi_A(\lambda) = (a_{11} - \lambda)(a_{22} - \lambda)(a_{33} - \lambda)$ , hence the roots of  $\chi_A(\lambda)$  are the diagonal entries  $a_{11}, a_{22}, a_{33}$ . The result now follows.

**2.D.8.** (a) The first claim is based on the fact that  $\det(A)$  is the product of eigenvalues of  $A$ . On the other hand, we know that  $A$  is invertible if and only if  $\det(A) \neq 0$ . Combining these two statements we obtain that  $A$  is invertible if and only if 0 is not an eigenvalue of  $A$ .

(b) The solution arises as an application of part (a). You may like to write down the matrix  $A_n$  for small values of  $n$  and then generalize (by induction over  $n$ ). For instance, since

$$A_1 = 1, \quad A_2 = \begin{pmatrix} 1 & 1 \\ 1 & 1 \end{pmatrix}, \quad A_3 = \begin{pmatrix} 1 & 0 & 1 \\ 1 & 1 & 0 \\ 0 & 1 & 1 \end{pmatrix}, \quad A_4 = \begin{pmatrix} 1 & 0 & 0 & 1 \\ 1 & 1 & 0 & 0 \\ 0 & 1 & 1 & 0 \\ 0 & 0 & 1 & 1 \end{pmatrix},$$

we see that  $\det(A_2) = \det(A_4) = 0$  but  $\det(A_1) \neq 0$  and  $\det(A_3) \neq 0$ . Thus, an option is to compute the determinant of  $A_n$  and show that  $\det(A_n) \neq 0$  if and only if  $n$  is odd. An alternative method is suggested by the statement, and is based on the characteristic polynomial:

$$\chi_{A_n}(\lambda) = \det(A_n - \lambda E) = \begin{vmatrix} 1-\lambda & 0 & 0 & 0 & \cdots & 0 & 0 & 1 \\ 1 & 1-\lambda & 0 & 0 & \cdots & 0 & 0 & 0 \\ 0 & 1 & 1-\lambda & 0 & \cdots & 0 & 0 & 0 \\ 0 & 0 & 1 & 1-\lambda & \cdots & 0 & 0 & 0 \\ \vdots & \vdots & \vdots & \vdots & \ddots & \vdots & \vdots & \vdots \\ 0 & 0 & 0 & 0 & \cdots & 1 & 1-\lambda & 0 \\ 0 & 0 & 0 & 0 & \cdots & 0 & 1 & 1-\lambda \end{vmatrix}.$$

By expanding the determinant with respect to the first column, for example, we see that  $\chi_{A_n}(\lambda) = (1-\lambda)^n + (-1)^{n-1}$ . Based on this expression we deduce that  $A_n$  is invertible if and only if  $n$  is odd (we are looking for those  $n$  such that  $\chi_{A_n}(\lambda)$  does not admit  $\lambda = 0$  as a root).

**2.D.10.** The given matrix  $A_1$  is diagonalizable, since it has two eigenvalues,  $\lambda_1 = 1$  with algebraic and geometric multiplicity 1, and  $\lambda_2 = 2$  with algebraic and geometric multiplicity 2. The eigenspace  $V_1$  is generated by the eigenvector  $(0, 1, -1/2)^T$  (or any non-zero multiple of this vector), and  $V_2$  is generated by the eigenvectors  $(1, 0, -2)^T$  and  $(0, 1, 0)^T$  (or any non-zero multiple of them). Thus, for example, the matrices  $D_1$  and  $P_1$  presented below satisfy  $A_1 = P_1 D_1 P_1^{-1}$ :

$$D_1 = \text{diag}(1, 2, 2), \quad P_1 = \begin{pmatrix} 0 & 1 & 0 \\ 2 & 0 & 1 \\ -1 & -2 & 0 \end{pmatrix}.$$

To verify all these results via Sage, execute the following block:

```
A1=matrix(SR, [[2, 0, 0], [4, 2, 2], [-2, 0, 1]])
p(t) =A1.characteristic_polynomial(t)
show(p(t).factor())
show(p.roots())
show(A1.eigenvectors_right())
u1=vector([0, 2, -1])
u2=vector([1, 0, -2])
u3=vector([0, 1, 0])
P1=column_matrix([u1, u2, u3])
D1=diagonal_matrix([1, 2, 2])
bool(A1==P1*D1*P1.inverse())
```

For the matrix  $A_2$ , which only differs by  $A_1$  in one sign, the result is negative, in particular  $A_2$  is *not* diagonalizable. It has the same eigenvalues with  $A_1$ , i.e.,  $\lambda_1 = 1$  and  $\lambda_2 = 2$ , with algebraic multiplicity 1 and 2, respectively. However, in this case,  $\lambda_2$  has a geometric multiplicity 1 and thus is impossible to obtain a basis of eigenvectors for the matrix  $A_2$ .

**2.D.11.** Suppose that  $AA^T = A^T A = E$ . Then we see that

$$\langle \varphi_A(u), \varphi_A(w) \rangle = \langle Au, Aw \rangle = (Aw)^T Au = w^T A^T Au = w^T u = \langle u, w \rangle,$$

for any  $u, w \in V$ . Hence  $\varphi_A$  is orthogonal. For the converse, assume that  $\varphi_A$  is orthogonal. Then we have  $\langle \varphi_A(u), \varphi_A(w) \rangle = \langle Au, Aw \rangle = \langle u, w \rangle$ , or equivalently  $w^T A^T Au = w^T u$ , or  $(A^T Au)^T u = w^T u$ . Hence  $\langle u, w \rangle = \langle u, A^T Au \rangle$ . By linearity this final relation can be equivalently written as  $\langle u, (E - A^T A)w \rangle = 0$  for any  $u, w \in V$ . Recall now that  $\langle \cdot, \cdot \rangle$  is a scalar product and hence non-degenerate, which means that the condition  $\langle x, y \rangle = 0$  for any  $x$  implies  $y = 0$ . Thus we obtain  $(E - A^T A)w = 0$  for all  $w \in V$ , which yields the desired relation  $E - A^T A = 0$ , i.e.,  $A$  is orthogonal.

**2.E.3.** (i) The row operation  $R_2 \rightarrow R_2 - 3R_1$  transforms  $A$  as follows

$$A = \begin{pmatrix} 1 & 0 & 2 \\ 3 & 1 & -1 \\ 2 & 4 & 2 \end{pmatrix} \xrightarrow{R_2 \rightarrow R_2 - 3R_1} \begin{pmatrix} 1 & 0 & 2 \\ 0 & 1 & -7 \\ 2 & 4 & 2 \end{pmatrix}.$$

To determine the corresponding elementary matrix, which we may denote by  $E_1$ , we apply the same row operation on the  $3 \times 3$  identity matrix. This gives

$$E = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix} \xrightarrow{R_2 \rightarrow R_2 - 3R_1} \begin{pmatrix} 1 & 0 & 0 \\ -3 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix} =: E_1.$$

To confirm this, note that the product  $E_1 A$  yields the same result as performing the row operation on  $A$ , i.e.,

$$E_1 A = \begin{pmatrix} 1 & 0 & 0 \\ -3 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix} \begin{pmatrix} 1 & 0 & 2 \\ 3 & 1 & -1 \\ 2 & 4 & 2 \end{pmatrix} = \begin{pmatrix} 1 & 0 & 2 \\ 0 & 1 & -7 \\ 2 & 4 & 2 \end{pmatrix}.$$

Every elementary matrix is invertible and the inverse of an elementary matrix is also an elementary matrix. It is found by performing the reverse row operation on the identity matrix, which for our case is the row operation  $R_2 \rightarrow R_2 + 3R_1$ . Hence

we have  $E_1^{-1} = \begin{pmatrix} 1 & 0 & 0 \\ 3 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix}$ , such that  $E_1 E_1^{-1} = \begin{pmatrix} 1 & 0 & 0 \\ -3 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix} \begin{pmatrix} 1 & 0 & 0 \\ 3 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix} = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix} = E = E_1^{-1} E_1$ .

(ii) By applying the row operation  $R_2 \rightarrow R_2 - \frac{3}{2}R_1$  we obtain  $A = \begin{pmatrix} 1 & 0 & 2 \\ 3 & 1 & -1 \\ 2 & 4 & 2 \end{pmatrix} \xrightarrow{R_2 \rightarrow R_2 - \frac{3}{2}R_1} \begin{pmatrix} 1 & 0 & 2 \\ 0 & -5 & -4 \\ 2 & 4 & 2 \end{pmatrix}$ . For

the corresponding elementary matrix we have  $E = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix} \xrightarrow{R_2 \rightarrow R_2 - \frac{3}{2}R_1} \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & -\frac{3}{2} \\ 0 & 0 & 1 \end{pmatrix} := E_2$ . As a confirmation,

we see that the product  $E_2 A$  matches the result of the row operation on  $A$ , i.e.,  $E_2 A = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & -\frac{3}{2} \\ 0 & 0 & 1 \end{pmatrix} \begin{pmatrix} 1 & 0 & 2 \\ 3 & 1 & -1 \\ 2 & 4 & 2 \end{pmatrix} =$

$\begin{pmatrix} 1 & 0 & 2 \\ 0 & -5 & -4 \\ 2 & 4 & 2 \end{pmatrix}$ . For the inverse we get  $E_2^{-1} = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & \frac{3}{2} \\ 0 & 0 & 1 \end{pmatrix}$ .

(iii) In a similar way we find that the elementary matrix representing the row operation  $R_3 \rightarrow \frac{1}{2}R_3$ , and its inverse, corresponding to the row operation  $R_3 \rightarrow 2R_3$ :

$$E_2 = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1/2 \end{pmatrix}, \quad E_2^{-1} = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 2 \end{pmatrix}.$$

**2.E.5.** Here is a block in Sage that confirms the expressions of  $E_1, \dots, E_8$  and of their inverses, given in 2.E.4:

```
# Define the elementary matrices
E1 = elementary_matrix(QQ, 3, row1=0, scale=1/2)
E2 = elementary_matrix(QQ, 3, row1=1, row2=0, scale=-1)
E3 = elementary_matrix(QQ, 3, row1=2, row2=0, scale=-4)
E4 = elementary_matrix(QQ, 3, row1=1, scale=-2)
E5 = elementary_matrix(QQ, 3, row1=2, scale=-1/5)
E6 = elementary_matrix(QQ, 3, row1=1, row2=2, scale=-1)
E7 = elementary_matrix(QQ, 3, row1=0, row2=2, scale=-3/2)
E8 = elementary_matrix(QQ, 3, row1=0, row2=1, scale=-1/2)
# Print the elementary matrices
show(E1, E2, E3, E4, E5, E6, E7, E8)
# Compute their inverses
E1_inv = E1.inverse()
E2_inv = E2.inverse()
E3_inv = E3.inverse()
E4_inv = E4.inverse()
E5_inv = E5.inverse()
E6_inv = E6.inverse()
E7_inv = E7.inverse()
E8_inv = E8.inverse()
# Print the inverses
show(E1_inv, E2_inv, E3_inv, E4_inv, E5_inv, E6_inv, E7_inv, E8_inv)
```

**2.E.6.** We have four unknowns  $x_1, x_2, x_3, x_4$ , and four equations. Hence the matrix  $A$  has size  $4 \times 4$ , and  $b = (3, 4, 1, 5)^T \in \mathbb{R}^4$ . Let us present the solution using Sage, and compute the reduced row echelon form of the extended matrix  $B$ :

```
B=matrix([[3, 3, 2, 1, 3], [2, 1, 1, 0, 4],
[0, 5, -4, 3, 1],[5, 3, 3, -3, 5]])
Br=B.rref(); show(Br); print(Br.pivots())
```

The output is the matrix

$$\left( \begin{array}{cccc|c} 1 & 0 & 0 & 0 & 4 \\ 0 & 1 & 0 & 0 & -2 \\ 0 & 0 & 1 & 0 & -2 \\ 0 & 0 & 0 & 1 & 1 \end{array} \right)$$

and the quadruple  $(0, 1, 2, 3)$ . Therefore, the pivots are lying on the first four columns and the corresponding linear system admits a unique solution, given by  $x_1 = 4, x_2 = -2, x_3 = -2, x_4 = 1$ . Try to present a formal computation of the reduced row echelon form.

**2.E.9.** There are infinite many solutions represented by the vector  $(x_1 = 1 + t, x_2 = \frac{3}{2}, x_3 = t, x_4 = -\frac{1}{2})^T$ , with  $t \in \mathbb{R}$ .

**2.E.10.** This linear system has no solution. Can you explain why this claim is true?

**2.E.12.** The solution has the form  $\{(-10t, (\mu + 4)t, (3\mu - 8)t)^T : t \in \mathbb{R}\}$ .

**2.E.13.** For  $a = 0$  the system has no solution. For  $a \neq 0$  the system has infinitely many solutions.

**2.E.14.** Let us use the extended matrix of apply elementary row transformation to obtain

$$\left( \begin{array}{cccc|c} 1 & -a & -2 & b & \\ 1 & 1-a & 0 & b-3 & \\ 1 & 1-a & a & 2b-1 & \end{array} \right) \sim \left( \begin{array}{cccc|c} 1 & -a & -2 & b & \\ 0 & 1 & 2 & -3 & \\ 0 & 1 & a+2 & b-1 & \end{array} \right) \sim \left( \begin{array}{cccc|c} 1 & -a & -2 & b & \\ 0 & 1 & 2 & -3 & \\ 0 & 0 & a & b+2 & \end{array} \right).$$

Above, we first subtracted the first row from the second and the third; Then we subtracted the second row from the third. We see that the system has a unique solution (determined by backward elimination), if and only if  $a \neq 0$ . If  $a = 0$  and  $b = -2$ , we have a zero row in the extended matrix. Choosing  $x_3 \in \mathbb{R}$  as a parameter then gives infinitely many distinct solutions. For  $a = 0$  and  $b \neq -2$  the last equation  $a = b + 2$  cannot be satisfied and the system has no solution. Note that:

- For  $a = 0, b = -2$  we have infinite solutions of the form  $(x_1, x_2, x_3)^T = (-2 + 2t, -3 - 2t, t)^T$ , with  $t \in \mathbb{R}$ .
- For  $a \neq 0$  the unique solution has the form  $\left( \frac{-3a^2 - ab - 4a + 2b + 4}{a}, -\frac{2b + 3a + 4}{a}, \frac{b + 2}{a} \right)^T$ .

**2.E.17.** We compute:

$$\sigma = (1, 7)(2, 6)(5, 3), \quad \tau = (1, 6)(6, 8)(8, 7)(7, 3)(2, 4), \quad \rho = (1, 4)(4, 10)(10, 7)(7, 9)(9, 3)(2, 6)(6, 5).$$

**2.E.18.** For  $\sigma$  we compute 17 inversions, and its parity is thus odd. For  $\tau$  we enumerate 12 inversions, and hence its parity is even. Finally for  $\rho$  we enumerate 25 inversions, so its parity is odd.

**2.E.24.** A confirmation of the inverse of  $A$  and the given solution can be obtained as follows:

```
A=matrix(QQ, [[1, 1, 1, 1], [1, 1, -1, -1], [1, -1, 1, -1], [1, -1, -1, 1]])
det(A)
Ainv=A.inverse()
show(Ainv)
b=vector(QQ, [2, 3, 3, 5])
x=Ainv*b; show(x)
```

As for the computation of the algebraic complements  $A_{ij}$ , one can proceed with the following block:

```
B11=A.matrix_from_rows_and_columns ([1, 2, 3], [1, 2, 3]);show(B11)
A11=(-1)^(1+1)*det(B11); show(" A11 is equal to",A11)
B12=A.matrix_from_rows_and_columns ([1, 2, 3], [0, 2, 3]);show(B12)
A12=(-1)^(1+2)*det(B12); show(" A12 is equal to",A12)
B13=A.matrix_from_rows_and_columns ([1, 2, 3], [0, 1, 3]);show(B13)
A13=(-1)^(1+3)*det(B13); show(" A13 is equal to",A13)
B14=A.matrix_from_rows_and_columns ([1, 2, 3], [0, 1, 2]);show(B14)
A14=(-1)^(1+4)*det(B14); show(" A14 is equal to",A14)
B21=A.matrix_from_rows_and_columns ([0, 2, 3], [1, 2, 3]);show(B21)
A21=(-1)^(1+2)*det(B21); show(" A21 is equal to",A21)
B22=A.matrix_from_rows_and_columns ([0, 2, 3], [0, 2, 3]);show(B22)
A22=(-1)^(2+2)*det(B22); show(" A22 is equal to",A22)
B23=A.matrix_from_rows_and_columns ([0, 2, 3], [0, 1, 3]);show(B23)
A23=(-1)^(2+3)*det(B23); show(" A23 is equal to",A23)
B24=A.matrix_from_rows_and_columns ([0, 2, 3], [0, 1, 2]);show(B24)
A24=(-1)^(2+4)*det(B24); show(" A24 is equal to",A24)
B31=A.matrix_from_rows_and_columns ([0, 1, 3], [1, 2, 3]);show(B31)
```

```

A31=(-1)^(3+1)*det(B31); show(" A31 is equal to",A31)
B32=A.matrix_from_rows_and_columns ([0, 1, 3], [0, 2, 3]);show(B32)
A32=(-1)^(3+2)*det(B32); show(" A32 is equal to",A32)
B33=A.matrix_from_rows_and_columns ([0, 1, 3], [0, 1, 3]);show(B33)
A33=(-1)^(3+3)*det(B33); show(" A33 is equal to",A33)
B34=A.matrix_from_rows_and_columns ([0, 1, 3], [0, 1, 2]);show(B34)
A34=(-1)^(3+4)*det(B34); show(" A34 is equal to",A34)
B41=A.matrix_from_rows_and_columns ([0, 1, 2], [1, 2, 3]);show(B41)
A41=(-1)^(4+1)*det(B41); show(" A41 is equal to",A41)
B42=A.matrix_from_rows_and_columns ([0, 1, 2], [0, 2, 3]);show(B42)
A42=(-1)^(4+2)*det(B42); show(" A42 is equal to",A42)
B43=A.matrix_from_rows_and_columns ([0, 1, 2], [0, 1, 3]);show(B43)
A43=(-1)^(4+3)*det(B43); show(" A43 is equal to",A43)
B44=A.matrix_from_rows_and_columns ([0, 1, 2], [0, 1, 2]);show(B44)
A44=(-1)^(4+4)*det(B44); show(" A43 is equal to",A44)
Ain=(-1/16)*matrix(QQ, [[A11, A21, A31, A41],
[A12, A22, A32, A42], [A13, A23, A33, A43], [A14, A24, A34, A44]])
show(Ain); bool(Ain==A.inverse())
    
```

Inside this cell, the matrices  $B_{ij}$  represent the matrices  $\hat{A}_{ij}$ . The final command verifies that the matrix constructed via the algebraic complement, named here  $A_{in}$ , is the inverse of  $A$ . Or we can test our computation for the matrix  $\text{adj}(A)$ , e.g., by adding the code

```

Adtr=matrix(QQ, [[A11, A21, A31, A41], [A12, A22, A32, A42],
[A13, A23, A33, A43], [A14, A24, A34, A44]])
show(Adtr); show(A.adjugate())
bool(Adtr==A.adjugate())
    
```

**2.E.25.** To do this, we will use a slightly different method from those presented in 2.B.11. Both methods can be employed to further explore applications of Cramer's rule, such as solving linear systems with parameters. Here we will define a function to construct the matrices  $A_i$  in Cramer's notation (see 2.B.11). This will enable us to express the solution to  $Ax = b$  as  $(x_i = \det(A_i)/\det(A) : i = 1, \dots, n)$ . This function can be introduced by the block given here:

```

def column_replace (M, column ,u):
    n1=M.nrows ()
    n2=M.ncols ()
    P = matrix (n1 ,n2)
    for i in range (n1):
        for j in range (n2):
            P[i,j]=M[i,j]
    for i in range (n1):
        P[i,column -1]= u[i ,0]
    return P
    
```

To solve our task, we can now add the following cell:

```

A= matrix ([[1 ,1 ,1 ,1] , [1 , 1 , -1, -1] , [1 ,-1, 1, -1] , [1 ,-1 ,-1, 1]])
b= matrix (4 ,1 , [2 ,3 ,3 ,5])
A1= column_replace (A ,1,b)
A2= column_replace (A ,2,b)
A3= column_replace (A ,3,b)
A4= column_replace (A ,4,b)
x= matrix (4 ,1 , [det(A1)/det(A), det(A2)/det(A), det(A3)/det(A), det(A4)/det(A)])
show(x)
    
```

Executing this block Sage returns the solution obtained above, i.e.,  $(\frac{13}{4}, -\frac{3}{4}, -\frac{3}{3}, \frac{1}{4})^T$ .

**2.E.27.** One may compute first  $F^{-1}$ . Then, based on the formula  $F^{-1} = \frac{1}{\det(F)}\text{adj}(F)$  we deduce that

$$\text{adj}(F) = (\alpha\delta - \beta\gamma) F^{-1} = \begin{pmatrix} \delta & -\beta & 0 \\ -\gamma & \alpha & 0 \\ 0 & 0 & \alpha\delta - \beta\gamma \end{pmatrix},$$

for all  $\alpha, \beta, \gamma, \delta \in \mathbb{R}$ .

**2.E.28.** The corresponding adjoint matrices have the form

$$\operatorname{adj}(A) = \begin{pmatrix} 1 & 1 & -2 & -4 \\ 0 & 1 & 0 & -1 \\ -1 & -1 & 3 & 6 \\ 2 & 1 & -6 & -10 \end{pmatrix}, \quad \operatorname{adj}(B) = \begin{pmatrix} 6 & -2i \\ -3 + 2i & 1 + i \end{pmatrix}.$$

**2.E.29.** We can easily verify that  $A$  satisfies  $A^2 = A$ . In Sage give the cell

```
A=matrix([[2, -3, -5], [-1, 4, 5], [1, -3, -4]]); bool(A==A*A)
```

Sage returns True. As for the product  $AB$ , we get  $AB = A(A - I) = A^2 - A = A - A = 0$ . Moreover, for  $B^2$  we see that

$$B^2 = (A - I)(A - I) = A^2 - 2A - I = I - A = -B = \begin{pmatrix} -1 & 3 & 5 \\ 1 & -3 & -5 \\ -1 & 3 & 5 \end{pmatrix}.$$

In Sage a verification of these results it is very fast. For example add the following syntax in the previous cell:

```
E=matrix([[1, 0, 0], [0, 1, 0], [0, 0, 1]]); B=A-E; show(A*B); show(B^2)
```

Finally, let us use Sage again to compute  $\det(A)$ , where we just need to add the command  $\det(A)$ . It gives  $\det(A) = 0$ , i.e.,  $A$  is a *singular* matrix. Try to present a formal computation of  $\det(A)$ . In fact, except of the identity matrix, all the other idempotent matrices have determinant zero (see 2.E.61 below).

**2.E.30.** Both relations are true. To prove this, we will use Cauchy's theorem, which states that  $\det(AB) = \det(A)\det(B)$  (see 2.2.7). Since  $\det(PP^{-1}) = \det(E) = 1$  we obtain

$$\det(B) = \det(PAP^{-1}) = \det(P)\det(A)\det(P^{-1}) = \det(P)\det(P^{-1})\det(A) = \det(PP^{-1})\det(A) = \det(A).$$

Hence,  $\det(B) = \det(A)$  and we also obtain  $\det(A^{-1}B) = \det(A^{-1})\det(B) = \det(A^{-1})\det(A) = \det(A^{-1}A) = 1$ .

**2.E.32.** This task is solved in a similar way with 2.E.31, and you can verify that the desired coordinates are given by  $(2 + \frac{1}{\sqrt{3}}, 2 - \frac{1}{\sqrt{3}})$ .

**2.E.33.** Let us write

$$(5, 1, 11)^T = p(3, 2, 2)^T + q(2, 3, 1)^T + r(1, 1, 3)^T$$

for some  $p, q, r \in \mathbb{R}$ . Solving the corresponding linear system we obtain a unique solution given by  $p = 2$ ,  $q = -2$  and  $r = 3$ .

**2.E.34.** We see that the vectors  $u_1, u_2, u_3$  are linearly dependent, whenever at least one of the following conditions is satisfied:  $a = b = 1$ , or  $a = c = 1$ , or  $b = c = 1$ .

**2.E.35.** It turns out that the given vectors are linearly independent. In order to prove our assertion, you may try to apply the method presented in 2.C.16.

**2.E.36.** It is easy to check that adding the polynomial  $x$  gives a basis of  $\mathbb{R}_3[x]$ .

**2.E.37.** For both cases we have to check the linear independence of the given vectors  $u_1, u_2, u_3$ .

(a) In the first case we compute  $\dim U = 2$ , for  $t \in \{1, 2\}$ , otherwise we have  $\dim U = 3$ .

(b) In the second case we compute  $\dim U = 2$  for  $t \neq 0$ , and  $\dim U = 1$  for  $t = 0$ .

**2.E.39.** According to the definition of intersection, the vectors in the intersection are in both, the span of the vectors  $(1, 1, -3)$ ,  $(1, 2, 2)$ , as well as in the span of the vectors  $(1, 1, -1)$ ,  $(1, 2, 1)$ ,  $(1, 3, 3)$ . We see that  $U$  is spanned by two linearly independent vectors, and hence  $U$  is a plane in  $\mathbb{R}^3$ . Next,  $V$  is spanned by three vectors, but these are linearly dependent:

$$\begin{vmatrix} 1 & 1 & 1 \\ 1 & 2 & 3 \\ -1 & 1 & 3 \end{vmatrix} = \begin{vmatrix} 1 & 1 & -1 \\ 1 & 2 & 1 \\ 1 & 3 & 3 \end{vmatrix} = 0.$$

Therefore,  $V$  is also a plane. If the vector  $(x_1, x_2, x_3)$  lies in  $U$ , then  $(x_1, x_2, x_3) = \lambda(1, 1, -3) + \mu(1, 2, 2)$ , for some scalars  $\lambda, \mu$ . Similarly, if the vector  $(x_1, x_2, x_3)$  lies in  $V$ , then  $(x_1, x_2, x_3) = \alpha(1, 1, -1) + \beta(1, 2, 1) + \gamma(1, 3, 3)$ , for some scalars  $\alpha, \beta, \gamma$ . This gives a system of six equations with eight unknowns. Solving such a system can be quite cumbersome, but we can make some simplifications. First notice that the subspace  $U$  is described by the following three equations:

$$x_1 = \lambda + \mu, \quad x_2 = \lambda + 2\mu, \quad x_3 = -3\lambda + 2\mu.$$

Solving this system of equations with respect to  $\lambda$  and  $\mu$ , or alternatively by eliminating  $\lambda$  and  $\mu$  from these equations, one obtains the single equation  $8x_1 - 5x_2 + x_3 = 0$ , which we may use to replace the first three. Now notice that the subspace  $V$  is describe by the following three equations:

$$x_1 = \alpha + \beta + \gamma, \quad x_2 = \alpha + 2\beta + \gamma, \quad x_3 = -\alpha + \beta + 3\gamma.$$

Solving this systems of equations with respect to  $\alpha$ ,  $\beta$  and  $\gamma$ , or alternatively by eliminating  $\alpha$ ,  $\beta$  and  $\gamma$  from these equations, we obtain the single equation  $3x_1 - 2x_2 + x_3 = 0$ , which we can use to describe  $V$ . Hence, it is now straightforward that after introducing a new parameter  $t$ , we can express intersection by  $(x_1, x_2, x_3) = t \cdot (3, 5, 1)$ .

**2.E.40.** The answer is given by the matrix  $\begin{pmatrix} 5/6 & -1/6 & 1/3 \\ -1/6 & 5/6 & 1/3 \\ 1/3 & 1/3 & 1/3 \end{pmatrix}$ .

**2.E.41.** The answer is given by the matrix  $\begin{pmatrix} 5/9 & 2/9 & -4/9 \\ 2/9 & 8/9 & 2/9 \\ -4/9 & 2/9 & 5/9 \end{pmatrix}$ .

**2.E.42.** (a) The vector that determines the subspace  $U$  is perpendicular to each of the three vectors that generate  $W$ . Thus the subspaces are orthogonal and the first claim holds.

(b) It is *not* true that  $\mathbb{R}^4 = U \oplus W$ . This is because the subspace  $W$  is only two-dimensional, since  $(-1, 0, -1, 2)^T = (-1, 0, 1, 0)^T - 2(0, 0, 1, -1)^T$ .

**2.E.43.** Let

$$A = \begin{pmatrix} 1 & 0 & 1 \\ 0 & 1 & 2 \\ 0 & 0 & 1 \\ 1 & 1 & 0 \end{pmatrix}$$

be the  $4 \times 3$  matrix induced by the vectors  $E_1, E_2, E_3$ . Recall that the maximum number of linearly independent row vectors in  $A$  coincides with the rank of  $A$ . Because the determinant of the first three rows equals to  $1 \neq 0$ , the rank of  $A$  equals to 3,  $\text{rank}(A) = 3$ . Hence the vectors  $E_1, E_2, E_3$  are linearly independent. Recall that to verify this conclusion by Sage it suffices to add the block

```
V = RR^4
E1 = vector(RR, [1, 0, 0, 1])
E2 = vector(RR, [0, 1, 0, 1])
E3 = vector(RR, [1, 2, 1, 0])
V.linear_dependence([E1, E2, E3]) == []
```

On the other hand, for the rank of  $A$  the appropriate cell is

```
A = matrix(SR, [[1, 0, 1], [0, 1, 2], [0, 0, 1], [1, 1, 0]])
A.rank()
```

In the first case Sage's output is True, while in the second Sage prints out the desired number 3.

Since  $E_1, E_2, E_3$  are linearly independent and span  $W$ , they form a basis of  $W$ . We will use this basis to obtain an orthogonal basis by applying the usual Gram–Schmidt procedure. Set

$$w_1 = E_1, \quad w_2 = E_2 - \frac{\langle E_2, w_1 \rangle}{\|w_1\|^2} w_1, \quad w_3 = E_3 - \frac{\langle E_3, w_1 \rangle}{\|w_1\|^2} w_1 - \frac{\langle E_3, w_2 \rangle}{\|w_2\|^2} w_2.$$

Since  $\langle E_2, w_1 \rangle = 1$  and  $\|w_1\|^2 = 2$  this gives  $w_2 = (-\frac{1}{2}, 1, 0, \frac{1}{2})^T$ . We also compute  $\langle E_3, w_1 \rangle = 1$ ,  $\langle E_3, w_2 \rangle = \frac{3}{2}$  and  $\|w_2\|^2 = \frac{3}{2}$ . Hence  $w_3 = E_3 - \frac{1}{2}E_1 - w_2$ , that is  $w_3 = (\frac{1}{2}, 1, 1, -1)^T$ , with  $\|w_3\|^2 = \frac{13}{4}$ . Thus an orthonormal basis of  $W$  consists of the vectors

$$\hat{w}_1 = \frac{w_1}{\|w_1\|} = \left(\frac{1}{\sqrt{2}}, 0, 0, \frac{1}{\sqrt{2}}\right)^T, \quad \hat{w}_2 = \frac{w_2}{\|w_2\|} = \left(\frac{-1}{\sqrt{6}}, \sqrt{\frac{3}{2}}, 0, \frac{1}{\sqrt{6}}\right)^T, \quad \hat{w}_3 = \frac{w_3}{\|w_3\|} = \left(\frac{1}{\sqrt{13}}, \frac{2}{\sqrt{13}}, \frac{2}{\sqrt{13}}, \frac{-2}{\sqrt{13}}\right)^T.$$

By definition, we have  $\mathbb{R}^4 = W \oplus W^\perp$  and hence  $\dim W^\perp = \dim \mathbb{R}^4 - \dim W = 1$ . Choosing any vector of the orthonormal basis of  $\mathbb{R}^4$ , say  $e_2 = (0, 1, 0, 0)$ , we extend the above basis to a basis to  $\mathbb{R}^4$ , namely  $\{Z_1 = \hat{w}_1, Z_2 = \hat{w}_2, Z_3 = \hat{w}_3, Z_4 = e_2\}$  (we encourage the reader to verify this statement in Sage). By applying the Gram–Schmidt method to this basis we obtain an orthogonal basis  $\{\hat{Z}_1, \dots, \hat{Z}_4\}$  of  $\mathbb{R}^4$ , given by  $\hat{Z}_j = Z_j = \hat{w}_j$  for  $j = 1, 2, 3$  and

$$\hat{Z}_4 = Z_4 - \frac{\langle Z_4, \hat{w}_1 \rangle}{\|\hat{w}_1\|^2} \hat{w}_1 - \frac{\langle Z_4, \hat{w}_2 \rangle}{\|\hat{w}_2\|^2} \hat{w}_2 - \frac{\langle Z_4, \hat{w}_3 \rangle}{\|\hat{w}_3\|^2} \hat{w}_3.$$

It follows that  $W^\perp = \text{span}_{\mathbb{R}}\{\hat{Z}_4\}$ , and the explicit computation of  $\hat{Z}_4$  is left to the reader.

**2.E.47.** Using the Gram-Schmidt orthogonalization process we obtain the basis:  $\{(1, 1, 1, 1)^T, (1, 1, 1, -3)^T, (-2, 1, 1, 0)^T\}$ .

**2.E.48.** For example, one can obtain the orthogonal bases  $\{(1, 0, 1, 0)^T, (0, 1, 0, -7)^T\}$  for the first part, and  $\{(1, 2, 2, -1)^T, (2, 3, -3, 2)^T, (2, -1, -1, -2)^T\}$  for the second part.

**2.E.49.** The solution is  $a = 9/2, b = -5$  (since  $1 + b + 4 + 0 + 0 = 0$  and  $1 - b + 0 + 3 - 2a = 0$ ).

**2.E.50.** The orthogonal complement  $V^\perp$  is the set of all scalar multiples of the vector  $(4, 2, 7, 0)^T$ .

**2.E.51.** Obviously, there are infinitely many possible extensions. For example, a very simple one is given by the set

$$\{u_1, u_2, u_3 = (1, 0, 0, -1)^T, u_4 = (1, 0, -1, 1)^T\}.$$

**2.E.52.** The basis consists only from the vector  $u_1 = (3, -7, 1, -5, 9)^T$  (or any non-zero scalar multiple of  $u_1$ ).

**2.E.53.** The answers are given as follows:

(a)  $W^\perp = \text{span}_{\mathbb{R}} \{(1, 0, -1, 1, 0)^T, (1, 3, 2, 1, -3)^T\}$ .

(b)  $W^\perp = \text{span}_{\mathbb{R}} \{(1, 0, -1, 0, 0)^T, (1, -1, 1, -1, 1)^T\}$ .

**2.E.54.** Obviously, any squared matrix  $A$  can be written as  $A = \frac{1}{2}(A + A^T) + \frac{1}{2}(A - A^T)$ . Setting  $A_s = \frac{1}{2}(A + A^T)$  and  $A_a = \frac{1}{2}(A - A^T)$ , respectively, it is clear that

$$A_s^T = \frac{1}{2}(A + A^T)^T = A_s, \quad A_a^T = \frac{1}{2}(A - A^T)^T = -A_a.$$

This proves the first statement, i.e.,  $A = A_s + A_{\text{skew}}$ . For the given matrix  $A$  we compute

$$A_s = \frac{1}{2} \left\{ \begin{pmatrix} 1 & 0 & 2 \\ 6 & 3 & 0 \\ 2 & 2 & 4 \end{pmatrix} + \begin{pmatrix} 1 & 6 & 2 \\ 0 & 3 & 2 \\ 2 & 0 & 4 \end{pmatrix} \right\} = \begin{pmatrix} 1 & 3 & 2 \\ 3 & 3 & 1 \\ 2 & 1 & 4 \end{pmatrix}$$

and

$$A_a = \frac{1}{2} \left\{ \begin{pmatrix} 1 & 0 & 2 \\ 6 & 3 & 0 \\ 2 & 2 & 4 \end{pmatrix} - \begin{pmatrix} 1 & 6 & 2 \\ 0 & 3 & 2 \\ 2 & 0 & 4 \end{pmatrix} \right\} = \begin{pmatrix} 0 & -3 & 0 \\ 3 & 0 & -1 \\ 0 & 1 & 0 \end{pmatrix}.$$

Observe that a skew-symmetric matrix, as  $A_a$ , has zeros in the diagonal. In Sage, to find  $A_s$  and  $A_a$  we can proceed with the cell

```
A=matrix([[1, 0, 2], [6, 3, 0], [2, 2, 4]]); show(A)
As=(A+A.transpose())/2; Aa=(A-A.transpose())/2; show(As); show(Aa)
As.is_symmetric() # this command is used to verify that A_s is symmetric
```

Notice an alternative to compute the transpose of a matrix  $A$  in Sage, is the shortcut  $A.T$ , a notation which is common in some other programming environments like NumPy. Hence for example to determine the matrix  $A_s$  in Sage one could type

```
A=matrix([[1, 0, 2], [6, 3, 0], [2, 2, 4]])
As=(A+A.T)/2; print(As)
```

**2.E.55.** (a) The assertions are obvious:

$$(A + A^T)^T = A^T + (A^T)^T = A^T + A = A + A^T, \quad (A - A^T)^T = A^T - (A^T)^T = A^T - A = -(A - A^T).$$

(b) By assumption  $A$  is skew-symmetric, i.e.,  $A = -A^T$  and  $n$  is odd. Recall that  $\det(X) = \det(X^T)$  and  $\det(cX) = c^n \det(X)$  for any  $n \times n$  matrix  $X$ , see 2.B.8. Thus,  $\det(A) = \det(A^T) = \det(-A) = (-1)^n \det(A) = -\det(A)$  which implies that  $2 \det(A) = 0$ , i.e.,  $\det(A) = 0$ .

(c) The proof for the claim about the trace is also easy: Since a skew-symmetric matrix  $A = (a_{ij})$  satisfies  $a_{ij} = -a_{ji}$  for any  $i, j$ , we have  $a_{ii} = 0$  for all  $i = j$ . Thus, all the diagonal entries of a skew-symmetric matrix are zero.

**2.E.58.** The given identity occurs easily by (\*), which for  $\lambda = 1$  gives  $\chi_A(1) = \det(A - E) = -1 + \text{tr}(A) + c_1 + \det(A)$ , so we can replace  $c_1$  in (\*) by  $\det(A - E) + 1 - \text{tr}(A) - \det(A)$ .

For the given matrix  $A$  we compute  $\text{tr}(A) = 12$  and  $\det(A) = 60$ . Hence an application gives

$$\chi_A(\lambda) = \det(A - \lambda E) = -\lambda^3 + 12\lambda^2 - 47\lambda + 60.$$

Using Sage we find that  $\chi_A(\lambda)$  has three roots:  $\lambda_1 = 3, \lambda_2 = 4$ , and  $\lambda_3 = 5$ . These are the eigenvalues of  $A$ , all with algebraic multiplicity one. Try to solve the equation  $\chi_A(\lambda) = 0$  in a formal way. For a description in Sage of the given expression of the characteristic polynomial, but also for a verification of the determinant and trace, type

```
A=matrix(SR, [[32, -67, 47], [7, -14, 13], [-7, 15, -6]])  
print(A.trace( )); print(A.det( ))
```

```
p(t) = A.characteristic\_polynomial(t)
show(p(t)); show(p.roots())
```

**2.E.59.** Possible examples illustrated by the matrices  $A, B$  and  $C$  provided below, which correspond to the cases (i), (ii) and (iii), respectively:

$$A = \begin{pmatrix} 6 & 0 & 0 & 0 \\ 0 & 7 & 0 & 0 \\ 0 & 0 & 7 & 0 \\ 0 & 0 & 0 & 7 \end{pmatrix}, \quad B = \begin{pmatrix} 6 & 0 & 0 & 0 \\ 0 & 7 & 1 & 0 \\ 0 & 0 & 7 & 0 \\ 0 & 0 & 0 & 7 \end{pmatrix}, \quad C = \begin{pmatrix} 6 & 0 & 0 & 0 \\ 0 & 7 & 1 & 0 \\ 0 & 0 & 7 & 1 \\ 0 & 0 & 0 & 7 \end{pmatrix}.$$

Explain the reasoning behind the derivation of these matrices and then explore additional solutions.

**2.E.60.** There is a triple eigenvalue  $-1$ . The corresponding eigenspace is spanned by the eigenvectors  $(1, 0, 0)^T$  and  $(0, 2, 1)^T$ , hence it is 2-dimensional (over  $\mathbb{R}$ ).

**2.E.65.** The matrix has a double eigenvalue  $-1$ , and its associated eigenspace is spanned over  $\mathbb{R}$  by the vectors  $(2, 0, 1)^T$  and  $(1, 1, 0)^T$ . Further, the matrix has  $0$  as the eigenvalue, with eigenvector  $(1, 4, -3)^T$ . Combining this with the statements in 2.E.63, we deduce that the mapping induced by the given matrix  $M$  is an axial symmetry through the line induced by the last vector, composed with the projection on the plane perpendicular to the last vector. Verify that this plane is given by the equation  $x + 4y - 3z = 0$ .

**2.E.66.** (i) Let us present the computations in Sage, where we can use the command `A.commutator(B)` to compute the commutator  $[A, B] = AB - BA$  of two squared matrices  $A, B$ . The corresponding block is here:

```
s1=matrix(SR, [[0, 1], [1, 0]])
s2=matrix(SR, [[0, -i], [i, 0]])
s3=matrix(SR, [[1, 0], [0, -1]])
show(s1.commutator(s2)); bool(s1.commutator(s2)==2*i*s3)
show(s1.commutator(s3)); bool(s1.commutator(s3)==-2*i*s2)
show(s2.commutator(s3)); bool(s2.commutator(s3)==2*i*s1)
```

Execute this block to read Sage's output.

(ii) To verify the claims posed in the second part one can proceed by adding in the previous cell the code

```
bool(s1*s1==identity_matrix(2))
bool(s2*s2==identity_matrix(2))
bool(s3*s3==identity_matrix(2))
ev1=s1.eigenvalues()
ev2=s2.eigenvalues()
ev3=s3.eigenvalues()
bool(ev1==ev2); bool(ev1==ev3); bool(ev2==ev3); show(ev1)
```

Let us also verify the claim for the eigenvalues by a formal computation, e.g., for  $\sigma_1$ . The point is to compute its characteristic polynomial  $\chi_{\sigma_1}(\lambda) = \det(\sigma_1 - \lambda E)$ , where here  $E = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}$ . We have

$$\sigma_1 - \lambda E = \begin{pmatrix} -\lambda & 1 \\ 1 & -\lambda \end{pmatrix} \implies \chi_{\sigma_1}(\lambda) = \begin{vmatrix} -\lambda & 1 \\ 1 & -\lambda \end{vmatrix} = \lambda^2 - 1.$$

Thus there are two roots,  $\lambda_{\pm} = \pm 1$ . Similarly for  $\sigma_2$  and  $\sigma_3$ . Try to you determine the corresponding eigenvectors.

(iii) The claim in this part can be proved similarly, and left as an exercise.

**2.E.67.** This is direct and left for practice.

## Linear models and matrix calculus

where are the matrices useful?  
– basically almost everywhere...

### A. Linear optimization

The idea of maximizing or minimizing a linear function subject to linear constraints arises naturally in many fields. For instance we may want to maximize profits, minimize costs, etc. Linear programming builds upon notions from linear algebra discussed in Chapter 2 and is a dynamic tool for solving linear optimization problems subject to linear constraints.<sup>1</sup>

In a linear programming problem (LP problem in short) we seek for a vector on some Euclidean space maximizing (or minimizing) the value of some linear functional, among all vectors satisfying a given system of linear constraints that govern the process. In 3.1.2 this linear functional is called the objective function.

**3.A.1.** To illustrate the idea let us begin with LP problems in two dimensions, where a solution occurs graphically. As usual, we view vectors  $x$  on  $\mathbb{R}^2$  as column matrices  $(x_1, x_2)^T$  with  $x_1, x_2 \in \mathbb{R}$ . We want to maximize the value of the linear function  $h(x_1, x_2) = x_1 + x_2$  (objective function) subject to the constraints

$$x_1 + 2x_2 \leq 3, \quad 2x_1 + x_2 \leq 3, \quad x_1 \geq 0, \quad x_2 \geq 0.$$

<sup>1</sup>The name "programming" refers to process planning and was introduced before the computers were invented, cf. the footnote on page 195.

We have already developed a useful package of tools and it is time to show some applications of matrix calculus. The first three parts of this chapter are independent and the readers more interested in the theory might skip any of them and continue with the fourth part straight ahead.

It might seem that the assumption of linearity of relations between quantities is too restrictive. But this is often not so. In real problems, linear relations may appear directly. A problem may be solved as a result of an iteration of many linear steps. If this is not the case, we may still use this approach at least to approximate real non-linear processes.

We should also like to compute with matrices (and linear mappings) as easily as we can compute with scalars. In order to do that, we prepare the necessary tools in the second part of this chapter. We also present a useful application of matrix decompositions to the pseudoinverse matrices, which are needed for numerical mastery of matrix calculus.

We try to illustrate all the phenomena with rather easy problems. Still some parts of this chapter are perhaps difficult for first reading. This in particular concerns the very first part providing some glimpses towards the linear optimization (linear programming), and the third part devoted to iterated processes (the Frobenius-Perron theory).

The rest of the chapter comes back to some more advanced parts of the matrix calculus (the Jordan canonical form, decompositions, and pseudo-inverses of matrices). The reader should feel free to move forward if getting lost.

### 1. Linear optimization

The simplest linear processes are given by linear mappings  $\varphi : V \rightarrow W$  on vector spaces. As we can surely imagine, the vector  $v \in V$  can represent the state of some system we are observing, while  $\varphi(v)$  gives the result after some process is realized.

If we want to reach a given result  $b \in W$  of such a process, we solve the problem

$$\varphi(x) = b$$

for some unknown vector  $x$  and a known vector  $b$ .

In fixed coordinates we then have the matrix  $A$  of a mapping  $\varphi$  and coordinate expression of the vector  $b$ . We have mastered such problems in the previous chapter. Now we

**Solution.** The inequalities are graphically represented by half-planes in  $\mathbb{R}^2$ , and the intersection of these half-planes determines the “feasible region” of solutions. Thus, a feasible solution is any point in  $\mathbb{R}^2$  satisfying all the given constraints. The non-negativity constraints  $x_i \geq 0$  for  $i = 1, 2$  clearly restrict all the feasible solutions to the first quadrant. Therefore, the feasible region is the shaded (hatched) area in the diagram below. While it is possible to construct linear programming (LP) problems with an empty feasible region, we are primarily interested in those with a non-empty feasible region.

In a linear maximization problem, an “optimal solution” is a point within the feasible region that maximizes the objective function’s value.

For our example, an optimal solution appears at a unique vertex. To see this, let us consider the vector  $c = (1, 1)^T$ , such that  $c^T x = x_1 + x_2$ . Consider also the objective function line  $x_1 + x_2 = k$  ( $k \in \mathbb{R}$ ), perpendicular to the vector  $c$ . As illustrated in the figure above, we now begin moving this line upwards in the direction of the vector  $c$ , maintaining the same slope, without leaving the feasible region. By doing so, we can determine the point where the moving line intersects the feasible region for the last time, that is, at the point  $(1, 1)$ . This point provides the maximum value  $k = 2$  for the objective function  $h$ . □

*On the other hand, there exist LP problems with infinitely many optimal solutions. Nevertheless, at least one of these optimal solutions must occur at a vertex of the feasible region. Let us describe such an example.*

**3.A.2.** Consider the problem of maximizing the functional  $h(x_1, x_2) = 2.5x_1 + x_2$  under the constraints

$$3x_1 + 5x_2 \leq 15, \quad 5x_1 + 2x_2 \leq 10, \quad x_1 \geq 0, \quad x_2 \geq 0.$$

draw more interesting conclusions in the setup of *linear optimization models* (called also *linear programming*).

**3.1.1. Linear optimization.** In the practical column, the previous chapter started with a painting problem, and we shall continue here in a similar way. Imagine that our very specialized painter in a black&white world is willing to paint facades of either small family houses or of large public buildings, and that he (of course) uses only black and white colours. He can arbitrarily choose proportions between  $x_1$  units of area for the small houses or  $x_2$  units for the large buildings. Assume that his maximal workload in a given interval of time is  $L$  units of area, his net income (that is, after subtracting the costs) is  $c_1$  per unit of area for small houses and  $c_2$  per unit of area for large buildings. Furthermore, he has only  $W$  kg of white colour and  $B$  kg of black colour at his disposal. Finally, a unit of area for small houses requires  $w_1$  kg of white colour and  $b_1$  kg of black colour. For large buildings the corresponding values are  $w_2$  and  $b_2$ .

If we write all this information as inequalities, we obtain the conditions

- (1)  $x_1 + x_2 \leq L$
- (2)  $w_1x_1 + w_2x_2 \leq W$
- (3)  $b_1x_1 + b_2x_2 \leq B$ .

The total net income of the painter, which is the following linear form  $h$ ,

$$h(x_1, x_2) = c_1x_1 + c_2x_2,$$

is to be maximized.

Each of the given inequalities clearly determines a half-plane in the plane of the variables  $(x_1, x_2)$ , bounded by a line given by the corresponding equality, and we must also assume that both  $x_1$  and  $x_2$  are non-negative real numbers (because the painter cannot paint negative areas). Thus we have constraints for the values  $(x_1, x_2)$  – either the constraints are unsatisfiable, or they allow points inside a polygon with at most five vertices. See the diagram.

the axis in the diagram should be called  $x_1$  and  $x_2$ ! Add the line of constant value for  $h$ , best through one of the vertices with hand-written description “optimal constant value of  $h$ ”

**Solution.** Obviously, we have  $h = c^T x$  where  $c = (2.5, 1)^T$  and the feasible region is the shaded polygon in the figure below. All the points on the thick side of the polygon are optimal solutions. This is because  $h$  is parallel to the line  $5x_1 + 2x_2 = 10$ , induced by the second constraint. Indeed, we see that both the points  $(2, 0)$  and  $(\frac{20}{19}, \frac{45}{19})$  are optimal solutions to the problem, with  $h(0, 2) = h(\frac{20}{19}, \frac{45}{19}) = 5$ . The line segment  $p$  joining these points has the form

$$(x_1, x_2) = t(2, 0) + (1-t)(\frac{20}{19}, \frac{45}{19}) = (\frac{20}{19} + \frac{18}{19}t, \frac{45}{19} - \frac{45}{19}t)$$

with  $t$  ranging from 0 to 1. Then, any point  $(x_1, x_2)$  on  $p$  maximizes  $h$  and hence serves as an optimal solution:

$$h(x_1, x_2) = \frac{5}{2}(\frac{20}{19} + \frac{18}{19}t) + (\frac{45}{19} - \frac{45}{19}t) = 5.$$

Finally, we may encounter LP problems with an unbounded feasible region, where the objective function can achieve arbitrarily large values, resulting in the absence of optimal solutions (unbounded objective). For example, this occurs when attempting to maximize  $x_1 + x_2$  in the first quadrant without any additional constraints, or when adding the constraint  $x_2 - x_1 \leq 1$ .

Another possible scenario involves an unbounded linear programming problem that still has infinitely many optimal solutions. This situation is illustrated by the following example, where the details left as an exercise.

**3.A.3.** Maximize  $h = 2x_2 - x_1$  subject to the constraints  $x_1 - x_2 \geq -1, -0.5x_1 + x_2 \leq 2, x_1 \geq 0, x_2 \geq 0$ .

Linear programming applies to a wide range of problems and in the sequel we will explore several of its applications. Examples include maximizing the profits of a production process, minimizing the area on a chip, optimizing

How to solve such a problem? We seek the maximum value of a linear form  $h$  over subsets  $M$  of a vector space which are defined by linear inequalities. In the plane,  $M$  is given by the intersection of half planes.

Next, note that every linear form over real vector space  $h : V \rightarrow \mathbb{R}$  (that is, arbitrary linear scalar function) is monotone in every chosen direction. More precisely, if we choose a fixed starting vector  $u \in V$  and “directional” vector  $v \in V$ , then composition of our form  $h$  with parametrization yields

$$t \mapsto h(u + tv) = h(u) + th(v).$$

This expression is indeed either increasing or decreasing, or constant (depending on whether  $h(v)$  is positive, negative or zero), as a function of  $t$ .

Thus, if the set  $M$  is bounded as at our picture above, we easily find the solution by testing the value of  $h$  at the vertices of the boundary polygon. In general, we must expect that problems similar to the one with the painter are either unsatisfiable (if the given set with constraints is empty), or the profit is unbounded (if the constraints allow for unbounded directions in the space and the form  $h$  is non-zero in some of the unbounded directions) or they attain a maximal solution in at least one of the “vertices” of the set  $M$ . Normally the maximum is attained at a single point of  $M$ , but sometimes it is attained on a part of the boundary of the set  $M$ .

Try to choose explicit values for the parameters  $w_1, w_2, b_1, b_2, c_1, c_2$ , draw the above picture for these parameters and find the explicit solution to the problem (if it exists)!

**3.1.2. Terminology.** In general we speak of a *linear programming problem* whenever we seek either the maximum or minimum value of a linear form  $h$  over  $\mathbb{R}^n$  on a set bounded by a system of linear inequalities which we call *linear constraints*. The vector on the right side is then called the *vector of constraints*. The linear form  $h$  is also called the *objective function*.<sup>1</sup> In real practice we meet hundreds or thousands of constraints for dozens of variables.

The *standard maximization problem* is defined by seeking a maximum of the objective function while the restrictive inequalities are  $\leq$  and the variables are non-negative. On the other hand, the *standard minimization problem* is defined by seeking a minimum of the objective function while the restrictive inequalities are  $\geq$  and the variables are non-negative.

It is easy to see that every general linear programming problem can be transformed into a standard one of either types. Aside from sign changes, we can work with a decomposition of the variables that have no sign restriction into a difference of two non-negative ones. Without loss of generality we will work only with the standard maximization problem.

<sup>1</sup>Leonid Kantorovich and Tjalling Koopmans shared the 1975 Nobel prize in economics for their formulations and solution of economical and logistics problems in a similar way during the second world war. But it was George B. Dantzig who independently developed general linear programming formulation in the period 1946-49, motivated by planning problems in US Air Force. Among others, he invented the simplex method algorithm.

supply chain logistics, scheduling tasks efficiently, and determining the best investment portfolio mix.

**3.A.4.** A company manufactures two models A and B of a product. Each piece of model A requires ten labor hours for fabrication and one labor hour for finishing and packing. For model B, each piece requires sixteen labor hours for fabrication and two labor hours for finishing and packing. The profit is €500 for each piece of model A and €850 for each piece of model B. Assuming there are 180 labor hours available monthly for fabrication and 20 labor hours available for finishing and packing, how many pieces of model A and B should be manufactured to maximize the profit?

**Solution.** Let us encode the given data in a table:

	model A	model B	labour hours
fabricate	10 hours/piece	16 hours/piece	180 hours
finish & pack	1 hour/piece	2 hours/piece	20 hours
profit	€500/piece	€850/piece	

Suppose that  $x_1$  is the number of pieces of model A and  $x_2$  is the number of pieces of model B that are manufactured. The profit function is given by  $h(x_1, x_2) = 500x_1 + 850x_2$ , and we want to maximize it subject to the following constraints:  $10x_1 + 16x_2 \leq 180$ ,  $x_1 + 2x_2 \leq 20$ , with  $x_1 \geq 0$  and  $x_2 \geq 0$ . Here, the first inequality represents the constraint on the labour hours of fabricating, the second one pertains the labour hours of finishing and packing, and the last two are natural non-negativity conditions. Equivalently we have the LP problem of maximizing the given profit  $h = h(x_1, x_2)$  with respect to the conditions  $5x_1 + 8x_2 \leq 90$ ,  $x_1 + 2x_2 \leq 20$ , with  $x_i \geq 0$  for  $i = 1, 2$ . Draw a figure yourself to see, that this is a bounded LP problem and hence the maximum of  $h$  will appear in one of the corners of the corresponding feasible region. The vertices of the feasible region are  $(18, 0)$ ,  $(0, 10)$ , and  $(10, 5)$ . Since  $h(18, 0) = 9000$ ,  $h(0, 10) = 8500$ ,  $h(10, 5) = 9250$ , we deduce that the company must produce 10 pieces of model A and 5 pieces of model B, to achieve the maximum profit of €9250.

□

**3.A.5. Minimize the costs of feeding.** A stable in the west of Czech Republic purchases fodder for the winter: hay and oats. The nutritional values of the fodder, along with the daily requirements (portions) per foal, are detailed in the following table.

g per kg	Hay	Oats	Requirements
Dry basis	841	860	$\geq 6300$ g
Digestible nitrogen stuff	53	123	$\geq 1150$ g
Starch	0.348	0.868	$\leq 5.35$ g
Calcium	6	1.6	$\geq 30$ g
Phosphate	2.8	3.5	$\leq 44$ g
Natrium	0.2	1.4	$\approx 7$ g
Costs	€1.80	€1.60	

**3.1.3. Formulation using linear equations.** Finding an optimum is not always as simple as in the previous 2-dimensional case. The problem can contain many variables and constraints and even deciding whether the set  $M$  of the feasible points is non-empty can be a problem.

We do not have the ambition to go into detailed theory here. But we mention at least some ideas which show that the solution can be always found, and then we build an effective algorithm solving the problem in the next paragraphs.

We begin by comparison with systems of linear equations – because we understand those well. We write the equations (1)-(3) in 3.1.1 in the general form:

$$A \cdot x \leq b,$$

where  $x$  is now an  $n$ -dimensional vector,  $b$  is an  $m$ -dimensional vector and  $A$  is the corresponding matrix. By an inequality between vectors we mean individual inequalities between all coordinates. We want to maximize the product  $c \cdot x$  for a given row vector of coefficients of the linear form  $h$  and the feasible values of  $x$ . If we add new auxiliary variables  $x_s$ , one for every equation and add another variable  $z$  for the value of the linear form  $h$ , we can rewrite the whole system as a system of linear equations

$$(1) \quad \begin{pmatrix} 1 & -c & 0 \\ 0 & A & E_m \end{pmatrix} \cdot \begin{pmatrix} z \\ x \\ x_s \end{pmatrix} = \begin{pmatrix} z - c \cdot x \\ A \cdot x + x_s \end{pmatrix} = \begin{pmatrix} 0 \\ b \end{pmatrix}$$

where the matrix is composed of the blocks with  $1 + n + m$  columns and  $1 + m$  rows, with corresponding individual components of the vectors. We call the new variables  $x_s$  the *slack variables*. Moreover, we require non-negativity for all coordinates  $x$  and  $x_s$ . If the given system of equations has a solution, we seek values for the variables  $z$ ,  $x$  and  $x_s$ , such that all  $x$  and  $x_s$  are non-negative and  $z$  is maximized.

Specifically, in our problem of the black&white painter from 3.1.1, the system of linear equations looks like this:

$$\begin{pmatrix} 1 & -c_1 & -c_2 & 0 & 0 & 0 \\ 0 & 1 & 1 & 1 & 0 & 0 \\ 0 & w_1 & w_2 & 0 & 1 & 0 \\ 0 & b_1 & b_2 & 0 & 0 & 1 \end{pmatrix} \cdot \begin{pmatrix} z \\ x_1 \\ x_2 \\ x_3 \\ x_4 \\ x_5 \end{pmatrix} = \begin{pmatrix} 0 \\ L \\ W \\ B \end{pmatrix}$$

In paragraph 4.1.11 on page 328 we will discuss this situation from the viewpoint of affine geometry. Now we just notice that being on the boundary of the set of feasible points  $M$  of the problem is equivalent to having some of the slack variables vanishing. Our algorithm will try to move from one such position to another while increasing  $h$ . But we shall need some conceptual preparation first.

**3.1.4. Duality of linear programming.** Consider the real matrix  $A$  with  $m$  rows and  $n$  columns, vector of constraints  $b$  and row vector  $c$  giving the objective function. From this data we can consider two problems of linear programming for  $x \in \mathbb{R}^n$  and  $y \in \mathbb{R}^m$ .

During each daily meal, each foal requires a minimum of 2 kg of oats. The average cost, including transportation, is €1.80 per kg of hay and €1.60 per kg of oats. Design a daily diet for one foal that minimizes costs. ○

As explained earlier, when the feasible region of a linear programming problem with two variables is non-empty and bounded, the maximum value of the given linear cost function  $h$  will be found at one of the extreme points (corners) of this region, in the direction of the normal vector to the line defined by  $h$ . This principle also holds true in higher dimensions, as we will see below.

**3.A.6. Linear programming on  $\mathbb{R}^n$ .** Consider a function  $f : \mathbb{R}^n \rightarrow \mathbb{R}$  of the form

$$f(x_1, \dots, x_n) = c_0 + c_1x_1 + \dots + c_nx_n$$

for some constants  $c_0, c_1, \dots, c_n$ . Due to the appearance of the constant term  $c_0$  we see that  $f$  is an affine function.<sup>2</sup> Since  $f$  is affine, the difference of the values of  $f$  at the points  $A = (a_1, \dots, a_n)$  and  $B = A + u = (a_1 + u_1, \dots, a_n + u_n)$  equals to  $f(u) = f(u_1, \dots, u_n) = c_1u_1 + \dots + c_nu_n$ . Notice the latter is the dot product of the vectors  $(c_1, \dots, c_n)^T$  and  $(u_1, \dots, u_n)^T$  on  $\mathbb{R}^n$ . Next we will refer to  $f$  by the term “objective function”.

The relation between the scalar product and the cosine of the angle between vectors ensures that fixing the value of the given function  $f$  defines a hyperplane in  $\mathbb{R}^n$  with normal the vector  $(c_1, \dots, c_n)^T$ . This hyperplane splits the space  $\mathbb{R}^n$  into two half-spaces. Clearly the given function grows if moving towards one of those half-spaces and declines towards the other one. This is essentially the same principle as we saw when discussing the visibility of segments in dimension 2 (we checked whether the observer is to the left or to the right from the oriented segment, cf. 1.5.12). At the same time, each linear inequality also defines a half-space and we shall learn the properties of intersections of half-spaces in Chapter 4 (they form the so-called simplexes). These observations lead to an algorithm for finding the extremal values of the linear objective function  $f$  on the set of admissible points defined by linear inequalities.

For the sake of simplicity, we shall deal with the “standard problem” of linear programming. This means that we will treat the task of maximizing the linear function

$$h(x_1, \dots, x_n) = \sum_{j=1}^n c_jx_j = c^T x$$

subject to the conditions  $\sum_{j=1}^n a_{ij}x_j \leq b_i$  and  $x_j \geq 0$ , with  $i = 1, \dots, m$ ,  $j = 1, \dots, n$ , respectively. According to the discussion in 3.1.6, our first task is to add the (non-negative) *slack variables*  $x_s$  (also called *slacks*), one for each of the less-than inequalities to reduce them to equalities:

<sup>2</sup>Recall that affine functions are essentially linear functions plus a constant offset.

DUAL PROBLEMS OF LINEAR PROGRAMMING

**Maximization problem:** Maximize  $c \cdot x$  under the conditions  $A \cdot x \leq b$  and  $x \geq 0$ .

**Minimization problem:** Minimize  $y^T \cdot b$  under the conditions  $y^T \cdot A \geq c$  and  $y \geq 0$ .

We say that these two problems are *dual problems of linear programming*. Before deriving further properties of linear programming we need some terminology.

We say that the problem is *solvable* if there is an *admissible vector*  $x$  (or admissible vector  $y^T$ ) which satisfies all constraints. A solvable maximization (minimization) problem is *bounded*, if the objective function is bounded from above (below) over the set of admissible vectors.

**Lemma (Weak duality theorem).** *If  $x \in \mathbb{R}^n$  is an admissible vector for the standard maximization problem, and if  $y \in \mathbb{R}^m$  is an admissible vector for the dual minimization problem, then*

$$c \cdot x \leq y^T \cdot b$$

**PROOF.** It is a simple observation. Since  $x \geq 0$  and  $c \leq y^T \cdot A$ , it follows that  $c \cdot x \leq y^T \cdot A \cdot x$ . But also  $y \geq 0$  and  $A \cdot x \leq b$ , hence

$$c \cdot x \leq y^T \cdot A \cdot x \leq y^T \cdot b,$$

which is what we wanted to prove. □

We see immediately that if both dual problems are solvable, then they must be bounded. Even more interesting is the following corollary, which is directly implied by the inequality in the previous proof.

**Corollary.** *If there exist admissible vectors  $x$  and  $y$  of dual linear problems such that for the objective functions  $c \cdot x = y^T \cdot b$ , then both are optimal solutions for the corresponding problems.*

**3.1.5. Theorem (Strong duality theorem).** *If a standard problem of linear programming is solvable and bounded, then its dual is also bounded and solvable. There exists an optimal solution for each of the problems, and the optimal values of the corresponding objective functions are equal.*

**PROOF.** As already proved in the latter corollary, once it is established that the values of the objective functions for the dual problems equal, we have the required optimal solutions to both problems. It remains to prove the other implication, i.e. the existence of an optimal solution under the assumptions in the theorem, as well as the fact, that the objective functions share their values in such a case. This will be verified by delivering an efficient algorithm in the next paragraph. □

We notice yet another corollary of the just formulated duality theorem:

**Corollary (Equilibrium theorem).** *Consider two admissible vectors  $x$  and  $y$  for the standard maximization problem and its dual problem as defined in 3.1.4. Then both vectors are*

$\sum_{j=1}^n a_{ij}x_j + (x_s)_i = b_i$ , for all  $i = 1, \dots, m$ . Therefore, our goal is to maximize  $h$  over a vector space of solutions defined by a system of linear equations, while ensuring all coordinate values are non-negative. This represents the “canonical form” of a linear programming problem.

In fact, it is useful to have a notation in which the slacks are more or less indistinguishable from the original variables. Therefore, we will often write  $(x_1, \dots, x_n, x_{n+1}, \dots, x_{n+m})$ , instead of  $(x_1, \dots, x_n, (x_s)_1, \dots, (x_s)_m)$ , and then the above equations take the form

$$\sum_{j=1}^n a_{ij}x_j + x_{n+i} = b_i, \quad i = 1, \dots, m.$$

If there are more general inequalities, we can transform them into our standard form by multiplying them by  $-1$ . Additionally, minimizing  $h$  is equivalent to maximizing  $-h$ . Therefore, we can reduce all linear programming problems to the standard form described above.

*The simplex method is an iterative process where we begin with a less-than optimal “solution” that meets the given equations and non-negativity constraints. We then seek for a new solution that improves upon it by increasing the objective function value. Using the Gauss elimination method, we iterate this process until we reach a solution that cannot be further improved—thus achieving an optimal solution. Next, we will analyze the key steps in detail, summarizing the discussion given in 3.1.1 and 3.1.6. To illustrate these steps clearly, we will demonstrate them using a straightforward example.*

**Guide example.** Consider the task of maximizing  $h(x_1, x_2) = 140x_1 + 100x_2$  under the constraints

$$8x_1 + 8x_2 \leq 960, \quad 4x_1 + 2x_2 \leq 400, \quad 4x_1 + 3x_2 \leq 420,$$

together with the positivity conditions  $x_1 \geq 0, x_2 \geq 0$ . The canonical form occurs by maximizing  $h$  subject to

$$\begin{array}{rcccccc} 8x_1 & + & 8x_2 & + & x_3 & & = & 960, \\ 4x_1 & + & 2x_2 & + & & x_4 & = & 400, \\ 4x_1 & + & 3x_2 & + & & & x_5 & = & 420, \end{array}$$

with  $x_i \geq 0$  for any  $i = 1, \dots, 5$ . The slacks are the variables  $x_3, x_4, x_5$  and in terms of matrices we have

$$\tilde{A} = (A|I_3) = \left( \begin{array}{cc|ccc} 8 & 8 & 1 & 0 & 0 \\ 4 & 2 & 0 & 1 & 0 \\ 4 & 3 & 0 & 0 & 1 \end{array} \right), \quad b = \begin{pmatrix} 960 \\ 400 \\ 420 \end{pmatrix},$$

and  $x = (x_1, x_2, x_3, x_4, x_5)^T$  such that  $\tilde{A}x = b$ .

**3.A.7. The simplex algorithm.** To keep the exposition simple, from now on we restrict ourselves to the case where all  $b_i$  are nonnegative,  $b_i \geq 0$  for any  $i = 1, \dots, m$ .

*Step 1.* Using the canonical form of a LP program, we construct the *initial simplex tableau*. The first row of this tableau consists of the coefficients of  $h$  (with negatives signs), while

*optimal if and only if  $y_i = 0$  for all coordinates with index  $i$  for which  $\sum_{j=1}^n a_{ij}x_j < b_i$  and simultaneously  $x_j = 0$  for all coordinates with index  $j$  such that  $\sum_{i=1}^m y_i a_{ij} > c_j$ .*

**PROOF.** Suppose both relations regarding the zeros among  $x_i$  and  $y_i$  are true.

Since the summands with strict inequality have zero coefficients, we have

$$\sum_{i=1}^m y_i b_i = \sum_{i=1}^m y_i \sum_{j=1}^n a_{ij}x_j = \sum_{i=1}^m \sum_{j=1}^n y_i a_{ij}x_j$$

and for the same reason

$$\sum_{i=1}^m \sum_{j=1}^n y_i a_{ij}x_j = \sum_{j=1}^n c_j x_j.$$

This shows one implication, by the duality theorem.

Suppose now that both  $x$  and  $y$  are optimal vectors. Then

$$\sum_{i=1}^m y_i b_i \geq \sum_{i=1}^m \sum_{j=1}^n y_i a_{ij}x_j \geq \sum_{j=1}^n c_j x_j.$$

But the left- and right-hand sides are equal, and hence there is equality everywhere. If we rewrite the first equality as

$$\sum_{i=1}^m y_i \left( b_i - \sum_{j=1}^n a_{ij}x_j \right) = 0,$$

then we see that it can be satisfied only if the relation from the statement holds. But it is a sum of non-negative numbers and equals zero. From the second equality we similarly derive the second part and the proof is finished.  $\square$

The duality theorem and equilibrium theorem are useful when solving linear programming problems, because they show us relations between zeros among the additional variables and the fulfillment of the constraints. As usual, it is good to know that the problem is solvable in principle and to have some theory related to that, but we still need some clever ideas to make it all into an efficient algorithmic procedure. The next paragraph will provide some insight to this.

**3.1.6. The algorithm.** As already explained, the linear programming problem of maximizing the linear objective function  $h = cx$  under the conditions  $Ax \leq b$  can be turned into solving the system of equations (1) in 3.1.3, where we added the slack variables  $x_s$ . If all entries in  $b$  are non-negative, then the choice of  $x_s = b$  and  $x = 0$  provides an admissible solution of the system with the value of the objective function  $h = 0$ . This is the choice of the origin  $x = 0$  as one of the vertices of the distinguished region  $M$  of the admissible points. We can understand this as choosing the variables  $x_s$  as the *basic variables*, whose values are given by the right hand sides of the equation, while all the other variables are set to zero.

In the general case (allowing for negative entries in  $b$ ), we shall see in 4.1.11 that we always can find an admissible vertex. That is, the choice of the basic variables in the above

the subsequent rows are derived from the matrices  $(A|I)$  and  $b$ , i.e.,

$$\begin{array}{cccccc|c} -c_1 & \cdots & -c_n & 0 & 0 & \cdots & 0 & 0 \\ a_{11} & \cdots & a_{1n} & 1 & 0 & \cdots & 0 & b_1 \\ a_{21} & \cdots & a_{2n} & 0 & 1 & \cdots & 0 & b_2 \\ \vdots & & \vdots & \vdots & \vdots & \ddots & \vdots & \vdots \\ a_{m1} & \cdots & a_{mn} & 0 & 0 & \cdots & 1 & b_m \end{array}$$

In this initial tableau, there are  $m$  basic variables and  $n$  non-basic variables, a configuration that remains consistent throughout the process. Recall that a basic variable is one that can take non-zero values, whereas a non-basic variable is one that equals zero in the current solution of the problem. Basic variables correspond to the columns of the tableau, where exactly one entry is equal to one, and all other entries are zero. To initiate the algorithm, we choose all slack variables as basic variables. This is achieved by setting to zero the initial decision variables  $x_1, \dots, x_n$  in the equation  $\sum_{j=1}^n a_{ij}x_j + x_{n+i} = b_i$ , for all  $i$ . This initialization ensures an initial feasible solution, though not necessarily optimal.

For the guide example the initial tableau has the form

$$\begin{array}{c|cccccc|c} & x_1 & x_2 & x_3 & x_4 & x_5 & & \\ \hline R_0 & -h & -140 & -100 & 0 & 0 & 0 & 0 \\ R_1 & x_3 & 8 & 8 & 1 & 0 & 0 & 960 \\ R_2 & x_4 & \textcircled{4} & 2 & 0 & 1 & 0 & 400 \\ R_3 & x_5 & 4 & 3 & 0 & 0 & 1 & 420 \end{array}$$

where  $R_0, \dots, R_3$  denote the rows of the table. An initial feasible solution is given by  $x_1 = x_2 = 0$  and  $x_3 = 960$ ,  $x_4 = 400$ ,  $x_5 = 420$ . This satisfies  $h = 0$  and since we have negative values in  $R_0$ , a better solution exists.

*Step 2.* We now move in the iterated steps (compare the more theoretical explanation in 3.1.6).

(a) We locate the column with the most negative value in the first row of the tableau (locating the first column from the left having a non positive value also works). This column, which we assume here that is the  $j$ th column, is called the *work column*. For the guide example, the work column corresponds to the variable  $x_1$ , since  $-140 < -100$ .

(b) In the work column we pick up the positive entry  $a_{ij}$  in  $A$  which provides the minimal relation  $b_i/a_{ij}$ . If more than one element yields the same smallest ratio, we choose one. We call this entry the *pivot*. For our guide example, the pivot appears in row  $R_2$  circled (this is because  $400/4 < 420/4 < 960/8$ ).

(c) To configure the new tableau we proceed with the Gaussian method. Our goal is to eliminate the current work column, and determine the new pivot and the new basic variable (recall that within each iteration of the simplex method, exactly one variable goes from non-basic to basic and exactly one variable goes from basic to non-basic).

To illustrate this via the guide example, denote by  $\hat{R}_2 = (1, 1/2, 0, 1/4, 0, 100)$  the result of the row  $R_2$  divided by the pivot 4. The elementary row operations  $R_0 \rightarrow R_0 + 140\hat{R}_2$ ,

sense, describing an admissible solution. Next, we shall assume to have such a vertex already.

The idea of the algorithm is to perform equivalent row transformations of the entire system in such a way, that we move to other vertices of the region  $M$  and the function  $h$  increases. In order to move to more interesting vertices in  $M$ , we must bring some of the slack variables to zero while the appropriate column for the unit matrix would move to one of those columns corresponding to the variables  $x$ . A simple check reveals that in order to do this, we must choose some of the negative entries in the first row of the matrix 3.1.3(1), pick up this column and choose a row in such a way that using the Gaussian elimination to push the other entries in this particular column to zero, the right hand sides of the equations remain non-negative. The latter condition means that we have to choose the index  $i$  such that  $b_i/a_{ij}$  is minimal. This entry in the matrix is called the *pivot* for the next step in the elimination. Of course, the non-positive coefficients  $a_{ij}$  are not taken into consideration, since they would not lead to any increase in the objective function. When there are no more negative entries in the first row, we are finished, and the claim is that the optimal value of  $h$  appears in the right hand top corner of the matrix.

Before indicating the proof of all the above claims, we show how all this works for the simple problem from 3.F.1. In practice, the very first column of the matrix in question does not change during the procedure at all, so we can omit it completely. Thus we deal with the matrix tableaux:

$$\begin{array}{cc|cccc|c} -4 & -6 & 0 & 0 & 0 & 0 & 0 \\ \hline 1 & 2 & 1 & 0 & 0 & 0 & 120 \\ 1 & 4 & 0 & 1 & 0 & 0 & 180 \\ -1 & 1 & 0 & 0 & 1 & 0 & -90 \\ 1 & 0 & 0 & 0 & 0 & 1 & 110 \end{array}$$

We cannot find an admissible solution by fixing  $x_s$  as the basic variables here, since there are negative values in  $b$ . We try to initiate the above algorithm by changing the sign in the last but one row and performing the Gaussian elimination for the very first column aiming to have only the 1 in the last but one row there. We obtain:

$$\begin{array}{cc|cccc|c} 0 & -10 & 0 & 0 & -4 & 0 & 360 \\ \hline 0 & \textcircled{3} & \boxed{1} & 0 & 1 & 0 & 30 \\ 0 & 5 & 0 & \boxed{1} & 1 & 0 & 90 \\ \boxed{1} & -1 & 0 & 0 & -1 & 0 & 90 \\ 0 & 1 & 0 & 0 & 1 & \boxed{1} & 20 \end{array}$$

We choose the boxed entries for the basic variables, this represents the values  $x_1 = 90$ ,  $x_2 = 0$ ,  $x_3 = 30$ ,  $x_4 = 90$ ,  $x_5 = 0$ ,  $x_6 = 20$ , and  $h = 360 = 4 \cdot 90 = -4 \cdot (-90)$  which is an admissible solution. We have also circled the pivot for the next step, i.e. the element in the second column which we want to replace with 1 and eliminate the rest of the column (remember this is the one yielding the smallest ratio with the

$R_1 \rightarrow R_1 - 8\hat{R}_2$ , and  $R_3 \rightarrow R_3 - 4\hat{R}_2$  yield the second simplex tableau, given by

		$x_1$	$x_2$	$x_3$	$x_4$	$x_5$	
$\hat{R}_0$	$-h$	0	-30	0	35	0	14000
$\hat{R}_1$	$x_3$	0	4	1	-2	0	160
$\hat{R}_2$	$x_1$	1	1/2	0	1/4	0	100
$\hat{R}_3$	$x_5$	0	1	0	-1	1	20

The variable  $x_4$  is replaced by  $x_1$ , which becomes basic, and hence we moved it to the column of basic variables. Together with  $x_3, x_5$  they are now the new basic variables, and we have the solution  $x_1 = 100, x_2 = 0 = x_4, x_3 = 160, x_5 = 20$  (the values of the basic variables are read from the last column). Since there is still a negative number in  $\hat{R}_0$ , we proceed.

(d) We repeat steps (a), (b) and (c) and terminate the procedure when there are no more given entries in the first row.

For our example by the second tableau one deduces the new work column, that of  $x_2$ , and the new pivot, which is the circled number 1. Applying the elementary row operations  $\hat{R}_0 \rightarrow \hat{R}_0 + 30\hat{R}_3, \hat{R}_1 \rightarrow \hat{R}_1 - 4\hat{R}_3$ , and  $\hat{R}_2 \rightarrow \hat{R}_2 - \frac{1}{2}\hat{R}_3$  we arrive to the third tableau:

		$x_1$	$x_2$	$x_3$	$x_4$	$x_5$	
$-h$		0	0	0	5	30	14600
$x_3$		0	0	1	2	-4	80
$x_1$		1	0	0	3/4	-1/2	90
$x_2$		0	1	0	-1	1	20

The new basic variable is  $x_2$  and replaces  $x_5$ . So we have the solution  $x_1 = 90, x_2 = 20, x_3 = 80$  and  $x_4 = 0 = x_5$ . Since the above tableau is the final one, this solution is optimal and we may read the maximal value of  $h$  in the right top corner of the tableau, that is,  $h(90, 20) = 14600$ .

In the solution obtained above all the original variables are among the basic ones and so their values are non-zero. This is based on the assumption  $b \geq 0$ . The problem 3.F.1 presented in the final section of this chapter encodes the more general situation and its explanation via this simplex algorithm is given in 3.1.6.

**3.A.8. A note on duality.** By the theoretical discussion in 3.1.4 we know that when the primal LP problem is a maximization one, its *dual* is a minimization problem and conversely. The number of decision variables in a dual problem is the same as the number of less-than inequalities in the optimization primal problem, while the number of the constrains in the dual problem equals to the number of decision variables in the primal one. Note that when some constraint appears as an equality in the primal (maximization) problem, then the corresponding dual variable is unrestricted. The coefficients of the objective function of the primal problem form the right hand side of the constrains on the dual one, while the right hand side of the primal determines the objective function of the dual LP problem.

last right hand column entry among the positive elements  $-30/3 = 10$  which is less than  $90/5 = 16$  and  $20/1 = 20$ ). This leads to the next admissible vertex in our region  $M$  and, of course the value for  $h$  will increase:

		$x_1$	$x_2$	$x_3$	$x_4$	$x_5$		
		0	0	10/3	0	-2/3	0	460
		0	1	1/3	0	1/3	0	10
		0	0	-5/3	1	-2/3	0	40
		1	0	1/3	0	-2/3	0	100
		0	0	-1/3	0	2/3	1	10

with  $x_1 = 100, x_2 = 10, x_3 = x_5 = 0, x_4 = 40, x_6 = 10$ , and  $h = 460 = 4 \cdot 100 + 6 \cdot 10 = \frac{10}{3} \cdot 120 - \frac{2}{3} \cdot (-90)$ . We still have one of the entries in the first line negative. We circled the next pivot leading to

		$x_1$	$x_2$	$x_3$	$x_4$	$x_5$		
		0	0	9/3	0	0	1	470
		0	1	1/2	0	0	-1/2	5
		0	0	-2	1	0	1	50
		1	0	0	0	0	1	110
		0	0	-1/2	0	1	3/2	15

with the final values  $x_1 = 110, x_2 = 5, x_3 = 0, x_4 = 50, x_5 = 15, x_6 = 0$ , and

$$h = 470 = 4 \cdot 110 + 6 \cdot 5 = \frac{9}{3} \cdot 120 + 1 \cdot 110.$$

Let us remind why we can be sure that this is the optimal solution. Thanks to fact that the first line is exclusively non-negative, we have got admissible solution of the dual problem which leads to the same value as the solution of the original one. Thus the equilibrium theorem claims we are done!

**CORRECTNESS OF THE ALGORITHM.** Let us come back to the above claims in some detail. We should check whether the algorithm provides the right answer when it terminates, but we should also check under which conditions it terminates.

We start with the first part. The special feature of the above algorithm reshuffling the basic variables is that the slack variables parts of the matrix are closely linked to the dual linear programming problem. Moreover, there is an invariant of the entire procedure:

**Claim.** Writing  $(-\hat{c}, \hat{c}_s, \hat{h})$  for the current first line in the matrix and  $(\hat{x}, \hat{x}_s)$  for the current values of the variables, we obtain  $c \cdot \hat{x} = \hat{c}_s \cdot b = \hat{h}$  at each step.

In particular at the moment of the termination of the above algorithm, the coefficients  $y = \hat{c}_s$  in the first row represent admissible values of the dual problem (while the values  $\hat{c}$  stay for the slack variables in the dual problem), and the right hand top corner provides the value of the corresponding objective function  $y^T \cdot b$ . Since the two objective functions are equal, we know that the algorithm provides the optimal solution.

For our guide example the dual problem is the task of minimizing  $960y_1 + 400y_2 + 420y_3$  subject to

$$\begin{aligned} 8y_1 + 4y_2 + 4y_3 &\geq 140, \\ 8y_1 + 2y_2 + 3y_3 &\geq 100, \end{aligned}$$

with  $y_i \geq 0$  for all  $i = 1, 2, 3$ .

The final tableau of the primal problem also provides the solution of the dual one. According to the strong duality theorem (see 3.1.5), the minimal value is again 14600, while the corresponding values of the dual variables  $y_1, y_2$  and  $y_3$  are obtained by the first row in the corresponding final tableau, that is,  $y_1 = 0, y_2 = 5, y_3 = 30$ .

**3.A.9.** For the following LP problems, find their standard form and describe the corresponding dual problem.

(a) Maximize  $h = x_1 + 2.5x_2$  subject to

$$2x_1 + 3x_2 \leq 20, \quad x_1 + x_2 \geq -1, \quad x_1 - 2x_2 = 1,$$

with  $x_1 \geq 0, x_2 \geq 0$ .

(b) Minimize  $h = 2x_1 + 3x_2 + 2x_4$  subject to

$$x_1 + 2x_2 + 2x_3 \leq -6, \quad x_1 + 4x_2 - 2x_4 = 5, \quad x_2 - x_3 + 4x_4 \geq 2,$$

with  $x_i \geq 0$  for all  $i = 1, \dots, 4$ . ○

**3.A.10. LP problems with redundant constraints.** Use the simplex method to solve the LP problem of maximizing the linear function  $h = 4x_1 + 9x_2$  subject to the conditions

$$x_1 + 4x_2 \leq 8, \quad x_1 + 2x_2 \leq 4, \quad x_1 \geq 0, \quad x_2 \geq 0.$$

**Solution.** The corresponding feasible region is the grey region in the figure below, and as we see the first constraint is redundant. The evaluation of  $h$  at the three corners of this triangle shows that  $h$  maximizes at  $(x_1 = 0, x_2 = 2)$ . We want to verify this result by the simplex method.

The canonical form of the problem is the following: maximize  $h = 4x_1 + 9x_2 + 0x_3 + 0x_4$  subject to

$$\begin{aligned} x_1 + 4x_2 + x_3 &= 8, \\ x_1 + 2x_2 + x_4 &= 4, \end{aligned}$$

with  $x_i \geq 0$  for  $i = 1, \dots, 4$ . The variables  $x_3, x_4$  are the slacks and we begin with the first simplex tableau:

		$x_1$	$x_2$	$x_3$	$x_4$	
$R_0$	$-h$	-4	-9	0	0	0
$R_1$	$x_3$	1	4	1	0	8
$R_2$	$x_4$	1	2	0	1	4

The work column is the column of  $x_2$  and as pivot one may fix the circled number 4. To eliminate the work column replace  $R_1$  by  $\hat{R}_1 := \frac{1}{4}R_1$  and apply the row operations  $R_0 \rightarrow R_0 + 9\hat{R}_1$  and  $R_2 \rightarrow R_2 - 2\hat{R}_1$ . This enters the variable  $x_2$  to the

**PROOF OF THE CLAIM.** As we know, the Gaussian elimination can be expressed as multiplication by a suitable transition matrix  $T$  from the left. Our “pivoting” corresponds always to a (block wise) matrix

$$T = \begin{pmatrix} 1 & y^T \\ 0 & R \end{pmatrix},$$

with an invertible matrix  $R$ . Thus (dealing with the standard problem)

$$T \cdot \begin{pmatrix} 1 & -c & 0 & 0 \\ 0 & A & E_m & 0 \end{pmatrix} = \begin{pmatrix} 1 & -c + y^T A & y^T & y^T b \\ 0 & RA & R & Rb \end{pmatrix}$$

and the second row corresponds (since  $R$  is invertible) to the equality  $A\hat{x} + \hat{x}_s = b$ . Consequently, we arrive at

$$-\hat{c}\hat{x} = (-c + y^T A)\hat{x} = -c\hat{x} + y^T(b - \hat{x}_s).$$

Now, notice the components  $\hat{x}_s$  vanish whenever the corresponding components of  $y^T \neq 0$ , i.e.,  $y^T \hat{x}_s = 0$ . Similarly,  $\hat{c}\hat{x} = 0$  and so we read from the latter displayed equality  $\hat{c}\hat{x} = y^T b$ , as claimed. □

The termination of the algorithm is a more subtle question. While it terminates nearly always, it might happen that the algorithm cycles without enlarging the objective function. We shall not go into more details here, a simple example is given in ??.

Put a cycling simple example to the practice column, maybe in the end of the chapter. □

**3.1.7. Notes about linear models in economy.** Our simple scheme of the black&white painter from the paragraph 3.1.1 can be used to illustrate one of the typical economical models, the *model of production planning*. The model tries to capture the problem completely, that is, to capture both external and internal relations. The left-hand sides of the equations (1), (2), (3) in 3.1.1, and the objective function  $h(x_1, x_2)$  express various production relations. Depending on the character of the problem, we have on the right-hand sides either exact values (and so we solve equations) or capacity constraints and goal optimization (then we obtain linear programming problems).

Thus in general we can solve the problem of source allocation with supplier constraints and either minimize costs or maximize income.

Among economical models, we can find many modifications. One of them is the problem of *financial planning*, which is connected to the optimization of portfolio. We are setting up a volume of investment into individual investment possibilities with the goal to meet the given constraints for risk factors while maximizing the profit, or dually minimize the risk under the given volume.

Another common model is *marketing application*, for instance allocation of costs for advertisement in various media or placing advertisement into time intervals. Restrictions are in this case determined by budget, target population, etc.

Very common are models of *nutrition*, that is, setting up how much of different kinds of food should be eaten in order to meet total volume of specific components, e.g. minerals and vitamins.

column of basic variables, while  $x_3$  leaves. Thus the second simplex tableau has the form

		$x_1$	$x_2$	$x_3$	$x_4$	
$\hat{R}_0$	$-h$	$-5/4$	$0$	$9/4$	$0$	$18$
$\hat{R}_1$	$x_2$	$1/4$	$1$	$1/4$	$0$	$2$
$\hat{R}_2$	$x_4$	$1/2$	$0$	$-1/2$	$1$	$0$

We observe that in this table the basic variable  $x_4$  takes the zero value, and this means that there exists a redundant constraint. Such a basic feasible solution with at least one basic variable equal to zero is called *degenerate*. Now, the column of  $x_1$  is the new driver and the new pivot is the circled  $1/2$ . We replace  $\hat{R}_2$  by  $\check{R}_2 := 2\hat{R}_2$  and apply the row operations  $\hat{R}_1 \rightarrow \hat{R}_1 - \frac{1}{4}\check{R}_2$  and  $\hat{R}_0 \rightarrow \hat{R}_0 + \frac{5}{4}\check{R}_2$ . Thus  $x_1$  enters the column of basic variables,  $x_4$  leaves and the final tableau is given by

		$x_1$	$x_2$	$x_3$	$x_4$	
$\check{R}_0$	$-h$	$0$	$0$	$1$	$5/2$	$18$
$\check{R}_1$	$x_2$	$0$	$1$	$1/2$	$-1/2$	$2$
$\check{R}_2$	$x_1$	$1$	$0$	$-1$	$2$	$0$

This gives us the optimal solution ( $x_2 = 2, x_1 = 0$ ), which is degenerate, with the optimal value of the objective function being  $h = 18$ .  $\square$

**3.A.11. Cycling.** Observe that during the second iteration above, the value of the given  $h$  did *not* increase. When a sequence of iterations returns to a previously constructed tableau, we say that the simplex method *cycles*. In this case the method enters a loop, without improving the objective function value, see also the end of section 3.1.6 Cycling can occur only in the presence of degeneracy. However, there are many LP problems that are degenerate and do *not* cycle (as above). Examples of LP problems for which the simplex method cycles are in general difficult to construct, and rare in practice. We describe such an example in Section 3.F.5, where also a remedy to this pitfall is presented.

Numerous software packages are available to handle the simplex method and solve linear programming problems via a computer. As it is customary in our book, next we will use Sage to implement the tasks at hand.

**3.A.12. LP treated by Sage.** In Sage, for handling linear programming problems, one can utilize the mixed integer linear programming (MILP) package. Next, we will demonstrate the procedure using our guide example from section 3.A.7. Let us summarize the main steps:

1. We initialize the linear programming algorithm:

```
p = MixedIntegerLinearProgram()
```

2. We introduce the non-negative decision variables:

```
v = p.new_variable(real=True,
nonnegative=True)
```

Problems of linear programming arise with personal tasks, where workers with specific qualifications and other properties are distributed into working shifts. Common are also problems of *merging*, problems of *splitting* and problems of *goods distribution*.

## 2. Difference equations

We have already met difference equations in the first chapter, albeit briefly and of first order only. Now we consider a more general theory for linear equations with constant coefficients. This not only provides very practical tools but also represents a good illustration for the concepts of vector spaces and linear mappings.

### HOMOGENEOUS LINEAR DIFFERENCE EQUATION OF ORDER $k$

**3.2.1. Definition.** A homogeneous linear difference equation (or homogeneous linear recurrence) of order  $k$  is given by the expression

$$a_0x_n + a_1x_{n-1} + \dots + a_kx_{n-k} = 0, \quad a_0 \neq 0, \quad a_k \neq 0,$$

where the coefficients  $a_i$  are scalars, which can possibly depend on  $n$ .

A solution of this equation is a sequence of scalars  $x_i$ , for all  $i \in \mathbb{N}$  (or  $i \in \mathbb{Z}$ ), which satisfy the equation with any  $n$ .

We often understand the sequence in question as a function

$$x_n = f(n) = -\frac{a_1}{a_0}f(n-1) - \dots - \frac{a_k}{a_0}f(n-k).$$

By giving any  $k$  consecutive values  $x_i$  in the sequence, all other values of  $x_i$  are determined uniquely. Indeed, we work over a field of scalars, thus the values  $a_0$  and  $a_k$  are invertible and hence, using the recurrent definition, any  $x_n$  can be computed uniquely from the preceding  $k$  values, and similarly for  $x_{n-k}$ . Induction thus immediately proves that all remaining values are uniquely determined.

The space of all infinite sequences  $x_i$  forms a vector space, where addition and multiplication by scalars work coordinate-wise. The definition immediately implies that a sum of two solutions of a homogeneous linear difference equation or a multiple of a solution is again a solution. Analogously as with homogeneous linear systems we see that the set of all solutions forms a subspace.

Initial conditions on the values  $x_0, \dots, x_{k-1}$  of the solution represent a  $k$ -dimensional vector in  $\mathbb{K}^k$ . The sum of initial conditions determines the sum of the corresponding solutions, similarly for scalar multiples. Note also that substituting zeros and ones into initial  $k$  values immediately yields  $k$  linearly independent solutions of the difference equation. Thus, although the vectors are infinite sequences, the set of all solutions has finite dimension. The dimension equals the order of the equation  $k$ . Moreover, we can easily obtain a basis of all those solutions. Again we speak of the *fundamental*

For the guide example there are two decision variables and to introduce them one should additionally type

```
x1, x2 = v["x1"], v["x2"]
```

3. We set the objective function by typing

```
p.set_objective(140*x1 + 100*x2)
```

4. Next we set the constraints. For the guide example this can be done as follows:

```
p.add_constraint(8*x1 + 8*x2 <= 960)
p.add_constraint(4*x1 + 2*x2 <= 400)
p.add_constraint(4*x1 + 3*x2 <= 420)
```

5. If  $k$  is the maximum of the objective function, let the program know about this by typing

```
k = p.solve()
```

Since  $x_1, x_2$  are the coordinates of the solution, we should also include the code

```
x1, x2 = p.get_values(x1, x2)
```

6. Finally, to get the output we write

```
print("Answer =", round(k, 2))
print("(x1, x2) =", (x1, x2))
```

and Sage prints out the following answer:

```
Answer = 14600.0
(x1, x2) = 90.0 20.0
```

Let us summarize the code all together, without interruptions.

```
p = MixedIntegerLinearProgram()
v = p.new_variable(real=True,
nonnegative=True)
x1, x2 = v["x1"], v["x2"]
p.set_objective(140*x1 + 100*x2)
p.add_constraint(8*x1 + 8*x2 <= 960)
p.add_constraint(4*x1 + 2*x2 <= 400)
p.add_constraint(4*x1 + 3*x2 <= 420)
k = p.solve()
x1, x2 = p.get_values(x1, x2)
print("Answer =", round(k, 2))
print("(x1, x2) =", (x1, x2))
```

Similarly can be treated problems with more decision variables. For instance, if you need three variables give the cell

```
v = p.new_variable(real=True,
nonnegative=True)
x1, x2, x3 = v["x1"], v["x2"], v["x3"]
```

Further tasks in linear programming and applications of Sage are described in section F. It is noteworthy that an elegant application of linear programming involves game theory. In 3.F.6 we shall explore an application in this direction concerning zero-sum games, also known as “matrix games”. In these games, the interests of the two players are directly opposed, meaning one player’s loss is the other player’s gain. The term “zero-sum” indicates that the sum of the payoffs for both players always equals zero, regardless of the game’s outcome. As detailed in

system of solutions and all other solutions are its linear combinations.

As we have just checked, if we choose  $k$  indices  $i, i + 1, \dots, i + k - 1$  in sequence, the homogeneous linear difference equation gives a linear mapping  $\mathbb{K}^k \rightarrow \mathbb{K}^\infty$  of  $k$ -dimensional vectors of initial values into infinitely-dimensional sequences of the same scalars. The independence of such solutions is equivalent to the independence of the initial values – which can be easily checked by a determinant: If we have a  $k$ -tuple of solutions  $(x_n^{[1]}, \dots, x_n^{[k]})$ , it is independent if and only if the following determinant, sometimes called the *Casoratian*, is non-zero for one  $n$

$$C_n = \begin{vmatrix} x_n^{[1]} & \cdots & x_n^{[k]} \\ x_{n+1}^{[1]} & \cdots & x_{n+1}^{[k]} \\ \vdots & \ddots & \vdots \\ x_{n+k-1}^{[1]} & \cdots & x_{n+k-1}^{[k]} \end{vmatrix} \neq 0.$$

Notice the determinant  $C_{n+1}$  is obtained from  $C_n$  by replacing the first row in  $C_n$  by the last row in  $C_{n+1}$  expressed as the linear combination of the rows in  $C_n$  given by the difference equation and then putting the first row to position of the last one. Thus  $C_{n+1} = (-1)^k \frac{a_0}{a_k} C_n$ , with values  $a_0, a_k$  corresponding to  $n+k$ . In particular, linearly independent initial conditions lead to independent  $k$ -dimensional vectors for all consecutive  $k$  components of the solution.

**3.2.2. Recurrences with constant coefficients.** It is difficult to find a universal mechanism for finding a solution (that is, a directly computable expression) of general homogeneous linear difference equations. We shall come back to this problem in the end of chapter 13.

In practical models there are very often equations, where the coefficients are constant. In this case it is possible to guess a suitable form for the solution and indeed to find  $k$  linearly independent solutions. This would then be a complete solution of the problem, since all other solutions would be linear combinations of them.

For simplicity we start with equations of second order. Such recurrences are very often encountered in practical problems, where there are relations based on two previous values. A linear difference equation (recurrence) of second order with constant coefficients is thus a formula

$$(1) \quad f(n+2) = a f(n+1) + b f(n) + c,$$

where  $a, b, c$  are known scalar coefficients.

Consider a population model. We assume that the individuals in a population mature and start breeding two seasons later (that is, they add to the value  $f(n+2)$  by a multiple  $b f(n)$  with positive  $b > 1$ ), while immature individuals at the same time weaken and destroy part of the mature population (that is, the coefficient  $a$  at  $f(n+1)$  is negative). Furthermore, it might be that somebody destroys (uses, eats) a fixed amount  $-c$  of individuals every season.

3.F.6, such problems can be effectively addressed using stochastic matrices.

### B. Recurrence relations

 A recurrence relation for a given sequence defines a relationship among its terms, often useful for modeling recurring patterns or behaviours. Such relations are particularly valuable in scenarios where recursive nature is observed repeatedly. For instance, they serve as a powerful tool for describing growth models.

Without doubt, the simplest recurrence relations are the “homogeneous linear recurrence relations” (with constant coefficients), expressed as:

$$x_{n+k} = \alpha_1 x_{n+k-1} + \alpha_2 x_{n+k-2} + \dots + \alpha_k x_n,$$

where  $\alpha_i$  are complex numbers with  $\alpha_k \neq 0$ . The number  $k$  is called the order of the recurrence relation, see also the Section 3.2.1 for details. When the right-hand side includes a constant term, we get the notion of a “non-homogeneous linear recurrence relations” (with constant coefficients).

We begin with a well-known example of a second-order homogeneous linear recurrence relation, historically used to model populations of rabbits.

#### 3.B.1. Rabbits and the Fibonacci sequence.

 Consider a scenario where, at the start of spring, a stork brings two newborn rabbits, one male and one female, to a meadow. Each female rabbit becomes fertile at two months old and gives birth to a pair of newborns, one male and one female, every month thereafter. Specifically, each female is pregnant for one month before producing new offsprings. How many pairs of rabbits will be present after nine months, assuming no deaths and that none “move in”?

**Solution.** After the first month, there is still only one pair of rabbits, but the female is already pregnant. By the end of the second month, the first offspring are born, resulting in two pairs. Each subsequent month, the number of new pairs matches the number of pregnant females from the previous month. This corresponds to the number of at least one month old pairs, which coincides with the number of pairs that were there two months ago.

Let us denote by  $F_n$  the total number of pairs after  $n$  months. According to the explanation given above, for the first months we compute

$$F_1 = 1, F_2 = 1, F_3 = F_2 + F_1 = 2, F_4 = F_3 + F_2 = 3, F_5 = F_4 + F_3 = 5, F_6 = F_5 + F_4 = 8, \dots$$

Hence  $F_n$  should be equal to the sum of the number of pairs in the previous two months, and this is described by the following homogeneous linear recurrence relation:

$$F_{n+2} = F_{n+1} + F_n, \quad n = 1, 2, \dots$$

A similar situation with  $c = 0$  and both other coefficients positive determines the famous Fibonacci sequence of numbers  $y_0, y_1, \dots$ , where  $y_{n+2} = y_{n+1} + y_n$ , see 3.B.1.

If we have no idea how to solve a mathematical problem, we can always blindly try some known solutions of similar problems. Thus, let us substitute into the equation (1) with coefficient  $c = 0$  a similar solution as with the linear equations from the first chapter (cf. 1.2.1), that is, we try  $f(n) = \lambda^n$  for some scalar  $\lambda$ . By substitution into the equation we obtain

$$\lambda^{n+2} - a\lambda^{n+1} - b\lambda^n = \lambda^n(\lambda^2 - a\lambda - b) = 0.$$

This relation will hold either for  $\lambda = 0$  or for the choice of the values

$$\lambda_1 = \frac{1}{2}(a + \sqrt{a^2 + 4b}), \quad \lambda_2 = \frac{1}{2}(a - \sqrt{a^2 + 4b}).$$

It is easy to see that such solutions work. We just had to choose the scalar  $\lambda$  suitably. But we are not finished, since we want to find a solution for any two initial values  $f(0)$  and  $f(1)$ . So far, we have only found two specific sequences satisfying the given equation (or possibly even only one sequence if  $\lambda_2 = \lambda_1$ ).

As we have already derived for linear recurrences, the sum of two solutions  $f_1(n)$  and  $f_2(n)$  of our equation  $f(n+2) - a f(n+1) - b f(n) = 0$  is again a solution of the same equation. The same holds for scalar multiples of the solution. Our two specific solutions thus generate the more general solutions

$$f(n) = C_1 \lambda_1^n + C_2 \lambda_2^n$$

for arbitrary scalars  $C_1$  and  $C_2$ . For a unique solution of the specific problem with given initial values  $f(0)$  and  $f(1)$ , it remains only to find the corresponding scalars  $C_1$  and  $C_2$ .

**3.2.3. The choice of scalars.** We show how this can work with an example. Consider the problem:

$$(1) \quad y_{n+2} = y_{n+1} + \frac{1}{2}y_n, \quad y_0 = 2, y_1 = 0.$$

Here  $\lambda_{1,2} = \frac{1}{2}(1 \pm \sqrt{3})$  and clearly

$$y_0 = C_1 + C_2 = 2$$

$$y_1 = \frac{1}{2}C_1(1 + \sqrt{3}) + \frac{1}{2}C_2(1 - \sqrt{3})$$

is satisfied for exactly one choice of these constants. Direct calculation yields  $C_1 = 1 - \frac{1}{3}\sqrt{3}$ ,  $C_2 = 1 + \frac{1}{3}\sqrt{3}$  and our problem has unique solution

$$f(n) = (1 - \frac{1}{3}\sqrt{3})\frac{1}{2^n}(1 + \sqrt{3})^n + (1 + \frac{1}{3}\sqrt{3})\frac{1}{2^n}(1 - \sqrt{3})^n.$$

Note that even if the found solution for our equation with rational coefficients and rational initial values looks complicated and is expressed with irrational numbers, we know a priori that the solution itself is again rational. But without this “step aside” into a larger field of scalars, we would not be able to describe the general solution.

This relation, along with the initial conditions  $F_1 = 1$  and  $F_2 = 1$ , uniquely determines the number of pairs of rabbits at the meadow, in individual months.

Observe that for certain  $r$  the function  $r^n$  is a solution of the difference equation (without initial conditions). This  $r$  can be obtained by substitution into the recurrent relation:  $r^{n+2} = r^{n+1} + r^n$  and after dividing by  $r^n$  we obtain  $r^2 = r + 1$ . This is the *characteristic equation* of the given recurrent formula, and the numbers  $\frac{1-\sqrt{5}}{2}$  and  $\frac{1+\sqrt{5}}{2}$  are its roots.<sup>3</sup> Thus, according to the theory in 3.2.4, the solution of the given recurrent relation will be a sequence of the form

$$F_n = ax_n + by_n,$$

with  $x_n := (\frac{1-\sqrt{5}}{2})^n$ ,  $y_n := (\frac{1+\sqrt{5}}{2})^n$ , and  $a, b \in \mathbb{R}$  to be specified. To compute the constants  $a, b$ , we use the initial conditions. Alternatively, we can set  $F_0 = 0$  and compute  $a$  and  $b$  from the equations for  $F_0$  and  $F_1$ . We find  $a = -\frac{1}{\sqrt{5}}$ ,  $b = \frac{1}{\sqrt{5}}$  and hence the solution is given by

$$F_n = \frac{1}{\sqrt{5}}(y_n - x_n) = \frac{(1 + \sqrt{5})^n - (1 - \sqrt{5})^n}{2^n(\sqrt{5})}.$$

Although the Fibonacci sequence looks like a sequence of irrational numbers, the value of  $F_n$  is actually an integer for any natural  $n$ . Hence, all terms in the Fibonacci sequence are integers, as the term  $F_9$ , which gives the answer.  $\square$

*We proceed with additional exercises related to second-order linear homogeneous difference equations with constant coefficients.*

**3.B.2.** Find the next two terms of the sequence  $(a_n)_{n \geq 0}$  beginning as follows:

$$3, 5, 11, 21, 43, 85, \dots$$

by providing a recursive definition of  $a_n$ . Next solve the corresponding recurrence relation.

**Solution.** Set  $a_0 = 3$  and  $a_1 = 5$ . We see that the terms under question are  $a_6 = 171$  and  $a_7 = 341$ . Indeed, observe that  $a_2 = a_1 + 2a_0$ ,  $a_3 = 2a_2 + a_1$ , and so on. Thus the sequence  $a_n$  satisfies  $a_n = a_{n-1} + 2a_{n-2}$  for  $n = 0, 1, \dots$ , and this is the recurrence formula we are seeking for. The corresponding characteristic equation is the quadratic equation  $r^2 - r - 2 = 0$ , with roots the real numbers 2 and  $-1$ . Thus, the general solution has the form  $a_n = a2^n + b(-1)^n$ , with  $a, b \in \mathbb{R}$  to be computed. By the initial conditions we obtain the system  $\{3 = a + b, 5 = 2a - b\}$ , so  $a = 8/3$ ,  $b = 1/3$  and  $a_n = \frac{8}{3}2^n + \frac{1}{3}(-1)^n$ .  $\square$

<sup>3</sup>The number  $\frac{1+\sqrt{5}}{2}$  is called the *golden ratio* and has fascinated mathematicians since Pythagoras (570 – 495 B.C.).

We will often meet similar phenomena. Moreover, the general solution often allows us to discuss qualitative behaviour of the sequence of numbers  $f(n)$  without direct enumeration of the constants. For example, we may see whether the values approach some fixed value with increasing  $n$  or oscillate in some interval or whether they are unbounded.

**3.2.4. General homogeneous recurrences.** We substitute  $x_n = \lambda^n$  for some (yet unknown) scalar  $\lambda$  into the general homogeneous equation from the definition 3.2.1 (with constant coefficients). For every  $n$  we obtain the condition

$$\lambda^{n-k}(a_0\lambda^k + a_1\lambda^{k-1} \dots + a_k) = 0.$$

This means that either  $\lambda = 0$  or  $\lambda$  is the root of the so-called *characteristic polynomial* in the parentheses. The characteristic polynomial is independent of  $n$ .

Assume that the characteristic polynomial has  $k$  distinct roots  $\lambda_1, \dots, \lambda_k$ . For this purpose, we can extend the field of scalars we are working in, for instance  $\mathbb{Q}$  into  $\mathbb{R}$  or  $\mathbb{C}$ . Of course, if the initial conditions are in the original field then the solutions stay there since the recurrence equation itself does. Each of the roots gives us single possible solution

$$x_n = (\lambda_i)^n.$$

We need  $k$  linearly independent solutions.

Thus we should check the independence by substituting  $k$  values for  $n = 0, \dots, k - 1$  for  $k$  choices of  $\lambda_i$  into the Casoratian (see 3.2.1). Thus we obtain the Vandermonde matrix. It is a good but not entirely trivial exercise to show that for every  $k$  and any  $k$ -tuple of distinct  $\lambda_i$  the determinant of such a matrix non-zero, see 2.E.21 on the page 151. It follows that the chosen solutions are linearly independent.

Thus we have found the fundamental system of solutions of the homogeneous difference equation in the case that all the (possibly complex) roots of its characteristic polynomial are distinct.

Now we suppose  $\lambda$  is a multiple root. We ask whether  $x_n = n\lambda^n$  could be a solution. We arrive at the condition

$$a_0n\lambda^n + \dots + a_k(n - k)\lambda^{n-k} = 0.$$

This condition can be rewritten as

$$\lambda(a_0\lambda^n + \dots + a_k\lambda^{n-k})' = 0$$

where the dash denotes differentiation with respect to  $\lambda$  (cf. the infinitesimal definition in 5.1.6, and 12.3.7 for the purely algebraic treatment).

Moreover, a root  $c$  of a polynomial  $f$  has multiplicity greater than one if and only if it is a root of  $f'$ , see 12.3.7 for the proof. Our condition is thus satisfied.

With greater multiplicity  $\ell$  of the root of the characteristic polynomial we can proceed similarly and use the (now obvious) fact that a root with multiplicity  $\ell$  is a root of all derivatives of the polynomial up to order  $\ell - 1$  (inclusively).

**3.B.3.** Find the solution of the recurrence relation  $x_n = 6x_{n-1} - 9x_{n-2}$  with initial conditions  $x_0 = 2$ ,  $x_1 = 3$ . Additionally, validate your answer using Sage.

**Solution.** The characteristic equation has the form

$$r^2 - 6r + 9 = 0 \iff (r - 3)^2 = 0.$$

Hence  $r = 3$  is the unique (double) root. Thus, according to the theory in 3.2.4, the general solution must be of the form

$$x_n = a3^n + bn3^n,$$

for some  $a, b \in \mathbb{R}$  to be computed. Based on the initial conditions  $x_0 = 2$  and  $x_1 = 3$  we obtain  $a = 2$  and  $b = -1$ . Thus we deduce that  $x_n = 2 \cdot 3^n - n3^n = 3^n(2 - n)$ .

Sage provides a user-friendly package for handling recurrence relations. One useful function available is the `rsolve`, from the pure Python package `sympy`, designed for symbolic computations. This function can effectively handle linear recurrence relations. To begin, we typically start by entering the following cell:

```
from sympy import Function, rsolve
from sympy.abc import n
a = Function("a")
```

The next step is to input the recurrence relation that we want to solve, along with its initial conditions:

```
f = a(n) - 6*a(n-1) + 9*a(n-2)
initial = {a(0):2, a(1):3}
```

Now we can obtain the solution, by adding the syntax

```
rsolve(f, a(n), initial).expand()
```

Sage prints out the answer  $-3 * n * n + 2 * 3 * n$ . Let us summarize all the code together:

```
from sympy import Function, rsolve
from sympy.abc import n
a = Function("a")
f = a(n) - 6*a(n-1) + 9*a(n-2)
initial = {a(0):2, a(1):3}
rsolve(f, a(n), initial).expand()
```

□

**3.B.4.** Determine an explicit expression of the sequence satisfying the difference equation  $x_{n+2} = 3x_{n+1} + 3x_n$  with members  $x_1 = 1$  and  $x_2 = 3$ . Next verify your answer using Sage.

*Note that characteristic polynomial of a homogeneous difference equation may have complex roots. Therefore, when solving recurrence relations, we may encounter situations involving complex numbers. This requires transitioning from complex bases in the solution space to real ones, as discussed in Section 3.2.5. Let us explore such an example.*

Derivatives look like this:

$$\begin{aligned} f(\lambda) &= a_0\lambda^n + \dots + a_k\lambda^{n-k} \\ f'(\lambda) &= a_0n\lambda^{n-1} + \dots + a_k(n-k)\lambda^{n-k-1} \\ f''(\lambda) &= a_0n(n-1)\lambda^{n-2} + \dots + a_k(n-k)(n-k-1)\lambda^{n-k-2} \\ &\vdots \\ f^{(\ell)} &= a_0n \dots (n-\ell+1)\lambda^{n-\ell} + \dots \\ &\quad + a_k(n-k) \dots (n-k-\ell+1)\lambda^{n-k-\ell}. \end{aligned}$$

We look at the case of a triple root  $\lambda$  and try to find a solution in the form  $n^2\lambda^n$ . By substitution into the definition, we obtain the equation

$$a_0n^2\lambda^n + \dots + a_k(n-k)^2\lambda^{n-k} = 0.$$

Clearly the left side equals the expression  $\lambda^2 f''(\lambda) + \lambda f'(\lambda)$  and because  $\lambda$  is a root of both derivatives, the condition is satisfied.

Using induction, we prove that even for the general condition of the solution in the form  $x_n = n^\ell \lambda^n$ ,

$$a_0n^\ell \lambda^n + \dots + a_k(n-k)^\ell \lambda^{n-k} = 0,$$

the solution can be obtained as a linear combination of the derivatives of the characteristic polynomial starting with the expression (check the combinatorics!)

$$\lambda^\ell f^{(\ell)} + \binom{\ell}{2} \lambda^{\ell-1} f^{(\ell-1)} + \dots$$

We have thus come close to the complete proof of the following result:

HOMOGENOUS EQUATIONS WITH CONSTANT COEFFICIENTS

**Theorem.** *The solution space of a homogeneous linear difference equation of order  $k$  with constant coefficients, over the field of scalars  $\mathbb{K} = \mathbb{C}$ , is the  $k$ -dimensional vector space generated by the sequences  $x_n = n^\ell \lambda^n$ , where  $\lambda$  are (complex) roots of the characteristic polynomial and the powers  $\ell$  run over all natural numbers  $0, \dots, r_\lambda - 1$ , where  $r_\lambda$  is the multiplicity of the root  $\lambda$ .*

**PROOF.** The relation between the multiplicity of roots and the derivatives of real polynomials will be proved later (cf. 5.3.7), while the fact that every complex polynomial has exactly as many roots (counting multiplicities) as its degree will appear in 10.2.11. It remains to prove that the  $k$ -tuple of solutions thus found is linearly independent. Even in this case we can prove inductively that the corresponding Casoratian is non-zero. We have done this already in the case of the Vandermonde determinant before.

This approach is well illustrated by the calculation in the case of a root  $\lambda_1$  with multiplicity one and a root  $\lambda_2$  with

**3.B.5. Complex bases versus real bases.** Determine the solution of the difference equation  $x_{n+2} = 2x_{n+1} - 2x_n$ , with initial values  $x_1 = 2 = x_2$ . Moreover, express your solution in terms of a real basis corresponding to the associated solution space.

**Solution.** The roots of the characteristic polynomial  $r^2 - 2r + 2$  are the complex numbers  $1 + i$  and  $1 - i$ . Hence the sequences  $y_n = (1 + i)^n$  and  $z_n = (1 - i)^n$  form a basis of the (complex) vector space of solutions, see also the main theorem in 3.2.4. In particular, a general solution is given as a linear combination of  $y_n, z_n$  (with complex coefficients), that is,  $x_n = ay_n + bz_n$ , where  $a = a_1 + ia_2, b = b_1 + ib_2$ , with  $a_j, b_j \in \mathbb{R}$  for any  $j = 1, 2$ . The initial conditions will guide us to choose these scalars. They yield the following system of equations

$$1 = a_1 + ia_2 + b_1 + ib_2, \quad 2 = (a_1 + ia_2)(1 + i) + (b_1 + ib_2)(1 - i)$$

and by comparing the real and the complex part of both equations, we finally result to a system of four equations with four unknowns:  $a_1 + b_1 = 1, a_2 + b_2 = 0, a_1 - a_2 + b_1 + b_2 = 2$  and  $a_1 + a_2 - b_1 + b_2 = 0$ . We compute  $a_1 = b_1 = b_2 = \frac{1}{2}, a_2 = -1/2$ , and thus the sequence in question attains the following form:

$$x_n = \left(\frac{1}{2} - \frac{1}{2}i\right)(1 + i)^n + \left(\frac{1}{2} + \frac{1}{2}i\right)(1 - i)^n.$$

If we want to verify our solution via Sage, we may proceed as before, that is,

```
from sympy import Function, rsolve
from sympy.abc import n
a = Function("a")
f = a(n+2) - 2*a(n+1) + 2*a(n)
initial = {a(1):2, a(2):2}
rsolve(f, a(n), initial)
```

Sage's answer has the form

$$\left(\frac{1}{2} + \frac{1}{2}i\right)(1 - i)^n + \left(\frac{1}{2} - \frac{1}{2}i\right)(1 + i)^n$$

For the final task we use the sequences

$$u_n = \frac{1}{2}(y_n + z_n) = (\sqrt{2})^n \cos\left(\frac{n\pi}{4}\right),$$

$$v_n = \frac{i}{2}(z_n - y_n) = (\sqrt{2})^n \sin\left(\frac{n\pi}{4}\right).$$

Note that the transition matrix for changing the basis from the complex one to the real one, is given by  $T := \begin{pmatrix} \frac{1}{2} & -\frac{1}{2}i \\ \frac{1}{2} & \frac{1}{2}i \end{pmatrix}$ , with  $T^{-1} = \begin{pmatrix} 1 & 1 \\ i & -i \end{pmatrix}$ . Therefore, if  $(c, d)$  are the coordinates of the sequence  $x_n$ , then under the basis  $\{u_n, v_n\}$  we have

$$\begin{pmatrix} c \\ d \end{pmatrix} = T^{-1} \begin{pmatrix} a \\ b \end{pmatrix} = \begin{pmatrix} 1 \\ 1 \end{pmatrix}.$$

Thus, we now have an alternative expression for the sequence  $x_n$ , which involves square roots instead of complex numbers:  $x_n = (\sqrt{2})^n \cos\left(\frac{n\pi}{4}\right) + (\sqrt{2})^n \sin\left(\frac{n\pi}{4}\right)$ .  $\square$

multiplicity two:

$$\begin{aligned} C(\lambda_1^n, \lambda_2^n, n\lambda_2^n) &= \begin{vmatrix} \lambda_1^n & \lambda_2^n & n\lambda_2^n \\ \lambda_1^{n+1} & \lambda_2^{n+1} & (n+1)\lambda_2^{n+1} \\ \lambda_1^{n+2} & \lambda_2^{n+2} & (n+2)\lambda_2^{n+2} \end{vmatrix} \\ &= \lambda_1^n \lambda_2^{2n} \begin{vmatrix} 1 & 1 & n \\ \lambda_1 & \lambda_2 & (n+1)\lambda_2 \\ \lambda_1^2 & \lambda_2^2 & (n+2)\lambda_2^2 \end{vmatrix} \\ &= \lambda_1^n \lambda_2^{2n} \begin{vmatrix} 1 & 1 & n \\ \lambda_1 - \lambda_2 & 0 & \lambda_2 \\ \lambda_1(\lambda_1 - \lambda_2) & 0 & \lambda_2^2 \end{vmatrix} \\ &= -\lambda_1^n \lambda_2^{2n} \begin{vmatrix} \lambda_1 - \lambda_2 & \lambda_2 \\ \lambda_1(\lambda_1 - \lambda_2) & \lambda_2^2 \end{vmatrix} \\ &= \lambda_1^n \lambda_2^{2n+1} (\lambda_1 - \lambda_2)^2 \neq 0. \end{aligned}$$

In the general case the proof can be carried on inductively in a similar way.  $\square$

**3.2.5. Real basis of the solutions.** For equations with real coefficients, initial real conditions always lead to real solutions (and similarly with scalars  $\mathbb{Z}$  or  $\mathbb{Q}$ ). However, the corresponding fundamental solutions derived using the above theorem might exist only in the complex domain.

We try therefore to find other generators, which will be more convenient. Because the coefficients of the characteristic polynomial are real, each of its roots is either real or the roots are paired as complex conjugates.

If we describe the solution in polar form as

$$\lambda^n = |\lambda|^n (\cos n\varphi + i \sin n\varphi)$$

$$\bar{\lambda}^n = |\lambda|^n (\cos n\varphi - i \sin n\varphi),$$

we see immediately that their sum and difference leads to two linearly independent solutions

$$x_n = |\lambda|^n \cos n\varphi, \quad y_n = |\lambda|^n \sin n\varphi.$$

Difference equations very often appear as a model of dynamics of some system. A nice topic to think about is the connection between the absolute values of individual roots and the stability of the solution. We will not go into details here, because only in the fifth chapter we will speak of convergence of values to some limit value. There is space for some interesting numerical experiments: for instance with oscillations of suitable population or economical models.

**3.2.6. The non-homogeneous case.** As in the case of systems of linear equations we can obtain all solutions of *non-homogeneous linear difference equations*

$$a_0(n)x_n + a_1(n)x_{n-1} + \cdots + a_k(n)x_{n-k} = b(n),$$

where the coefficients  $a_i$  and  $b$  are scalars which might depend on  $n$ , with  $a_0(n) \neq 0, a_k(n) \neq 0$ . Again, we proceed by finding one solution and adding the complete vector space of dimension  $k$  of solutions to the corresponding homogeneous system. Indeed each such sum yields a solution. Since the difference of two solutions of a non-homogeneous system is

*It is often useful to treat recurrence relations using matrices. While we will describe many such cases in Section C, let us briefly provide an example to highlight this elegant application of matrices. For the reader's convenience, our description includes verifications using Sage, especially for matrix computations.*

**3.B.6. The matrix method via Sage.** Using tools from linear algebra, for  $n \geq 0$  find the solution of the difference equation  $x_{n+2} = 2x_{n+1} + 3x_n$ , with  $x_0 = 0$  and  $x_1 = 1$ .

**Solution.** Set  $p_n = \begin{pmatrix} x_{n+1} \\ x_n \end{pmatrix}$  such that  $p_0 = \begin{pmatrix} x_1 \\ x_0 \end{pmatrix} = \begin{pmatrix} 1 \\ 0 \end{pmatrix}$ . Then, for  $n \geq 0$  the difference equation under question can be expressed in terms of matrices as

$$\begin{aligned} p_{n+1} &= \begin{pmatrix} x_{n+2} \\ x_{n+1} \end{pmatrix} = \begin{pmatrix} 2x_{n+1} + 3x_n \\ x_{n+1} \end{pmatrix} \\ &= \begin{pmatrix} 2 & 3 \\ 1 & 0 \end{pmatrix} \begin{pmatrix} x_{n+1} \\ x_n \end{pmatrix} = Ap_n, \end{aligned}$$

where  $A = \begin{pmatrix} 2 & 3 \\ 1 & 0 \end{pmatrix}$ . The matrix  $A$  is usually referred to as the “companion matrix” of the recurrence and satisfies the relations

$$p_1 = Ap_0, \quad p_2 = Ap_1 = A^2p_0, \quad p_3 = Ap_2 = A^3p_0$$

and so forth. For example, we obtain  $p_1 = (2, 1)^T$  and  $p_2 = (7, 2)^T$ , which implies that  $x_2 = 2$ ,  $x_3 = 7$ , and so on. This approach inductively gives us the expression  $p_n = A^n p_0$ . Therefore, to find the vector  $p_n$  and consequently the desired sequence  $x_n$ , we simply need to compute  $A^n$ . This process is straightforward when  $A$  is diagonalizable.

For our case, using Sage and the syntax

```
var("l")
solve(l^2-2*l-3, l)
```

we find that the characteristic polynomial of  $A$ , represented by  $\lambda^2 - 2\lambda - 3$ , has roots  $\lambda_1 = 3$  and  $\lambda_2 = -1$ . Hence  $A$  has two eigenvalues, both with multiplicity one, and as we will see it is diagonalizable. The corresponding eigenvectors, that is, solutions of the equation  $AX = \lambda X$ , are given by  $X_1 = (1, 1/3)^T$  and  $X_2 = (1, -1)^T$ . In order to obtain these expressions we used Sage, via the block

```
A = matrix(QQ, [[2, 3], [1, 0]])
A.eigenvectors_right()
```

This prints out the answer  $[(3, [(1, 1/3)], 1), (-1, [(1, -1)], 1)]$ .<sup>4</sup> Recall that one may verify that  $A$  is diagonalizable, directly via the command `A.is_diagonalizable()`, which in our case prints `True`. Therefore, we have

$$A^n = PD^nP^{-1}, \quad D = \begin{pmatrix} 3 & 0 \\ 0 & -1 \end{pmatrix}, \quad P = \begin{pmatrix} 3 & 1 \\ 1 & -1 \end{pmatrix}$$

<sup>4</sup>Recall that in the expression  $(3, [(1, 1/3)])$  the first number 3 corresponds to the first eigenvalue, the pair  $(1, 1/3)$  encodes its eigenvector, that is  $X_1 = (1, 1/3)^T$ , and the last number 1 is the multiplicity of the eigenvalue. Similarly for the second component inside the list.

a solution of the homogeneous system, we obtain all solutions in this way.

When we were working with systems of linear equations, it was possible that there was no solution. This is not possible with difference equations. But it is not always easy to find that one particular solution of a non-homogeneous system, particularly if the behaviour of the scalar coefficients in the equation is complicated. Even for linear recurrences with constant coefficients it may not be easy to find a solution if the right-hand side is complicated.

But we can always try to find a solution in a form similar to the right hand side. Consider the case when the corresponding homogeneous system has constant coefficients and  $b(n)$  is a polynomial of degree  $s$ . The solution can then be found in the form of the polynomial

$$x_n = \alpha_0 + \alpha_1 n + \dots + \alpha_s n^s$$

with unknown coefficients  $\alpha_i$ ,  $i = 1, \dots, s$ . By substitution into the difference equation and comparing the coefficients of the individual powers of  $n$  we obtain a system of  $s + 1$  equations for  $s + 1$  variables  $\alpha_i$ . If this system has a solution, then we have found a solution of our original problem. If it has no solution, we can try again with an increase in the degree  $s$  of the polynomial in question.

For instance, the equation  $x_n - x_{n-2} = 2$  cannot have a constant solution, because substitution of the potential solution  $x_n = \alpha_0$  yields the requirement  $\alpha_0 - \alpha_0 = 0 = 2$ . But by setting  $x_n = \alpha_0 + \alpha_1 n$  we obtain a solution  $x_n = \alpha_0 + n$ , with  $\alpha_0$  arbitrary. Thus the general solution of our equation is

$$x_n = C_1 + C_2(-1)^n + n.$$

We use this method, the *method of indeterminate coefficients* for example in 3.F.8.

**3.2.7. Variation of constants.** Another possible way to solve such an equation is the *variation of constants* method. Here we find first a solution

$$y(n) = \sum_{i=1}^k c_i f_i(n)$$

of the homogeneous equation, where we consider the constants  $c_i$  as functions  $c_i(n)$  of the variable  $n$ . Then we look for a particular solution of the given equation in the form

$$y(n) = \sum_{i=1}^k c_i(n) f_i(n).$$

We illustrate the method on second order equations. Suppose that the homogeneous part of the second order non-homogeneous equation

$$x_{n+2} + a_n x_{n+1} + b_n x_n = f_n$$

has  $x_n^{(1)}$  and  $x_n^{(2)}$  as a basis of solutions. We will be looking for a particular solution of the non-homogeneous equation in the form

$$x_n = A_n x_n^{(1)} + B_n x_n^{(2)}$$

where for simplicity we have used the multiple  $3X_1 = (3, 1)^T$  in the first column of  $P$  (this is also an eigenvector corresponding to  $\lambda_1$ ). We compute  $P^{-1} = \begin{pmatrix} 1/4 & 1/4 \\ 1/4 & -3/4 \end{pmatrix}$ , which

one can verify by the relation  $P^{-1}AP = \begin{pmatrix} \lambda_1 & 0 \\ 0 & \lambda_2 \end{pmatrix} = D$ .

With all the necessary ingredients in hand, we now obtain

$$\begin{aligned} A^n &= \begin{pmatrix} 3 & 1 \\ 1 & -1 \end{pmatrix} \begin{pmatrix} 3 & 0 \\ 0 & -1 \end{pmatrix}^n \begin{pmatrix} 1/4 & 1/4 \\ 1/4 & -3/4 \end{pmatrix} \\ &= \begin{pmatrix} 3 & 1 \\ 1 & -1 \end{pmatrix} \begin{pmatrix} 3^n & 0 \\ 0 & (-1)^n \end{pmatrix} \begin{pmatrix} 1/4 & 1/4 \\ 1/4 & -3/4 \end{pmatrix} \\ &= \frac{1}{4} \begin{pmatrix} 3^{n+1} + (-1)^n & 3^{n+1} - 3(-1)^n \\ 3^n - (-1)^n & 3^n + 3(-1)^n \end{pmatrix}. \end{aligned}$$

To verify the expression for  $A^n$  one can Sage, by the following block (this relies on the fact that  $A$  is diagonalizable)

```
A = matrix(SR, [[2, 3], [1, 0]])
P = matrix(SR, [[3, 1], [1, -1]])
n = var('n')
D = matrix(SR, [[3**n, 0], [0, (-1)**n]])
An = P * D * P.inverse()
An
```

Returning back to our initial task we get:

$$\begin{aligned} p_n &= \begin{pmatrix} x_{n+1} \\ x_n \end{pmatrix} = A^n p_0 \\ &= \frac{1}{4} \begin{pmatrix} 3^{n+1} + (-1)^n & 3^{n+1} - 3(-1)^n \\ 3^n - (-1)^n & 3^n + 3(-1)^n \end{pmatrix} \begin{pmatrix} 1 \\ 0 \end{pmatrix} \\ &= \frac{1}{4} \begin{pmatrix} 3^{n+1} + (-1)^n \\ 3^n - (-1)^n \end{pmatrix}. \end{aligned}$$

From this expression It follows that  $x_n = \frac{1}{4}(3^n - (-1)^n)$ .  $\square$

**3.B.7.** Verify the solution given in 3.B.6 via Sage.  $\circ$

*Homogeneous recurrence relations of order higher than two, can essentially be treated in the same way. However, the characteristic polynomial in this case will be of a higher degree, making the overall procedure a bit more complicated. With this in mind, we present the following task.*

**3.B.8.** For the difference equation  $x_{n+4} = x_{n+3} + x_{n+1} - x_n$  find a real basis of the corresponding solution space.  $\circ$

**3.B.9.** Determine an explicit formula for the  $n$ th member of the unique solution  $\{x_n\}_{n=1}^{\infty}$  that satisfies  $-x_{n+3} = 2x_{n+2} + 2x_{n+1} + x_n$  with  $x_1 = x_2 = x_3 = 1$ .  $\circ$

*Non-homogeneous difference equations have numerous applications. Next, we will dedicate some space to describe examples of this kind (see also 3.2.6 and the problem 3.F.8 in the final section). Notice in Sage non-homogeneous recurrence relations can be treated exactly via the same method described above for the homogeneous case.*

with some conditions on  $A_n$  and  $B_n$  to be imposed. We have

$$\begin{aligned} x_{n+1} &= A_{n+1}x_{n+1}^{(1)} + B_{n+1}x_{n+1}^{(2)} = A_nx_{n+1}^{(1)} + B_nx_{n+1}^{(2)} + \\ &\quad (A_{n+1} - A_n)x_{n+1}^{(1)} + (B_{n+1} - B_n)x_{n+1}^{(2)} \\ &= A_nx_{n+1}^{(1)} + B_nx_{n+1}^{(2)} + \delta A_nx_{n+1}^{(1)} + \delta B_nx_{n+1}^{(2)}, \end{aligned}$$

where  $\delta A_n = A_{n+1} - A_n$  and  $\delta B_n = B_{n+1} - B_n$ .

In order to be able to use the same  $A_n, B_n$  in the expression for  $x_{n+1}$ , we impose for all  $n$  the condition

$$\delta A_nx_{n+1}^{(1)} + \delta B_nx_{n+1}^{(2)} = 0.$$

Thus, for all  $n$

$$x_{n+1} = A_nx_{n+1}^{(1)} + B_nx_{n+1}^{(2)},$$

and in particular

$$\begin{aligned} x_{n+2} &= A_{n+1}x_{n+2}^{(1)} + B_{n+1}x_{n+2}^{(2)} \\ &= A_nx_{n+2}^{(1)} + B_nx_{n+2}^{(2)} + \delta A_nx_{n+2}^{(1)} + \delta B_nx_{n+2}^{(2)}. \end{aligned}$$

Now,

$$\begin{aligned} f_n &= x_{n+2} + a_nx_{n+1} + b_nx_n \\ &= A_n(x_{n+2}^{(1)} + a_nx_{n+1}^{(1)} + b_nx_n^{(1)}) + B_n(x_{n+2}^{(2)} + \\ &\quad a_nx_{n+1}^{(2)} + b_nx_n^{(2)}) + \delta A_nx_{n+2}^{(1)} + \delta B_nx_{n+2}^{(2)} \\ &= \delta A_nx_{n+2}^{(1)} + \delta B_nx_{n+2}^{(2)} \end{aligned}$$

Hence the variations  $\delta A_n$  and  $\delta B_n$  are subject to the systems

$$\begin{aligned} \delta A_nx_{n+1}^{(1)} + \delta B_nx_{n+1}^{(2)} &= 0 \\ \delta A_nx_{n+2}^{(1)} + \delta B_nx_{n+2}^{(2)} &= f_n \end{aligned}$$

with solutions (compute the inverse matrix e.g. by means of the algebraic adjoint and the determinant)

$$\begin{aligned} \delta A_n &= A_{n+1} - A_n = -\frac{f_nx_{n+1}^{(2)}}{W_{n+1}} \\ \delta B_n &= B_{n+1} - B_n = \frac{f_nx_{n+1}^{(1)}}{W_{n+1}} \end{aligned}$$

where  $W_{n+1}$  is the Wronski determinant

$$W_{n+1} = \det \begin{pmatrix} x_{n+1}^{(1)} & x_{n+1}^{(2)} \\ x_{n+2}^{(1)} & x_{n+2}^{(2)} \end{pmatrix}.$$

It follows that

$$\begin{aligned} A_n - A_0 &= \sum_{j=0}^{n-1} -\frac{f_jx_{j+1}^{(2)}}{W_{j+1}} \\ B_n - B_0 &= \sum_{j=0}^{n-1} \frac{f_jx_{j+1}^{(1)}}{W_{j+1}}. \end{aligned}$$

**3.B.10.** Determine the sequence of real numbers that satisfies the non-homogeneous difference equation  $2x_{n+2} = -x_{n+1} + x_n + 2$  with initial conditions  $x_1 = 2, x_2 = 3$ .

**Solution.** The general solution of the homogeneous equation is of the form  $a(-1)^n + b(1/2)^n$ . A particular solution is the constant 1. The general solution of the non-homogeneous equation without initial conditions is thus

$$a(-1)^n + b\left(\frac{1}{2}\right)^n + 1.$$

Based on the initial conditions we compute  $a = 1$  and  $b = 4$ . Consequently, the solution is given by the sequence  $x_n = (-1)^n + 4\left(\frac{1}{2}\right)^n + 1$ .  $\square$

**3.B.11.** Find a sequence which satisfies the following non-homogeneous difference equation  $x_{n+2} = x_{n+1} + 2x_n + 1$  with the initial conditions  $x_1 = 2, x_2 = 2$ . Next verify your solution via Sage  $\circ$

### C. Models of growth and iterated processes

*Many population models are based on recurrence relations in vector spaces. In these models, the unknown is not a sequence of numbers, but a sequence of vectors, with matrices serving as the coefficients. Thus, matrices play a crucial role in population dynamics and can be used to simulate population growth. Next we will focus on such problems, and moreover explore how various iterated processes, such as discrete Markov chains, can model everyday situations and offer intriguing insights.*

**3.C.1. Alice and Bob together in savings.** We begin with a model of growth of saved money.

Alice and Bob are artists having a band together, and they are saving money for online shopping during the black Friday, to enrich their musical instruments. As the black Friday belongs to the last week of November, they start saving every December. This first month Alice gives 1€ and Bob gives 2€. Every consecutive month each of Alice and Bob gives as many as last month, plus one half of what the other has given the month before. How much money will Alice and Bob be able to spend together the next black Friday, by applying the above plan for exactly one year? Is it true or false that during the last month Alice and Bob will put away essentially the same amount of money?

**Solution.** Let us denote by  $a_n$  the amount of money that Alice saves in the  $n$ th month, and let  $b_n$  be the corresponding amount saved by Bob. In the first month they deposit  $a_1 = 1, b_1 = 2$ . The forthcoming savings can be encoded as follows:

$$a_{n+1} = a_n + \frac{1}{2}b_n, \quad b_{n+1} = b_n + \frac{1}{2}a_n.$$

Setting  $A_0 = B_0 = 0$  we obtain

$$A_n = \sum_{j=0}^{n-1} -\frac{f_j x_{j+1}^{(2)}}{W_{j+1}}$$

$$B_n = \sum_{j=0}^{n-1} \frac{f_j x_{j+1}^{(1)}}{W_{j+1}}.$$

and the acquired general solution of our recurrence equation is

$$x_n = C_1 x_n^{(1)} + C_2 x_n^{(2)} + \left(\sum_{j=0}^{n-1} -\frac{f_j x_{j+1}^{(2)}}{W_{j+1}}\right) x_n^{(1)} + \left(\sum_{j=0}^{n-1} \frac{f_j x_{j+1}^{(1)}}{W_{j+1}}\right) x_n^{(2)}.$$

This method is used to solve the example 3.F.9.

**3.2.8. Linear filters.** Now we consider infinite sequences

$$x = (\dots, x_{-n}, x_{-n+1}, \dots, x_{-1}, x_0, x_1, \dots, x_n, \dots).$$

As in the case of systems of linear equations, we work with an operation  $T$  that maps the sequence  $x$  to the sequence  $z = Tx$  with elements

$$z_n = a_0 x_n + a_1 x_{n-1} + \dots + a_k x_{n-k}.$$

As already noticed, the sequences  $x = (x_n)$  are vectors with respect to coordinate-wise operations, and the vector space of all such sequences is infinitely-dimensional. The operation  $T$  is clearly a linear mapping on this space.

The sequences can be imagined as discrete values of a signal, often captured in very short time units.  $T$  plays the role of a filter that works with the signal. For example, this is how the sampling of an audio signal looks like. We are interested in estimating the properties such a *linear filter* can have.

Signals are often a linear combination of superimposed parts, which are themselves periodical. From our definition it is clear that *periodic sequences*  $x_n$ , that is, sequences satisfying for some fixed natural number  $p$  and all  $n$

$$x_{n+p} = x_n$$

will also have periodic images  $z = Tx$

$$z_{n+p} = a_0 x_{n+p} + a_1 x_{n-1+p} + \dots + a_k x_{n-k+p}$$

$$= a_0 x_n + a_1 x_{n-1} + \dots + a_k x_{n-k} = z_n$$

with the same period  $p$ .

We are interested in which input periodic sequences  $Tx$  remain roughly the same (up to a scalar multiple), and in which  $Tx$  will be suppressed close to zero values. This means, we are looking for the kernel of our linear mapping  $T$  and other eigen vectors. The kernel is the subspace of sequences given by the homogeneous difference equation

$$a_0 x_n + a_1 x_{n-1} + \dots + a_k x_{n-k} = 0, \quad a_0 \neq 0 \quad a_k \neq 0,$$

which we are able to solve.

Setting  $p_n := a_n + b_n$  for the common savings during the  $n$ th month, we obtain  $p_{n+1} = \frac{3}{2}p_n$ . This is obviously a geometric sequence and hence

$$p_n = 3 \left(\frac{3}{2}\right)^{n-1} .^5$$

Now, the saving period lasts exactly twelve months, so the sum  $p_1 + p_2 + \dots + p_{12}$  represents the total common savings. We compute

$$3 \left( 1 + \frac{3}{2} + \dots + \left(\frac{3}{2}\right)^{11} \right) = 3 \frac{\left(\frac{3}{2}\right)^{12} - 1}{\frac{3}{2} - 1} \approx 772,5.$$

To confirm this computation use the command `sum` in Sage, as follows:

```
var("n"); pn=3*(3/2)**(n-1)
N(sum(pn, n, 1, 12))
```

In this cell we first introduced  $n$  as a symbolic variable, and next programmed Sage to return the numerical approximation of the desired sum. This answers the first question: The next black Friday Alice and Bob will be able to spend almost 773€. To answer the second task, observe that

$$a_{n+1} = a_n + \frac{1}{2}b_n = \frac{1}{2}(a_n + p_n) = \frac{1}{2}a_n + \left(\frac{3}{2}\right)^n .$$

For a quick solution of this recurrence relation we apply Sage.

```
from sympy import Function, rsolve
from sympy.abc import n
a = Function("a")
f = a(n+1) - (1/2)*a(n) - (3/2)**n
initial = {a(1):1, a(2):2}
rsolve(f, a(n), initial)
```

which gives the answer  $(\frac{3}{2})^{*n} - 1/2^{*n}$ . This means that  $a_n = (\frac{3}{2})^n - (\frac{1}{2})^n$ , and hence during the 12th month the economies of Alice should reach the level of 130€, as it occurs by the expression  $(\frac{3}{2})^{12} - (\frac{1}{2})^{12}$ . Bob will save basically the same amount and the statement is true.  $\square$

**3.C.2. Remark.** Obviously, the example can be adapted to higher initial amounts, although the last months Alice and Bod may face problems to follow their plan. For instance, starting with  $a_1 = 10\text{€}$  and  $b_1 = 20\text{€}$ , we get  $p_1 = 30$ . Therefore, in this case one has

$$p_n = 30 \left(\frac{3}{2}\right)^{n-1}, \quad a_{n+1} = \frac{1}{2}a_n + 15 \left(\frac{3}{2}\right)^{n-1},$$

with solution  $a_n = 10\left(\frac{3^n}{2^n} - \frac{1}{2^n}\right)$ . For convenience, we list the relative savings in a table with accuracy two decimal digits.

<sup>5</sup>Recall that the geometric sequence  $x_n = \kappa x_{n-1}$  satisfies  $x_n = x_1 \kappa^{n-1}$ .

**3.2.9. Bad equalizer.** As an example, consider a very simple linear filter given by the equation

$$z_n = (Tx)_n = x_n + x_{n-2}.$$

Clearly, the kernel of  $T$  is generated by  $x_n = \cos(\frac{\pi}{2}n)$  and  $x_n = \sin(\frac{\pi}{2}n)$ , while the solutions to  $x_{n+2} = x_n$  correspond to the requirement  $(Tx)_n = 2x_n$ . The results of such an operation on a signal are illustrated by the two diagrams below. There we use two different frequencies of signals and display their discrete sampling (the solid lines and the points  $x_n$  on them). The dashed line represents the sampling  $z_n$  of the filtered signal.

The first case shows an amplifying of the signal, while the second frequency is close to the kernel which is killed by the filter. Notice that the filtered signal suffers serious shifts in phase, which varies with the frequencies. Cheap equalisers work in such a bad way.

Notice also how badly the original signal is sampled on the second picture. This is due to the fact that the sampling frequency is not much higher than the frequency of the signal.

### 3. Iterated linear processes

**3.3.1. Iterated processes.** In practical models we often encounter the situation where the evolution of a system in a given time interval is given by a linear process, and we are interested in the behaviour of the system after many iterations. The linear process often remains the same, thus from the mathematical point of view we are dealing with an iterated multiplication of the state vector by the same matrix.

While solving the systems of linear equations requires only minimal knowledge of properties of linear mappings, in order to understand the behaviour of an iterated system, we shall exploit the features of eigenvalues, eigenvectors and other structural features.

In fact, the determination of the solution of a linear recurrence equation by a set of initial conditions can be described as an iterated process. Imagine we keep the state vector of the

month	Alice	Bob	month	Alice	Bob
1st	10.00€	20.00€	7th	171.03€	171.43€
2nd	20.00€	25.00€	8th	256.75€	256.95€
3rd	32.50€	35.00€	9th	385.22€	385.32€
4th	50.00€	51.25€	10th	577.89€	577.94€
5th	75.62€	76.25€	11th	866.86€	866.88€
6th	113.75€	114.56€	12th	1300.30€	1300.31€

The dominant chord of the next series of problems is the description of suitable frameworks investigating age-structured population dynamics systems from a linear perspective based on discrete variables. In particular, first we will focus on the “Leslie growth model”, which effectively describes the growth of age-structured populations and is therefore very popular in population ecology.

Recall that this model is written as  $p_{n+1} = Ap_n$ , where  $A$  is the Leslie matrix and  $p_n = (p_n^1, \dots, p_n^m)^T$  is the population vector at time  $n$ , divided into  $m$  age classes. The relevant data for each age class consists of the reproduction rate and the rate of survival into the next age class. These vital rates form the essential part of  $A$ .

The matrix form makes the Leslie model flexible and mathematically very tractable. This is because the solutions of the Leslie model asymptotically exhibit exponential growth. Specifically, the population  $p_n$  grows at an exponential rate determined by  $\lambda_1$ , such that  $p_n \approx \lambda_1^n X_1$ . Here  $\lambda_1$  is the dominant eigenvalue (also known as the “Perron-Frobenius eigenvalue”, see 3.3.3) of  $A$  and  $X_1$  is the corresponding rescaled eigenvector. Furthermore, we can utilize  $X_1$  to infer long-term trends of the age classes, leading to the determination of the stable age distribution. For a more detailed explanation and the proofs of these statements, we encourage the reader to refer to the theoretical section starting at 3.3.2.

**3.C.3. Bushbabies and Leslie matrices.** A small team of biologists studies a colony of bushbabies<sup>6</sup> living in a specific region of South Africa. In the wild, these mammals typically have a lifespan of no more than four years. For research purposes, we can categorize their population into four distinct age classes, as follows:

class A:	0 to 1 year old	class C:	2 to 3 years old
class B:	1 to 2 years old	class D:	3 to 4 years old

The biologists determined that the breeding rates  $b_i$  for the four age classes in this colony are as follows:<sup>7</sup>  $b_1 = 0$ ,  $b_2 = 1$ ,  $b_3 = 2$  and  $b_4 = 1$ , respectively.<sup>8</sup>

<sup>6</sup>Also known as galagos or little night monkeys.

<sup>7</sup>Breeding rates are also called fertility rates and it is natural to assume that they are non-negative real numbers.

<sup>8</sup>Galagos give usually birth to a single offspring at their first pregnancy, and then produce twins in subsequent litters. In particular, they may give birth to two sets of twins a year. (source: <https://animaldiversity.org/>, <https://africageographic.com>)

last  $k$  values

$$Y_n = (x_n, \dots, x_{n-k+1})$$

(filled by the initial condition in the beginning of the process). In the next step we update the state vector

$$Y_{n+1} = (x_{n+1}, x_n, \dots, x_{n-k+2}),$$

where the first entry  $x_{n+1} = a_1x_n + \dots + a_kx_{n-k+1}$  is computed by means of a homogeneous difference equation, while the other entries are just a shift by one position with the last one forgotten. The corresponding square matrix of order  $k$  that satisfies  $Y_{n+1} = A \cdot Y_n$  is as follows:

$$A = \begin{pmatrix} a_1 & a_2 & \dots & a_{k-1} & a_k \\ 1 & 0 & \dots & 0 & 0 \\ 0 & 1 & \dots & 0 & 0 \\ \vdots & \vdots & & \ddots & \vdots \\ 0 & 0 & \dots & 1 & 0 \end{pmatrix}$$

A while ago, we derived an explicit procedure for the complete formula for the solution of such an iterated process with a special type of matrix. In general, it will not be easy even for very similar systems. A typical case is the study of the dynamics of populations in some biological systems which we discuss below.

The characteristic polynomial  $|A - \lambda E|$  of our matrix is

$$p(\lambda) = (-1)^k (\lambda^k - a_1\lambda^{k-1} - \dots - a_k),$$

as we can check directly or by expanding the last column and employing induction on  $k$ .

Thus, the eigenvalues are exactly the roots  $\lambda$  of the characteristic polynomial of the linear recurrence. We should have expected this, because having a nonzero solution  $x_n = \lambda^n$  to the linear recurrence means that the matrix  $A$  must bring  $(\lambda^k, \dots, \lambda)^T$  to its  $\lambda$ -multiple. Thus every such  $\lambda$  must be eigenvalue of the matrix  $A$ .

**3.3.2. Leslie model for population growth.** Imagine that

we are dealing with some system of individuals (cattle, insects, cell cultures, etc.) divided into  $m$  groups (according to their age, evolution stage, etc.). The state  $X_n$  is thus given by the vector

$$X_n = (u_1, \dots, u_m)^T$$

depending on the time  $t_n$  in which we are observing the system. A linear model of evolution of such system is then given by the matrix  $A$  of dimension  $m$ , which gives the change of the vector  $X_n$  to

$$X_{n+1} = A \cdot X_n$$

when time changes from  $t_n$  to  $t_{n+1}$ .

Therefore, except for the babies in age class A, all other (female) galagos in the colony can mate and produce offsprings.<sup>9</sup> The biologists also estimated the corresponding survival rates  $s_i$  for these four classes:  $s_1 = 0.4$ ,  $s_2 = 0.5$ ,  $s_3 = 0.2$ , and  $s_4 = 0$ . Notice that

$0 \leq s_i \leq 1$ , as each number represents the probability of a bushbaby surviving from one age class to the next. Graphically, the vital rates and the interactions between the age classes are represented by the following directed graph:

Suppose that the current age distribution of female bushbabies across the four age classes is given by the vector  $p_0 = (20, 20, 30, 10)^T$ . Apply the Leslie model to compute the population of babies and the total female population of the colony after one year. In addition, determine the population of female galagos in age classes C and D ten years later, and deduce that the total female population decreases. Finally provide the long-term trends for the four age classes.

**Solution.** The associated Leslie matrix is given by

$$A = \begin{pmatrix} b_1 & b_2 & b_3 & b_4 \\ s_1 & 0 & 0 & 0 \\ 0 & s_2 & 0 & 0 \\ 0 & 0 & s_3 & 0 \end{pmatrix} = \begin{pmatrix} 0 & 1 & 2 & 1 \\ 0.4 & 0 & 0 & 0 \\ 0 & 0.5 & 0 & 0 \\ 0 & 0 & 0.2 & 0 \end{pmatrix}.$$

Let us denote by  $A_t, \dots, D_t$  the amounts of the female population belonging to the age class A, ..., D, respectively, at time  $t$ . Then, the Leslie condition  $p_{t+1} = Ap_t$  gives

$$p_{t+1} = \begin{pmatrix} A_{t+1} \\ B_{t+1} \\ C_{t+1} \\ D_{t+1} \end{pmatrix} = \begin{pmatrix} B_t + 2C_t + D_t \\ 0.4A_t \\ 0.5B_t \\ 0.2C_t \end{pmatrix}.$$

Thus,  $p_1 = (A_1, B_1, C_1, D_1)^T = (90, 8, 10, 6)^T$ , and so after one year the model predicts the existence of 90 babies and in total a number of 114 female galagos (this is represented by the sum  $A_1 + \dots + D_1$ ).

For the second task, we utilize the rule  $p_{10} = Ap_9 = A^{10}p_0$ . Using the following cell in Sage

```
A=matrix(SR, [[0, 1, 2, 1],
               [0.4, 0, 0, 0],
               [0, 0.5, 0, 0],
               [0, 0, 0.2, 0]])
show(A**10)
```

<sup>9</sup>Note that our focus is solely on the female population.

As an example, we consider the *Leslie model for population growth*. Here there is the matrix

$$A = \begin{pmatrix} f_1 & f_2 & f_3 & \dots & f_{m-1} & f_m \\ \tau_1 & 0 & 0 & \dots & 0 & 0 \\ 0 & \tau_2 & 0 & \dots & 0 & 0 \\ 0 & 0 & \tau_3 & \ddots & 0 & 0 \\ \vdots & & & \ddots & \ddots & \vdots \\ 0 & 0 & 0 & \dots & \tau_{m-1} & 0 \end{pmatrix},$$

whose parameters are tied with the evolution of a population divided into  $m$  age groups such that  $f_i$  denotes the relative fertility of the corresponding age group (in the observed time shift from  $N$  individuals in the  $i$ -th group arise new  $f_i N$  ones – that is, they are in the first group), while  $\tau_i$  is the relative mortality in the  $i$ -th group in one time interval. Clearly such a model can be used with any number of age groups.

All coefficients are thus non-negative real numbers and the numbers  $\tau_i$  are between zero and one. Note that when all  $\tau$  are equal one, it is actually a linear recurrence with constant coefficients and thus has either exponential growth/decay (for real roots  $\lambda$  of the characteristic polynomial) or oscillation connected with potential growth/decay (for complex roots).

Before we introduce a more general theory, we consider in more detail this specific model.

Direct computation with the Laplace expansion of the last column yields the characteristic polynomial  $p_m(\lambda)$  of the matrix  $A$  for the model with  $m$  groups:

$$p_m(\lambda) = -\lambda p_{m-1}(\lambda) + (-1)^{m-1} f_m \tau_1 \dots \tau_{m-1}.$$

By induction we derive that this characteristic polynomial is of the form

$$p_m(\lambda) = (-1)^m (\lambda^m - a_1 \lambda^{m-1} - \dots - a_{m-1} \lambda - a_m).$$

The coefficients  $a_1, \dots, a_m$ , are all positive if all parameters  $\tau_i$  and  $f_i$  are positive. In particular,

$$a_m = f_m \tau_1 \dots \tau_{m-1}.$$

Consider the distribution of the roots of the polynomial  $p_m(\lambda)$ . We write the characteristic polynomial in the form

  $p_m(\lambda) = \pm \lambda^m (1 - q(\lambda))$  where  $q(\lambda) = a_1 \lambda^{-1} + \dots + a_m \lambda^{-m}$  is a strictly decreasing non-negative function for  $\lambda > 0$ . For  $\lambda$  positive but very small the value of  $q$  will be arbitrarily large, while for large  $\lambda$ , it will be arbitrarily close to zero. Thus, it seems there exists exactly one positive  $\lambda$  for which  $q(\lambda) = 1$  and thus also  $p_m(\lambda) = 0$ .<sup>2</sup> In other words, for every Leslie matrix (with all the parameters  $f_i$  and  $\tau_i$  positive), there exists exactly one positive real eigenvalue. For actual Leslie models of populations a typical situation is when the only real eigenvalue  $\lambda_1$  is greater or equal to one, while the absolute values of the other eigenvalues are strictly less than one.

<sup>2</sup>Actually, we shall spend a lot of time in chapter 5 to make such considerations precise, involving the convergence and continuity issues.

we obtain

$$A^{10} \approx \begin{pmatrix} 0.195 & 0.465 & 0.457 & 0.204 \\ 0.081 & 0.195 & 0.208 & 0.095 \\ 0.047 & 0.102 & 0.099 & 0.044 \\ 0.008 & 0.023 & 0.023 & 0.010 \end{pmatrix}.$$

Therefore, a further computation shows that

$$p_{10} = (A_{10}, \dots, D_{10})^T \approx (28.98, 12.75, 6.44, 1.44)^T.$$

It follows that  $C_{10} \approx 6.4$  and  $D_{10} \approx 1.4$ . We also deduce that after ten years, the total population of female galagos will be significantly smaller, specifically fewer than 50 individuals. The eventual extinction of the population can be inferred from the dominant eigenvalue of  $A$ . To determine this, one must compute the eigenvalues of  $A$  and compare them accordingly.

To compute the eigenvalues we will use Sage. However, instead of employing the conventional method from Chapter 2 (see ??), we will opt for a more convenient approach by obtaining the eigenvalues numerically. This can be done by using the command `A_num.eigenvalues`. This method applies specifically to matrices in numerical form. After defining the matrix  $A$ , the process unfolds as follows:

```
A_num = A.change_ring(RDF); show(A_num)
eig_numeric = A_num.eigenvalues()
show(eig_numeric)
```

Verify that this block accurately computes the eigenvalues of  $A$  in a highly suitable format. For a more comprehensive response, you can replace the final line with

```
print("Numerical eigenvalues:")
for eigenvalue in eig_numeric:
    print(eigenvalue.n(digits=10))
```

According to Sage there are two real eigenvalues,  $\lambda_1 \approx 0.9347$ , and  $\lambda_2 \approx -0.1121$ , and two complex  $\lambda_{3,4} \approx -0.4112 \pm i0.4607$ . Thus  $\lambda_1$  is the dominant eigenvalue of  $A$  and since  $\lambda_1 < 1$ , the colony will disappear with rate  $p_{t+1}/p_t$  equal to  $\lambda_1 \approx 0.9347$ .

An answer of the final task relies on the eigenvector  $\hat{X}_1$  corresponding to  $\lambda_1$ . Adding in the initial cell the code

```
eigV = A_num.eigenvectors_right()
show(eigV)
```

we see that  $\hat{X}_1$  has (approximately) the expression  $(0.8988, 0.3847, 0.2058, 0.04403)^T$ , but it is more convenient to rewrite this vector as  $\hat{X}_1 \approx (1, 0.427, 0.228, 0.048)^T$ . The number 1.703 approximates the sum of its entries, so the normalized eigenvector associated to  $\lambda_1$  has the form  $X_1 = \frac{1}{1.703} \hat{X}_1 \approx (0.587, 0.250, 0.133, 0.028)^T$ . From this we obtain the long term trends of the four age classes in the population: 0.58% of babies, 0.25% of age class B, while the population of female galagos older than two years old is smaller than 16.2%.  $\square$

**3.C.4. Remarks.** To illustrate the decrease of the population in the previous example, we may present a graph where the population's fading is depicted for a period of fifty years. Included is also the situation for babies' population.

If we begin with any state vector  $X$ , given as a sum of eigenvectors

$$X = X_1 + \dots + X_m$$

with eigenvalues  $\lambda_i$ , then iterations yield

$$A^k \cdot X = \lambda_1^k X_1 + \dots + \lambda_m^k X_m.$$

Thus under the assumption that  $|\lambda_i| < 1$  for all  $i \geq 2$ , all components in the eigensubspaces decrease very fast, except for the component  $\lambda_1^k X_1$ .

The distribution of the population among the age groups is thus very fast approaching the ratios of the components of the eigenvector to the dominant eigenvalue  $\lambda_1$ .

As an example, consider the matrix below where individual coefficients are taken from the model for sheep breeding, that is, the values  $\tau$  contain both natural deaths and activities of breeders.

$$A = \begin{pmatrix} 0 & 0.2 & 0.8 & 0.6 & 0 \\ 0.95 & 0 & 0 & 0 & 0 \\ 0 & 0.8 & 0 & 0 & 0 \\ 0 & 0 & 0.7 & 0 & 0 \\ 0 & 0 & 0 & 0.6 & 0 \end{pmatrix}.$$

The eigenvalues are approximately

$$1.03, 0, -0.5, -0.27 + 0.74i, -0.27 - 0.74i$$

with absolute values 1.03, 0, 0.5, 0.78, 0.78 and the eigenvector corresponding to the dominant eigenvalue is approximately

$$X^T = (30 \ 27 \ 21 \ 14 \ 8).$$

We have chosen the eigenvector whose coordinates sum to 100, thus it directly gives us the percentage distribution of the population.

Suppose instead that we wish for a constant population, and that one year old sheep are removed for consumption. Then we need ask how to decrease  $\tau_2$  so that the dominant eigenvalue would be one.

A direct check shows that the farmer could then eat about 10% more of one year old sheep to keep the population constant.

### 3.3.3. Matrices with non-negative elements.

Real matrices which have no negative elements have very special properties. They are very often present in practical models. Thus we introduce the *Perron-Frobenius theory* which deals with such matrices. Actually, we show some results of Perron, we omit the more general situations due to Frobenius.<sup>3</sup>

We begin with some definitions in order to formulate our ideas.

<sup>3</sup>Oskar Perron and Ferdinand Georg Frobenius were two great German mathematicians at the break of the 19th and 20th centuries. Even in this textbook we shall meet their names in Analysis, Number Theory, Algebra. Look up the index.

To obtain the graph, for any plot separately we can apply a command of the following type (we present the code for the first 5 years for the total population and the case of babies population is treated similarly).

```
list_plot({0: 80, 1: 114, 2: 76, 3: 78.4,
4: 79.2, 5: 66.32},
plotjoined=True, color="dodgerblue") \
+ text(r"total population", (22, 34),
color="black")
```

In this block the numbers 0, 1, 2, ... represent the years, and the numbers 80, 114, 76, ... represent the size of the female population the corresponding year. The female population at the  $k$ th year is given by  $m_k = A_k + B_k + C_k + D_k$ . Thus we need to compute the matrices  $A, A^2, \dots, A^{50}$  and then apply the Leslie condition  $p_k = A^k p_0$ , for any  $k$  with  $0 \leq k \leq 50$ . Recall that  $p_k = (A_k, B_k, C_k, D_k)^T$ . Finally, to join the two plots in one figure one can add in the previous cell the code

```
g1 = list_plot(0 : 80, ...), g2 = list_plot(0 : 20, ...),
and then use the command (g1 + g2).show().
```

**3.C.5.** Show that in 3.C.3 the result about the declination of the population will change if we assume that galagos of age class B give two female offsprings, instead of one, and the rest of the given data remains the same. Which are the long term trends of the four age classes in this case and which is the total population of the colony after ten years, if we assume that for any female bushbaby there exists a male one? Present a graph illustrating the increase of the female population for a period of thirty years. ○

*In the study of age-structured populations an interesting question is how we can stabilize the population under examination, so that it is neither growing nor declining. For the Leslie model, this is the case if and only if the dominant eigenvalue of the associated Leslie matrix equals one,  $\lambda_1 = 1$ . Below we describe this situation for two cases: one less realistic, involving the population of female galagos analyzed in 3.C.3, and one more realistic, involving the population of fish in a restricted environment, such as an artificial pond.*

POSITIVE AND PRIMITIVE MATRICES

**Definition.** A *positive matrix* means a square matrix  $A$  all of whose elements  $a_{ij}$  are real and strictly positive. A *primitive matrix* is a square matrix  $A$  whose power  $A^k$  is positive for some positive  $k \in \mathbb{N}$ .

Recall that *spectral radius of a matrix*  $A$  is the maximum of absolute values of all (complex) eigenvalues of  $A$ . The spectral radius of a linear mapping on a (finite dimensional) vector space coincides with the spectral radius of the corresponding matrix for some basis.

In the sequel, the *norm* of a matrix  $A \in \mathbb{R}^{n^2}$  or of a vector  $x \in \mathbb{R}^n$  will mean the sum of the absolute values of all elements. For a vector  $x$  we write  $|x|$  for its norm.

The following result is very useful and hopefully understandable. But the difficulty of its proof is rather not typical for this textbook. If you prefer, read just the theorem and skip the proof till later on.

PERRON THEOREM

**Theorem.** If  $A$  is a primitive matrix with spectral radius  $\lambda \in \mathbb{R}$ , then  $\lambda$  is a root of the characteristic polynomial of  $A$  with multiplicity one and  $\lambda$  is strictly greater than the absolute value of all other eigenvalues of  $A$ . Furthermore, there exists an eigenvector  $x$  associated with  $\lambda$  such that all elements  $x_i$  of  $x$  are positive.

**PROOF.** We shall present the proof only briefly and we shall rely on intuition from elementary geometry, as well as some results touched much later in this book.

Notice that the matrices  $A$  and  $A^k$  share the eigenvectors, while the corresponding eigenvalues are  $\lambda$  and  $\lambda^k$  respectively. Thus the assertion of the theorem holds if and only if the same is true for  $A^k$ . In particular, we may assume the matrix  $A$  itself is positive, without any loss of generality.

Many of the necessary concepts and properties will be discussed in chapter four and in the subsequent chapters devoted to analytical aspects, so the reader might come back to this proof later.

The first step is to show the existence of an eigenvector which has all elements positive. Consider the standard simplex

$$S = \{x = (x_1, \dots, x_n)^T, |x| = 1, x_i \geq 0, i = 1, \dots, n\}.$$

Since all elements in the matrix  $A$  are positive, the image  $A \cdot x$  for  $x \in S$  has all coordinates positive too. The mapping

$$x \mapsto |A \cdot x|^{-1} (A \cdot x)$$

thus maps  $S$  to itself. This mapping  $S \rightarrow S$  satisfies all the assumptions of the *Brouwer fixed point theorem*<sup>4</sup> and thus there

<sup>4</sup>This theorem is a great example of a blend of (homological) Algebra, (differential) Topology and Analysis. We shall discuss it in Chapter 9, cf. 9.1.16 on page 822.

**3.C.6. Stabilizing the size of bushbabies' colony.** Let us return to the colony of bushbabies studied in 3.C.3. Determine the necessary adjustments in the age-dependent vital rates that required to stabilize the population size. By age-dependent vital rates we mean the fertility rates  $b_1, \dots, b_4$  and the survival rates  $s_1, \dots, s_4$ .

**Solution.** Since we are using the Leslie model, the stabilization process is governed by the condition  $\lambda_1 = 1$ , where  $\lambda_1$  is the dominant eigenvalue of the corresponding Leslie matrix. This condition is independent of the initial population size. We consider the following possibilities (though there may be others):

1. Increase  $s := s_1$ , that is the survival rate of babies. Hence we use the Leslie matrix

$$A = \begin{pmatrix} 0 & 1 & 2 & 1 \\ s & 0 & 0 & 0 \\ 0 & 0.5 & 0 & 0 \\ 0 & 0 & 0.2 & 0 \end{pmatrix}$$

for some  $s$ , with  $0 \leq s \leq 1$ . Since we set  $\lambda_1 = 1$ , to determine the survival rate  $s$  we need to compute the determinant of  $A - E$ , where  $E$  is the identity matrix. For this one can use Sage, as follows:

```
s=var("s")
A=matrix(SR, 4, 4, [0, 1, 2, 1, s, 0, 0,
0, 0, 0.5, 0, 0, 0, 0, 0.2, 0])
E=identity_matrix(4)
(A-E).det()
```

which gives  $-2.1 * s + 1$ . Thus the equation  $\det(A - E) = 0$  has the solution  $s = 10/21 = 0.47619$ . Hence from 0.4 which was initially the breeding parameter  $s = s_1$  we need to increase it to 0.47619 to stabilize the size of the female population of bushbabies (under the assumptions that the other vital rates are as in 3.C.3).

2. Change in a proportional way the fertility rates  $b_i$  for  $i = 2, 3, 4$ . This means that we use the following Leslie matrix

$$A = \begin{pmatrix} 0 & s & 2s & s \\ 0.4 & 0 & 0 & 0 \\ 0 & 0.5 & 0 & 0 \\ 0 & 0 & 0.2 & 0 \end{pmatrix}$$

for some  $s > 0$ , which we should specify via the constraint  $\lambda_1 = 1$ . Using Sage we get  $\det(A - E) = -0.84s + 1$ , and the equation of  $\det(A - E) = 0$  gives  $s = 25/21 \approx 1.19048$ . Therefore, by setting  $b_2 = b_4 = 1.19048$  and  $b_3 = 2.38095$ , while maintaining the survival rates  $s_i$  as in 3.C.3, the population is stabilized.  $\square$

**3.C.7. Population of fishes in an artificial pond.** Suppose we have a simple model of a pond where a population of fish lives (e.g., bleak, vimba, or nase). Assume that 20% of babies survive their second year and, from that age on, they are able to reproduce. It is known that approximately 60% of these young fish survive during the third year, and in the following years, mortality can be ignored. We also assume that the birth rate is three times the number of fish that can reproduce.

exists vector  $y \in S$  such that it is mapped by this mapping to itself. That means that

$$A \cdot y = \lambda y, \quad \lambda = |A \cdot y|$$

and we have found an eigenvector that lies in  $S$ . By assumption,  $A \cdot y$  has got all coordinates positive, thus  $y$  must have the same property. Moreover,  $\lambda > 0$ .

In order to prove the rest of the theorem, we consider the mapping given by the matrix  $A$  in a more suitable basis, where the coordinates of the eigenvector would be  $(\lambda, \dots, \lambda)$ . Moreover, we multiply the mapping by the constant  $\lambda^{-1}$ . Thus we work with the matrix  $B$ ,

$$B = \lambda^{-1}(Y^{-1} \cdot A \cdot Y),$$

where  $Y$  is the diagonal matrix with coordinates  $y_i$  of the above eigenvector  $y$  on its diagonal. Evidently  $B$  is also a positive matrix. By the construction, the vector  $z = (1, \dots, 1)^T$  is its eigenvector with eigenvalue 1, because  $Y \cdot z = y$ .

It remains to prove that  $\mu = 1$  is a simple root of the characteristic polynomial of the matrix  $B$  and that all other roots have absolute value strictly smaller than one. Then the proof of the Perron theorem is finished.

In order to do that we use an auxiliary lemma, which is discussed below. Consider for the moment the matrix  $B$  to define the linear mapping  $\psi$  that maps the row vectors

$$u = (u_1, \dots, u_n) \mapsto u \cdot B = v,$$

that is, using multiplication from the right (i.e.,  $B$  is viewed as the matrix of a linear map on one-forms). Since  $z = (1, \dots, 1)^T$  is an eigenvector of the matrix  $B$  (with eigenvalue 1), the sum of the coordinates of the row vector  $v$

$$u \cdot B \cdot (1, \dots, 1)^T = \sum_{i,j=1}^n u_i b_{ij} = \sum_{i=1}^n u_i = 1,$$

whenever  $u \in S$ . Therefore the simplex  $S$  maps onto itself and thus has in  $S$  a (row) eigenvector  $w$  with eigenvalue one (a fixed point, by the Brouwer theorem again). Because some power  $B^k$  is positive by our assumption, the image of the simplex  $S$  under  $B^k$  lies inside of  $S$ .

We continue with the row vectors. Denote by  $P$  the shift of the simplex  $S$  into the origin by the eigenvector  $w$  we have just found. That is,  $P = -w + S$ . Evidently  $P$  is a set containing the origin and is defined by linear inequalities. Clearly,  $\psi(P) = -w + \psi(S) \subset P$  and, thus, the vector subspace  $V \subset \mathbb{R}^n$  generated by  $P$  is invariant with respect to the action of the matrix  $B$  through multiplication of the row vectors from the right. Moreover, if  $\psi(p) \in P$  sits on the boundary of  $P$ , then  $\psi(p + w)$  is on the boundary of  $S$ . Hence restriction of our mapping to  $V$ , and  $P$  itself satisfy the assumptions of the auxiliary lemma discussed below and thus all its eigenvalues are strictly smaller than one.

Now, the entire space decomposes as the sum  $\mathbb{R}^n = V \oplus \text{span}\{w\}$  of invariant subspaces,  $w$  is the eigenvector with eigenvalue 1, while all eigenvalues of the restriction to  $V$  are strictly smaller in absolute value.

Clearly, such a population would fill the pond very quickly. To maintain a balance, we need to introduce a predator, such as esox. Assume that an esox eats approximately 500 mature fish per year. How many predators of this type should be introduced into the pond to keep the population constant?

**Solution.** There are three age classes: babies, young fish and adult fish. Let  $p$  be the number of babies,  $m$  be the number of young fish and  $r$  be the number of adult fish. In terms of vectors, the state of the population in the next year is given by

$$\begin{pmatrix} p \\ m \\ r \end{pmatrix} \mapsto \begin{pmatrix} 3m + 3r \\ 0.2p \\ 0.6m + yr \end{pmatrix}.$$

The relative mortality of the adult fish caused by the predators equals to the difference  $1 - y$ , and we should specify the unknown  $y$ . This model is successfully described by a *generalized Leslie matrix*, having the form

$$A = \begin{pmatrix} 0 & 3 & 3 \\ 0.2 & 0 & 0 \\ 0 & 0.6 & y \end{pmatrix}.$$

To stabilize the population one of the eigenvalues of this matrix should be equal to 1, and this will give us the desired value of the unknown  $y$ . As before, in Sage we may type

```
y=var("y")
A= matrix(SR, 3, 3, [0, 3, 3, 0.2, 0,
0, 0, 0.6, y])
I3 = matrix(RR, [[1, 0, 0], [0, 1, 0],
[0, 0, 1]])
(A-I3).det ( )
```

This prints out the expression  $0.4 * y - 0.04$  with obvious solution  $y = 0.1$ . This means that in the next year only 10% is allowed to survive and the rest should be eaten by the predators. Let us denote the number of predators by  $x$ . Then, together they eat  $500x$  fish, which according to the previous computation should be  $0.9r$ . Consequently, the ratio of the number of fish to the number of predators is given by  $\frac{r}{x} = \frac{500}{0.9}$ . That is, one esox for (approximately) 556 fish.  $\square$

**3.C.8. Predators and preys.** In a population model, let  $D_k$  be the number of predators and  $K_k$  be the number of preys, in month  $k$ . The relation of these between month  $k$  and month  $k + 1$  is given by one of the following three linear systems:

(a)	$D_{k+1} = 0.6 D_k + 0.5 K_k,$ $K_{k+1} = -0.16 D_k + 1.2 K_k,$
(b)	$D_{k+1} = 0.6 D_k + 0.5 K_k,$ $K_{k+1} = -0.175 D_k + 1.2 K_k,$
(c)	$D_{k+1} = 0.6 D_k + 0.5 K_k,$ $K_{k+1} = -0.135 D_k + 1.2 K_k.$

Analyse the behaviour of this model for large time values.

**Solution.** We can encode all three cases as

$$\begin{pmatrix} D_k \\ K_k \end{pmatrix} = T_a \cdot \begin{pmatrix} D_{k-1} \\ K_{k-1} \end{pmatrix}, \quad k \in \mathbb{N},$$

The theorem is nearly proved. We have just to consider the problem that the mapping under question was given by multiplication of the row vectors from the right with the matrix  $B$ , while originally we were interested in the mapping given by the matrix  $B$  and multiplication of the column vectors were from the left. But this is equivalent to the multiplication of the transposed column vectors with the transposed matrix  $B$  in the usual way – from the left. Thus we have proved the claim about eigenvalues for the transpose of  $B$ . But transposing does not change the eigenvalues and so the proof is complete.  $\square$

A bounded polyhedron in  $\mathbb{R}^n$  is a nonempty subset defined by linear inequalities, sitting in some large enough ball. Simplex  $S$  from the proof or any its translation are examples. We shall provide concise explanation of all these concepts in chapter 4.

**Lemma.** Consider any bounded polyhedron  $P \subset \mathbb{R}^n$ , containing a ball around origin  $0 \in \mathbb{R}^n$ . If some iteration of the linear mapping  $\psi : \mathbb{R}^n \rightarrow \mathbb{R}^n$  maps  $P$  into its interior (that is  $\psi(P) \subset P$  and the image does not intersect with the boundary), then the spectral radius of the mapping  $\psi$  is strictly less than one.

**PROOF.** Consider the matrix  $A$  of the mapping  $\psi$  in the standard basis. Because the eigenvalues of  $A^k$  are the  $k$ -th powers of the eigenvalues of the matrix  $A$ , we may assume (without loss of generality) that the mapping  $\psi$  already maps  $P$  into  $P$ . Clearly  $\psi$  cannot have any eigenvalue  $\lambda$  with absolute value greater than one. This is easy to see, if the eigenvalue is real. In the complex case, there will be a 2-dimensional invariant plane in which  $\psi$  is a multiplication by  $|\lambda|$  composed with a rotation, thus  $|\lambda| > 1$  is in conflict with the invariance of  $P$  again.

Next, we argue by contradiction and assume that there exists an eigenvalue  $\lambda$  with  $|\lambda| = 1$ . Then there are two possibilities, either  $\lambda^k = 1$  for suitable positive integer  $k$  or there is no such  $k$ .

The image of  $P$  is a closed set (that means that if the points in the image  $\psi(P)$  get arbitrarily close to some point  $y$  in  $\mathbb{R}^n$ , then the point  $y$  is also in the image – this is a general feature of the linear maps on finite dimensional vector spaces). By our assumption, the boundary of  $P$  does not intersect with the image. Thus  $\psi$  cannot have a fixed point on the boundary and there cannot even be any point on the boundary to which some sequence of points in the image would converge.

The first argument excludes that some power of  $\lambda$  is one, because such a fixed point of  $\psi^k$  on the boundary of  $P$  would then exist and thus it would be in the image. In the remaining case there would be a two-dimensional subspace  $W \subset \mathbb{R}^n$  on which the restriction of  $\psi$  acts as a rotation by an irrational angle and thus there exists a point  $y$  in the intersection of  $W$  with the boundary of  $P$ . But then the point  $y$  could be approached arbitrarily close by the points from the set  $\psi^k(y)$  (through all iterations) and thus would have to be in the image too. This leads to a contradiction and thus the lemma is proved.  $\square$

where  $T_a := \begin{pmatrix} 0.6 & 0.5 \\ -a & 1.2 \end{pmatrix}$  and  $a \in \{0.16, 0.175, 0.135\}$ . The coefficient  $a$  represents the average number of preys killed by one predator per month.<sup>10</sup> It follows that

$$\begin{pmatrix} D_k \\ K_k \end{pmatrix} = T_a^k \cdot \begin{pmatrix} D_0 \\ K_0 \end{pmatrix}, \quad k \in \mathbb{N}.$$

Using the powers of the matrix  $T_a$  we can determine the evolution of the populations of predators and prey after a very long time. For such a procedure it is useful to summarize in a table the eigenvalues and the eigenvectors of  $T_a$ :

	$\lambda_1$	$\lambda_2$	$X_1$	$X_2$
$a = 0.16$	1	4/5	$(5, 4)^T$	$(5, 2)^T$
$a = 0.175$	19/20	17/20	$(10, 7)^T$	$(2, 1)^T$
$a = 0.135$	21/20	3/4	$(10, 9)^T$	$(10, 3)^T$

To compute  $T_a^k$  we may simply proceed by hand. As we know, if  $X = (X_1 \ X_2)$  is the matrix formed by the eigenvectors, then the matrix  $T_a^k$  occurs as follows:

$$T_a^k = X \cdot \begin{pmatrix} \lambda_1 & 0 \\ 0 & \lambda_2 \end{pmatrix}^k \cdot X^{-1}, \quad k \in \mathbb{N}.$$

For instance, for  $a = 0.16$  we have  $X = \begin{pmatrix} 5 & 5 \\ 4 & 2 \end{pmatrix}$ ,  $X^{-1} = \begin{pmatrix} -1/5 & 1/2 \\ 2/5 & -1/2 \end{pmatrix}$ , and  $\begin{pmatrix} 1 & 0 \\ 0 & 0.8 \end{pmatrix}^k \approx \begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix}$  for large  $k$ .

Thus, for large time values we get  $T_{0.16}^k \approx \begin{pmatrix} -1 & 5/2 \\ -4/5 & 2 \end{pmatrix}$ .

In a similar way, for large  $k$  one computes

$$T_{0.175}^k \approx \begin{pmatrix} 0 & 0 \\ 0 & 0 \end{pmatrix}, \quad T_{0.135}^k \approx 1.05^k \begin{pmatrix} -1/2 & 5/3 \\ -9/20 & 3/2 \end{pmatrix}.$$

Knowing  $T_a^k$  we are able to proceed with the systems. These are given by

$$\begin{aligned} \begin{pmatrix} D_k \\ K_k \end{pmatrix} &\approx \frac{1}{10} \begin{pmatrix} 5(-2D_0 + 5K_0) \\ 4(-2D_0 + 5K_0) \end{pmatrix}, \\ \begin{pmatrix} D_k \\ K_k \end{pmatrix} &\approx \begin{pmatrix} 0 \\ 0 \end{pmatrix}, \\ \begin{pmatrix} D_k \\ K_k \end{pmatrix} &\approx \frac{1.05^k}{60} \begin{pmatrix} 10(-3D_0 + 10K_0) \\ 9(-3D_0 + 10K_0) \end{pmatrix}, \end{aligned}$$

for  $a = 0.16$ ,  $a = 0.175$  and  $a = 0.135$ , respectively. A qualitative interpretation of these relations can produce valuable conclusions for the future of the populations. In particular:

- (a) If  $2D_0 < 5K_0$ , the sizes of both populations stabilise on non-zero sizes. if  $2D_0 \geq 5K_0$ , both populations die out.
- (b) Both populations die out.
- (c) For  $3D_0 < 10K_0$  we have a population boom of both kinds. For  $3D_0 \geq 10K_0$  both populations die out.

Note that there are many models that effectively describe predator-prey population dynamics. These models can be either discrete iterative models, or continuous models based on

<sup>10</sup>The value of  $a$  does *not* depend on the size of the population (in fact, for stable populations one can estimate the size of  $a$ ). As a consequence, observe that a small change of  $a$  can lead to different conclusions.

**3.3.4. Simple corollaries.** Once we know the Perron theorem, the following very useful claim has a surprisingly simple proof. It shows how strong is the primitivity assumption of a matrix.

**Corollary.** If  $A = (a_{ij})$  is a primitive matrix and  $x \in \mathbb{R}^n$  is its eigenvector with all coordinates non-negative and eigenvalue  $\lambda$ , then  $\lambda > 0$  is the spectral radius of  $A$ . Moreover,

$$\min_{j \in \{1, \dots, n\}} \sum_{i=1}^n a_{ij} \leq \lambda \leq \max_{j \in \{1, \dots, n\}} \sum_{i=1}^n a_{ij}.$$

**PROOF.** Because  $A$  is primitive, we can choose  $k$  such that  $A^k$  has only positive elements. Then  $A^k \cdot x = \lambda^k x$  is a vector with all coordinates strictly positive. Obviously  $\lambda > 0$ .

According to the Perron theorem, the spectral radius  $\mu$  of  $A$  is an eigenvalue and the associated eigenvectors  $y$  have positive coordinates only. Thus we may choose such an eigenvector with the property that the difference  $x - y$  has only strictly positive coordinates. Then for all large positive integer powers  $m$  we have

$$0 < A^m \cdot (x - y) = \lambda^m x - \mu^m y,$$

but also  $\lambda \leq \mu$ . If  $\mu = \lambda + \alpha$ ,  $\alpha > 0$ , then

$$0 < \lambda^m x - (\lambda + \alpha)^m y < \lambda^m (x - y - m \frac{\alpha}{\lambda} y)$$

which is clearly negative for  $m$  large enough. Hence  $\lambda = \mu$ .

It remains to estimate the spectral radius using the minimum and maximum of sums of individual columns of the matrix. We denote them by  $b_{\min}$  and  $b_{\max}$ . Choose  $x$  to be the eigenvector with the sum of coordinates equal to one and count:

$$\begin{aligned} \sum_{i,j=1}^n a_{ij} x_j &= \sum_{i=1}^n \lambda x_i = \lambda \\ \lambda &= \sum_{j=1}^n \left( \sum_{i=1}^n a_{ij} \right) x_j \leq \sum_{j=1}^n b_{\max} x_j = b_{\max} \\ \lambda &= \sum_{j=1}^n \left( \sum_{i=1}^n a_{ij} \right) x_j \geq \sum_{j=1}^n b_{\min} x_j = b_{\min}. \quad \square \end{aligned}$$

Note that for instance all Leslie matrices from 3.3.2, as soon as all their parameters  $f_i$  and  $\tau_j$  are strictly positive, are primitive. Thus we can apply the just derived results to them. (Compare this with the ad hoc analysis of the roots of the characteristic polynomial from 3.3.2)

**3.3.5. Markov chains.** A very frequent and interesting case of linear processes with only non-negative elements in a matrix is a mathematical model of a system which can be in one of  $m$  states with various probabilities. At a given point of time the system is in state  $i$  with probability  $x_i$ . The transition from the state  $i$  to the state  $j$  happens with probability  $t_{ij}$ .

We can write the process as follows: at time  $n$  the system is described by the *stochastic vector* (we also say *probability vector*)  $x_n = (u_1(n), \dots, u_m(n))^T$ .

differential equations. A prominent example is the Lotka and Volterra model, see 8.3.10. Further exercises related to the Leslie model and population growth are presented in Section F, see for example the tasks 3.F.12, 3.F.13 and 3.F.15.  $\square$

*In the remainder of this section, we delve into the discrete “Markov process”, a topic where matrix calculus intersects with probability theory. For a more theoretical treatment, see 3.3.5 and 3.4.7. We begin with a brief introduction to stochastic processes, a concept that will be extensively analyzed in Chapter 10. Here, we primarily focus on “discrete stochastic processes” (cf. 10.2.14).*

*Recall that a “random variable” in the context of a random experiment with sample space  $\Omega$ , is an  $\mathbb{R}$ -valued function  $X : \Omega \rightarrow \mathbb{R}$  satisfying the property that  $\{s : X(s) \in I\}$  is an event for any interval  $I \subseteq \mathbb{R}$ . For further details see 10.2.10.*

*In simpler terms, a random variable assigns a real number to each possible outcome of a random experiment. A random variable  $X$  that can take at most countably many values is termed discrete. For instance, the number of typographical errors on a page of a book represents a discrete random variable. A stochastic (or random) process is essentially a sequence of random variables  $\{X(t) \equiv X_t\}_{t=0}^\infty$ . Such processes depict the evolution over time of a random phenomenon, thereby encapsulating the concept of probabilistic dynamics. In the following we are only interested in discrete random variables and, consequently, in discrete stochastic processes.*

**3.C.9.** Describe examples of discrete stochastic processes.

**Solution.** There is plethora of such examples. Let  $X_n$  be the number of customers served in a bank, or the number of product sales in a market at the end of the  $n$ th working day. Then  $\{X_n : n = 0, 1, \dots\}$  is a discrete stochastic process. Another example occurs when  $X_n$  represents the number of arrivals at an emergency room between midnight and 8.00 am. Or  $X_n$  can represent the number of books sold in a bookstore, or the number of people who attend a concert, etc.  $\square$

*The values that a discrete random variable  $X_n$  takes are known as the states of the system at step  $n$ . We can denote these states using integers  $0, 1, 2, \dots$ , or symbols such as  $s_0, s_1$ , and so on. Given that  $X_{n-1} = j$  and  $X_n = i$ , the system is said to have made a “transition” from state  $s_j$  to state  $s_i$ . This is known as a chain.*

*“Discrete Markov processes”, also known as “Markov chains”, are stochastic processes with a finite number of possible states, where memory effects are strongly limited. This means that the probability having  $X_n = i$ , depends only on the immediate previous state of the system.*

*Next we will assume time-homogeneity, meaning the transition probabilities  $P(X_n = i | X_{n-1} = j)$  are constant*

This means that all components of the vector  $x$  are real non-negative numbers and their sum equals one. Components give the distribution of the probability of individual possibilities for the state of the system. The distribution of the probabilities at time  $n + 1$  is given via multiplication by the transition matrix  $T = (t_{ij})$ , that is,

$$x_{n+1} = T \cdot x_n.$$

Since we assume that the vector  $x$  captures all possible states of the system and moves again to some of these states with the total probability one, all columns of  $T$  are also given by stochastic vectors. We call such matrices *stochastic matrices*. Note that every stochastic matrix maps every stochastic vector  $x$  to a stochastic vector  $Tx$  again:

$$\sum_{i,j} t_{ij}x_j = \sum_j \left( \sum_i t_{ij} \right) x_j = \sum_j x_j = 1.$$

Such a sequence  $x_{n+1} = Tx_n$  is called a (discrete) *Markov process* and the resulting sequence of vectors  $x_0, x_1, \dots$  is called a *Markov chain*  $x_n$ .

Now we can exploit the Perron-Frobenius theory in its full power. Because the sum of the rows of the matrix is always equal to the vector  $(1, \dots, 1)$ , we see that the matrix  $T - E$  is singular and thus one is an eigenvalue of the matrix  $T$ . Furthermore, if  $T$  is a primitive matrix (for instance, when all elements are non-zero), we know from the corollary 3.3.4 that one is a simple root of the characteristic polynomial and all others have absolute value strictly smaller than one. This leads to:

ERGODIC THEOREM

**Theorem.** *Markov processes with primitive matrices  $T$  satisfy:*

- *there exists a unique eigenvector  $x_\infty$  of the matrix  $T$  with the eigenvalue 1, which is stochastic,*
- *the iterations  $T^k x_0$  approach the vector  $x_\infty$  for any initial stochastic vector  $x_0$ .*

**PROOF.** The first claim follows directly from the positivity of the coordinates of the eigenvector derived in the Perron theorem (notice the dominant eigenvalue comes with multiplicity one).

Next, assume that the algebraic and geometric multiplicities of the eigenvalues of the matrix  $T$  are the same. Then every stochastic vector  $x_0$  can be written (in the complex extension  $\mathbb{C}^n$ ) as a linear combination

$$x_0 = c_1 x_\infty + c_2 y_2 + \dots + c_n y_n,$$

where  $y_2, \dots, y_n$  extend  $x_\infty$  to a basis of the eigenvectors. But then the  $k$ -th iteration gives again a stochastic vector

$$x_k = T^k \cdot x_0 = c_1 x_\infty + \lambda_2^k c_2 y_2 + \dots + \lambda_n^k c_n y_n.$$

Now all eigenvalues  $\lambda_2, \dots, \lambda_n$  are in absolute value strictly smaller than one. So all components of the vector  $x_k$  but the first one approach (in norm) zero. But  $x_k$  is still stochastic,

over time and do not depend on  $n$ . This is a common assumption in many Markov chain models. The transition from state  $s_j$  to  $s_i$ , or simply from  $j$  to  $i$ , is encoded by the transition probability  $t_{ij} = P(X_n = i | X_{n-1} = j)$ , compare with 3.3.5. Thus, the dynamics of a discrete-time homogeneous Markov chain with state space consisting of  $m$  states, is described by the  $m \times m$  matrix  $T = (t_{ij})$ . This is known as the transition matrix of the Markov process, from the  $(n - 1)$ th step to the  $n$ th step. In our context,  $T$  is a column-stochastic matrix, meaning that  $t_{ij} \geq 0$  and  $\sum_i t_{ij} = 1$ . In other words, each column of  $T$  is a stochastic vector, (this has non-negative real numbers as entries, that sum to one, see also 3.3.5).

**3.C.10.** Two-state Markov chains are Markov chains having a state space consisting of two elements, typically denoted by  $S = \{0, 1\}$ . They can be used to model various situations, such as the operational status of everyday machines where the probability of a machine being out of operation the next day is known.

For example, consider a traffic light on a road in New York. Suppose the probability that a working traffic light will be out of order the next day is  $p$ , while the probability that an out-of-order traffic light will start operating the next day is  $q$ . Demonstrate that this scenario constitutes a Markov process and determine its transition matrix.

**Solution.** What happens at each day depends only on the previous day, and hence we have a two-stage (homogeneous) Markov process  $\{X_n\}$ , where  $X_n$  is the state of the traffic light on the  $n$ th day. By definition,  $X_n = 0$  if the traffic light will be out of order the  $n$ th day and  $X_n = 1$  otherwise. Thus one computes

$$\begin{aligned} t_{00} &= P(X_n = 0 | X_{n-1} = 0) = 1 - q, \\ t_{01} &= P(X_n = 0 | X_{n-1} = 1) = p, \\ t_{10} &= P(X_n = 1 | X_{n-1} = 0) = q, \\ t_{11} &= P(X_n = 1 | X_{n-1} = 1) = 1 - p. \end{aligned}$$

This means that  $T = \begin{pmatrix} t_{00} & t_{01} \\ t_{10} & t_{11} \end{pmatrix} = \begin{pmatrix} 1 - q & p \\ q & 1 - p \end{pmatrix}$ .  $\square$

**3.C.11. Remarks.** a) Markov chains on finite state spaces can alternatively be represented graphically through a “transition diagram”. This diagram is a directed graph where each vertex represents a state of the chain. Directed edges are drawn from vertex  $j$  to vertex  $i$ , labeled with the probability  $t_{ij}$ , whenever  $t_{ij} > 0$ . For example, in the case of a two-state Markov process as described earlier, the transition diagram takes the following form:

This graphical representation is particularly useful for visualizing the structure of the Markov chain, understanding the possible state transitions, and analyzing the overall behavior of the chain in terms of state probabilities and sequences of

thus the only possibility is that  $c_1 = 1$  and the second claim is proved.

In fact, even if the algebraic and geometric multiplicities of eigenvalues do not coincide we reach the same conclusion using a more detailed study of the root subspaces of the matrix  $T$ . (We meet them when discussing the Jordan matrix decomposition later in this chapter.) Consequently, even in the general case the eigensubspace  $\text{span}\{x_\infty\}$  comes with the unique invariant  $(n - 1)$ -dimensional complement, on which are all eigenvalues in absolute value smaller than one and the corresponding components in  $x_k$  approach zero as before. See the note 3.4.11 where we finish this argument in detail.  $\square$

**3.3.6. Iteration of the stochastic matrices.** We reformulate the previous theorem into a simple, but surprising result. By convergence to a limit matrix in the following theorem we mean the following: if we say that we want to bound the possible error  $\varepsilon > 0$ , then we can find a lower bound on the number of iterations  $k$  after which all the components of the matrix differ from the limit one by less than  $\varepsilon$ .

**Corollary.** Let  $T$  be a primitive stochastic matrix from a Markov process and let  $x_\infty$  be the stochastic eigenvector for the dominant eigenvalue 1 (as in the Ergodic Theorem above). Then the iterations  $T^k$  converge to the limit matrix  $T_\infty$ , whose columns all equal to  $x_\infty$ .

**PROOF.** Columns in the matrix  $T^k$  are images of the vectors of the standard basis under the corresponding iterated linear mapping. But these are images of the stochastic vectors and thus they all converge to  $x_\infty$ .  $\square$

**3.3.7. Final brief remark.** Before leaving the Markov processes, we shortly mention their more general versions with matrices which are not primitive. Here we would need the full Frobenius-Perron theory. Without going into technicalities, consider a process with a block wise diagonal or an upper triangular matrix  $T$ ,

$$T = \begin{pmatrix} P & R \\ 0 & Q \end{pmatrix}$$

and imagine first that  $P, Q$  are primitive and  $R = 0$ . Here we can again apply the above results block wise. In words, if we start in a stay  $x_0$  with all probability concentrated in the first block of coordinates, the process converges to the value  $x_\infty$  which again has all the probability distributed among the first block of coordinates, and the same for the other block.

If  $R > 0$  then we can always jump to the states corresponding to the first block from those in the second block with a non-zero probability and the iterations get more complicated:

$$\begin{aligned} T^2 &= \begin{pmatrix} P^2 & P \cdot R + R \cdot Q \\ 0 & Q^2 \end{pmatrix} \\ T^3 &= \begin{pmatrix} P^3 & P^2 \cdot R + P \cdot R \cdot Q + R \cdot Q^2 \\ 0 & Q^3 \end{pmatrix}. \end{aligned}$$

transitions, see 3.C.12 for another example.

b) Be aware that other authors may define the transition matrix  $T = (t_{ij})$  with  $t_{ij}$  being the probability of a transition from state  $i$  to state  $j$ , that is  $t_{ij} = P(X_n = j | X_{n-1} = i)$ . This is the opposite convention of ours, producing a row-stochastic matrix whose transpose matrix is our transition matrix.

**3.C.12. Absent-minded professor.** An absent-minded professor always carries an umbrella with him, but with probability of  $1/2$  he forgets it from wherever he is leaving. His daily routine is strict: in the morning he walks from his house to his office; from there, he goes to a restaurant for lunch, then returns to his office, and finally in the evening, he returns home. It is assumed the professor does not visit other locations, and if he forgets his umbrella at the restaurant, it remains there until his next visit. This situation can be modeled as a Markov process. Determine its transition matrix, diagram, and calculate the probability that after many days, in the morning, the umbrella is at the restaurant.

**Solution.** We assume as time unit the daytime, from morning to the next morning, and denote by  $X_n$  the place where the umbrella sits in the morning of the  $n$ th day. This defines a (homogeneous) Markov process  $\{X_n : n \in \mathbb{N}\}$ , with state space  $S = \{s_1 = \text{house}, s_2 = \text{office}, s_3 = \text{restaurant}\}$ . For simplicity we represent these states as  $\{1, 2, 3\}$ . Let us proceed with the transition matrix  $T = (t_{ij})$ , where  $t_{ij} = P(X_{n+1} = i | X_n = j)$  and  $1 \leq i, j \leq 3$ . We explain the computations for the first column and leave the verification of the rest two to the reader. By definition,  $t_{11} = P(X_{n+1} = 1 | X_n = 1)$ , and hence this is the probability that the umbrella starts its day at home and stays there till next morning. There are three distinct possibilities  $p_1, p_2, p_3$  for this scenario:

$p_1$ : The umbrella stays at home in the morning. Thus  $p_1 = \frac{1}{2}$ .  
 $p_2$ : The umbrella arrives to the office, it stays there during lunch, but in the evening is moved back to home. Thus  $p_2 = \frac{1}{2} \cdot \frac{1}{2} \cdot \frac{1}{2} = \frac{1}{8}$ .  
 $p_3$ : The professor takes the umbrella with him all the time and does not forget it somewhere. Thus  $p_3 = \frac{1}{2} \cdot \frac{1}{2} \cdot \frac{1}{2} \cdot \frac{1}{2} = \frac{1}{16}$  and in total  $t_{11} = p_1 + p_2 + p_3 = \frac{11}{16}$ .

Next,  $t_{21} = P(X_{n+1} = 2 | X_n = 1)$  is the probability that the umbrella starts its day at home and the next morning sits in the office. There are two possibilities  $q_1, q_2$  for such a scenario:

$q_1$ : The umbrella arrives to the office, it stays there during lunch, and in the evening it remains again there. Thus  $q_1 = \frac{1}{2} \cdot \frac{1}{2} \cdot \frac{1}{2} = \frac{1}{8}$ .  
 $q_2$ : The umbrella arrives to the office, then to the restaurant, then back to the office, and in the evening it remains at the office. Thus  $q_2 = \frac{1}{2} \cdot \frac{1}{2} \cdot \frac{1}{2} \cdot \frac{1}{2} = \frac{1}{16}$  and in total  $t_{21} = \frac{1}{8} + \frac{1}{16} = \frac{3}{16}$ . Finally for  $t_{31}$  we have  $t_{31} = 1 - t_{11} - t_{21} = 1/8$ . The repetition of this procedure for the rest entries of  $T$  yields

$$T = \begin{pmatrix} 11/16 & 3/8 & 1/4 \\ 3/16 & 3/8 & 1/4 \\ 1/8 & 1/4 & 1/2 \end{pmatrix}.$$

An interesting special case is when  $P = E$  and  $R$  is positive. Then  $Q - E$  must be a regular matrix and a simple computation yields the general iteration (notice  $E$  and  $Q$  commute and thus  $(E - Q)(E + Q + \dots + Q^{k-1}) = E - Q^k$ )

$$T^k = \begin{pmatrix} E & R(E - Q)^{-1}(E - Q^k) \\ 0 & Q^k \end{pmatrix}.$$

Thus, the entire first block of states is formed by eigenvectors with eigenvalue 1 (so these states stay constant with probability 1), while the behavior on the other block is more complicated.

### 4. More matrix calculus

We have seen that understanding the inner structure of matrices is a strong tool for both computation and analysis. It is even more true when considering numerical calculations with matrices. Therefore we return now to the abstract theory.

We introduce special types of linear mappings on vector spaces. We consider general linear mappings whose structure is understood in terms of the Jordan normal form (see 3.4.10). In all these cases, complex scalars are essential. So we extend our discussion of scalar product (see 2.3.18–2.3.22) to complex vector spaces. Actually, in many areas the complex vector spaces are the essential platform necessary for introducing the mathematical models. For instance, this is the case in the so-called quantum computing, which became a very active area of theoretical computer science. Many people hope to construct an effective quantum computer soon.

**3.4.1. Unitary spaces and mappings.** The definitions of scalar product and orthogonality easily extend to the complex case. But we do not mean the complex bilinear symmetric forms  $\alpha$ , since there the quadratic expressions  $\alpha(v, v)$  are not real in general and thus we would not get the right definition of length of vectors. Instead, we define:

#### UNITARY SPACES

*Unitary space* is a complex vector space  $V$  along with the mapping  $V \times V \rightarrow \mathbb{C}$ ,  $(u, v) \mapsto u \cdot v$  called *scalar product* and satisfying for all vectors  $u, v, w \in V$  and scalars  $a \in \mathbb{C}$  the following axioms:

- (1)  $u \cdot v = \overline{v \cdot u}$  (the bar stands for complex conjugation),
- (2)  $(au) \cdot v = a(u \cdot v)$ ,
- (3)  $(u + v) \cdot w = u \cdot w + v \cdot w$ ,
- (4) if  $u \neq 0$ , then  $u \cdot u > 0$  (notice  $u \cdot u$  is always real).

The real number  $\sqrt{v \cdot v}$  is called the *norm of the vector*  $v$  and a vector is *normalized*, if its norm equals one. Vectors  $u$  and  $v$  are said to be *orthogonal* if their scalar product is zero. A basis composed of mutually orthogonal and normalized vectors is called an *orthonormal basis* of  $V$ .

As for the transition graph it has the following form:

For the final task compute the eigenvector of  $T$  corresponding to the dominant eigenvalue 1. It is given by  $(y_1 = 2, y_2 = 1, y_3 = 1)^T$ , and we should rescale it to obtain the desired probability. This equals to  $y_3/(y_1 + y_2 + y_3) = 1/4$ .  $\square$

Let  $\{X_n : n \geq 0\}$  be a (homogeneous) Markov process with transition matrix  $T = (t_{ij})$  and let  $x^{(n)}$  be the probability distribution of the states at the  $n$ th transition, i.e., the vector whose  $i$ th component describes the probability of the system to be in state  $i$  after  $n$  steps:  $x_i^{(n)} = P(X_n = i)$ . We have  $\sum_i x_i^{(n)} = 1$  and it follows that each  $x^{(n)}$  is a stochastic vector. Moreover, in terms of the matrix  $T$  we know that  $x^{(n+1)} = Tx^{(n)}$ , which gives  $x^{(n)} = T^n x^{(0)}$ . This makes the Markov process computationally very tractable, since once  $T$  is known one can use matrix calculus to compute  $T^n$ . Let us describe such applications.

**3.C.13. Experiment in a laboratory.** In a laboratory an experiment is carried on with the same probability of success and failure. If the experiment succeeds, the probability of success of the second experiment is 0.7. If the first experiment fails, the probability of success of the second experiment is 0.6. This process is continued indefinitely. For any  $n \in \mathbb{N}$  determine the probability that the  $n$ th experiment is successful.

**Solution.** This is a two-state Markov process  $\{X_n : n \in \mathbb{N}\}$  with transition matrix

$$T = \begin{pmatrix} 7/10 & 3/5 \\ 3/10 & 2/5 \end{pmatrix}.$$

The corresponding state space admits the description {success, failure} which here we denote by  $\{1, 2\}$ . Now, for  $n \in \mathbb{N}$  consider the stochastic vectors  $x^{(n)} = (x_1^{(n)}, x_2^{(n)})^T$ , where  $x_1^{(n)}$  is the probability of the success of the  $n$ th experiment and  $x_2^{(n)}$  is the probability of its failure, that is,

$$\begin{aligned} x_1^{(n)} &= P(X_n = 1), \\ x_2^{(n)} &= P(X_n = 2) = 1 - x_1^{(n)}. \end{aligned}$$

By assumption we have  $x^{(1)} = (1/2, 1/2)^T$ , and by the theoretical result in 3.3.5 we obtain the relation

$$x^{(2)} = Tx^{(1)} = (13/20, 7/20)^T.$$

Similarly, for general  $n \in \mathbb{N}$  and the relation  $x^{(n+1)} = Tx^{(n)}$ , we obtain  $x^{(n+1)} = T^2 x^{(n-1)} = \dots = T^n x^{(1)}$ .

At first sight this is an extension of the definition of Euclidean vector spaces into the complex domain. We will continue to use the alternative notation  $\langle u, v \rangle$  for the scalar product of vectors  $u$  and  $v$ . As in the real domain, we obtain immediately from the definition the following simple properties of the scalar product for all vectors in  $V$  and scalars in  $\mathbb{C}$ :

$$\begin{aligned} u \cdot u &\in \mathbb{R} \\ u \cdot u &= 0 \quad \text{if and only if} \quad u = 0 \\ u \cdot (av) &= \bar{a}(u \cdot v) \\ u \cdot (v + w) &= u \cdot v + u \cdot w \\ u \cdot 0 &= 0 \cdot u = 0 \\ \left(\sum_i a_i u_i\right) \cdot \left(\sum_j b_j v_j\right) &= \sum_{i,j} a_i \bar{b}_j (u_i \cdot v_j), \end{aligned}$$

where the last equality holds for all finite linear combinations. It is a simple exercise to prove everything formally. For instance, the first property follows from (1) since the product  $u \cdot u$  has to be the complex conjugate to itself.

A standard example of the scalar product over the complex vector space  $\mathbb{C}^n$  is

$$(x_1, \dots, x_n)^T \cdot (y_1, \dots, y_n)^T = x_1 \bar{y}_1 + \dots + x_n \bar{y}_n.$$

This expression is also called the standard (positive definite) Hermitian form on  $\mathbb{C}^n$ . By conjugation of the coordinates of the second argument, this mapping satisfies all the required properties. The space  $\mathbb{C}^n$  with this scalar product is called the *standard unitary space* of dimension  $n$ . We can denote this scalar product of vectors  $x$  and  $y$  with matrix notation as  $\bar{y}^T \cdot x$  (here the complex conjugation indicated by the bar is performed on all components of  $y$ ).

As usual, those mappings which leave the additional structure invariant are of great importance.

#### UNITARY MAPPINGS

A linear mapping  $\varphi : V \rightarrow W$  between unitary spaces is called a *unitary mapping*, if for all vectors  $u, v \in V$

$$u \cdot v = \varphi(u) \cdot \varphi(v).$$

*Unitary isomorphism* is a bijective unitary mapping.

**3.4.2. Real and complex spaces with scalar product.** In the previous chapter we have already derived some simple properties of spaces with scalar products. The properties and proofs are very similar to the complex case.

In the sequel we shall work with real and complex spaces simultaneously and write  $\mathbb{K}$  for  $\mathbb{R}$  or  $\mathbb{C}$ . In the real case the conjugation is just the identity mapping (it is the restriction of the conjugation in the complex plane to the real line). As in the real case, we define the *orthogonal complement* for a vector subspace  $U \subset V$  in the unitary space  $V$  as

$$U^\perp = \{v \in V; u \cdot v = 0 \text{ for all } u \in U\},$$

which is clearly also a vector subspace in  $V$ .

Next we compute  $T^n$ . By running the following command in Sage we verify that  $T$  is diagonalizable and obtain its eigenvalues: The block

```
A=matrix(QQ, [[7/10, 3/5], [3/10, 2/5]])
A.eigenvalues()
```

Thus, the built-in function `A.is_diagonalizable()` provides a straightforward method to determine if a matrix  $A$  is diagonalizable. We also obtain the eigenvalues  $\lambda_1 = 1$  and  $\lambda_2 = 0.1$ .

As eigenvectors we choose the vectors  $e_1 = (2, 1)$  and  $e_2 = (-1, 1)$ . Since  $T$  is diagonalizable, we can compute  $T^n$  by applying the same method as in 3.B.6. Hence we should compute  $T^n = PD^nP^{-1}$ , where  $P = \begin{pmatrix} 2 & -1 \\ 1 & 1 \end{pmatrix}$  and  $D = \text{diag}(\lambda_1, \lambda_2) = \text{diag}(1, 1/10)$ . This gives

$$T^n = \frac{1}{3} \begin{pmatrix} 2 + 10^{-n} & 2 - 2 \cdot 10^{-n} \\ 1 - 10^{-n} & 1 + 2 \cdot 10^{-n} \end{pmatrix}, \quad n \in \mathbb{N}.$$

Here is a verification in Sage:

```
T=matrix(SR, [[7/10, 3/5], [3/10, 2/5]])
P=matrix(SR, [[2, -1], [1, 1]])
n=var("n")
D=matrix(SR, [[1**n, 0], [0, (1/10)**n]])
Tn=P*D*P.inverse(); Tn
```

Now, matrix multiplication of  $T^n$  with the vector  $x^{(1)}$  gives

$$x^{(n+1)} = \left( \frac{2}{3} - \frac{1}{6 \cdot 10^n}, \frac{1}{3} + \frac{1}{6 \cdot 10^n} \right)^T, \quad n \in \mathbb{N}.$$

Thus, for big  $n$  the probability of success of the  $n$ th experiment is close to  $2/3$ . In other words, for large  $n$  we have  $x_1^{(n+1)} \approx 2/3$ .  $\square$

To summarize, another significant advantage of studying Markov chains is their ability to predict the long-term behaviour of a system. Let us illustrate this fact with a straightforward example, related to forecasting weather pattern.

**3.C.14. Weather expectations.** Suppose that the days are divided into warm, medium, and cold, and that the following hold:

1. After a warm day the next day is warm with possibility 50%, and is medium with possibility 30%;
2. After a medium day the next day is medium with possibility 40%, and cold with possibility 30%;
3. After a cold day, the next day is cold with possibility 50% and medium with possibility 30%.

Without any further information, derive how many warm, medium and cold days can be expected in a year.

**Solution.** The problem is clearly a Markov process, since it is assumed that the daily weather depends only on the weather of the previous day.

Although we deal exclusively with finitely-dimensional spaces now, the results in the next two theorems have a natural generalization for Hilbert spaces, which are infinitely-dimensional spaces with scalar products. We shall meet them later, in connection with approximation in vector spaces of real or complex valued functions.

**Theorem.** For every finitely-dimensional space  $V$  of dimension  $n$  with scalar product we have:

- (1) There exists an orthonormal basis in  $V$ .
- (2) Every system of non-zero orthogonal vectors in  $V$  is linearly independent and can be extended to an orthogonal basis.
- (3) For every system of linearly independent vectors  $(u_1, \dots, u_k)$  there exists an orthonormal basis  $(v_1, \dots, v_n)$  such that  $\langle v_1, \dots, v_i \rangle = \langle u_1, \dots, u_i \rangle$ , for all  $1 \leq i \leq k$ , i.e. its vectors consecutively generate the same subspaces as the vector  $u_j$ .
- (4) If  $(u_1, \dots, u_n)$  is an orthonormal basis  $V$ , then the coordinates of every vector  $u \in V$  are expressed via

$$u = (u \cdot u_1)u_1 + \dots + (u \cdot u_n)u_n.$$

- (5) In any orthonormal basis, the scalar product has the coordinate form

$$u \cdot v = \bar{y}^T \cdot x = x_1\bar{y}_1 + \dots + x_n\bar{y}_n$$

where  $x$  and  $y$  are columns of coordinates of the vectors  $u$  and  $v$  in a chosen basis. Notably, every  $n$ -dimensional space with scalar product is isomorphic to the standard Euclidean  $\mathbb{R}^n$  or the unitary  $\mathbb{C}^n$ .

- (6) The orthogonal sum of unitary subspaces  $V_1 + \dots + V_k$  in  $V$  is always a direct sum.
- (7) If  $A \subset V$  is an arbitrary subset, then  $A^\perp \subset V$  is a vector subspace (and thus also unitary), and  $(A^\perp)^\perp \subset V$  is exactly the subspace generated by  $A$ . Furthermore,  $V = \text{span } A \oplus A^\perp$ .
- (8)  $V$  is an orthogonal sum of  $n$  one-dimensional unitary subspaces.

**PROOF.** (1), (2), (3): First we extend the given system of vectors into any basis  $(u_1, \dots, u_n)$  of the space  $V$  and then start the Gram-Schmidt orthogonalization from 2.3.21. This procedure works in the complex case. It yields an orthogonal basis with properties as required in (3). But from the Gram-Schmidt orthogonalization algorithm it is clear that if the original  $k$  vectors formed an orthogonal system of vectors, then they continue to do so after the orthogonalization process is applied. Thus we have also proved (2) and (1).

- (4): If  $u = a_1u_1 + \dots + a_nu_n$ , then

$$u \cdot u_i = a_1(u_1 \cdot u_i) + \dots + a_n(u_n \cdot u_i) = a_i \|u_i\|^2 = a_i$$

- (5): If  $u = x_1u_1 + \dots + x_nu_n, v = y_1u_1 + \dots + y_nu_n$ , then

$$\begin{aligned} u \cdot v &= (x_1u_1 + \dots + x_nu_n) \cdot (y_1u_1 + \dots + y_nu_n) \\ &= x_1\bar{y}_1 + \dots + x_n\bar{y}_n. \end{aligned}$$

This has a 3-dimensional state space  $S = \{w, m, c\}$ , where  $w$  is for warm,  $m$  for medium and  $c$  for cold., and state transition matrix given by  $T = \begin{pmatrix} 0.5 & 0.3 & 0.2 \\ 0.3 & 0.4 & 0.3 \\ 0.2 & 0.3 & 0.5 \end{pmatrix}$ .

Let us now consider the probabilistic vector  $x^{(n)} = (x_w^{(n)}, x_m^{(n)}, x_c^{(n)})^T$ , whose components are the probabilities the  $n$ th day to be warm, medium or cold. We indicate them by the numbers  $x_w^{(n)} = P(X_n = w)$ ,  $x_m^{(n)} = P(X_n = m)$ , and  $x_c^{(n)} = P(X_n = c)$ , respectively. Since all the elements  $T$  are positive, there exists a probabilistic vector  $x_\infty = (x_\infty^w, x_\infty^m, x_\infty^c)^T$ , which the vector  $x^{(n)}$  approaches as  $n$  grows. By the corollary of the Perron-Frobenius theorem (see 3.3.4),  $x_\infty$  must be the eigenvector of  $T$  corresponding to the eigenvalue 1. This gives rise to the condition  $Tx_\infty = x_\infty$ , which together with the condition that the vector  $x_\infty$  is stochastic, yield the following system of equations:

$$\begin{aligned} x_\infty^w &= 0.5 x_\infty^w + 0.3 x_\infty^m + 0.2 x_\infty^c, \\ x_\infty^m &= 0.3 x_\infty^w + 0.4 x_\infty^m + 0.3 x_\infty^c, \\ x_\infty^c &= 0.2 x_\infty^w + 0.3 x_\infty^m + 0.5 x_\infty^c, \\ 1 &= x_\infty^w + x_\infty^m + x_\infty^c. \end{aligned}$$

It is easy to see that  $x_\infty^w = x_\infty^m = x_\infty^c = \frac{1}{3}$  is the unique solution of this system. Thus, one should expect roughly the same number of warm, medium and cold days.  $\square$

The column-stochastic matrix  $T$  in Problem 3.C.14 is symmetric,  $T^T = T$ . Consequently, it is also “row-stochastic”, indicating that the sum of the entries in any row is one. A matrix which is both column- and row-stochastic is called a “doubly stochastic matrix”. A significant property of every doubly stochastic primitive matrix is that the corresponding vector  $x_\infty$  has all its components identical, as above. This means that, after sufficiently many iterations, all states in the corresponding Markov chain are reached with the same frequency.

A series of additional problems related to Markov chains is presented in Section F. In this section we address the development of an algorithm for determining the importance of web pages (see 3.F.20), along with other compelling tasks.

### D. More matrix calculus

In this section we explore fundamental concepts of linear algebra that underpin advanced applications across diverse fields. We begin with the notion of “unitary spaces”, see also 3.4.1.

Given the vector space  $V = \mathbb{F}^n$ , where  $\mathbb{F}$  is either  $\mathbb{R}$  or  $\mathbb{C}$ , consider the standard scalar product  $\langle \cdot, \cdot \rangle : V \times V \rightarrow \mathbb{F}$  defined by  $\langle x, y \rangle := \sum_j x_j \bar{y}_j = x^T \bar{y}$ , where  $x = (x_1, \dots, x_n)^T$  and  $y = (y_1, \dots, y_n)^T$  are vectors in  $\mathbb{F}^n$ , and the last expression is in terms of matrices. Since  $x^T \bar{y} \in \mathbb{F}$  is a scalar, we have  $x^T \bar{y} = (x^T \bar{y})^T = \bar{y}^T x = y^* x$ ,

(6): We need to show that for any tuple  $V_i, V_j$  from the given subspaces their intersection is the zero vector. If  $u \in V_i$  and  $u \in V_j$ , then  $u \perp u$ , that is,  $u \cdot u = 0$ . This is possible only for the zero vector  $u \in V$ .

(7): Let  $u, v \in A^\perp$ . Then  $(au + bv) \cdot w = 0$  for all  $w \in A$ ,  $a, b \in \mathbb{K}$  (from the distributivity of the scalar product). Thus  $A^\perp$  is a subspace in  $V$ . Let  $(v_1, \dots, v_k)$  be a basis of  $\text{span } A$  chosen among the elements of  $A$ , and let  $(u_1, \dots, u_k)$  be the orthonormal basis resulting from the Gram-Schmidt orthogonalization of the vectors  $(v_1, \dots, v_k)$ . We extend it to an orthonormal basis of the whole  $V$  (both exist by the already proven parts of this proposition). Because it is an orthogonal basis, necessarily  $\text{span}\{u_{k+1}, \dots, u_n\} = \text{span}\{u_1, \dots, u_k\}^\perp = A^\perp$  and  $A \subset \text{span}\{u_{k+1}, \dots, u_n\}^\perp$  (this follows from expressing the coordinates under the orthonormal basis). If  $u \perp \text{span}\{u_{k+1}, \dots, u_n\}$ , then  $u$  is necessarily a linear combination of the vectors  $u_1, \dots, u_k$ , but that happens whenever it is a linear combination of the vectors  $v_1, \dots, v_k$ , which is equivalent to  $u$  being in  $\text{span } A$ .

(8): This is equivalent to the formulation of the existence of the orthonormal basis.  $\square$

### 3.4.3. Important properties of the norm.

Now we have everything prepared for basic properties related to our definition of the norm of vectors. We speak also of the *length of vectors* defined by the scalar product. Note also that all claims always consider finite sets of vectors, Their validity does not depend on the dimension of the space  $V$  where it all takes place.

#### PROPERTIES OF NORM

**Theorem.** Let  $V$  be a vector space with scalar product,  $u$  and  $v$  vectors in  $V$ . Then

(1)  $\|u + v\| \leq \|u\| + \|v\|$ . Equality holds if and only if  $u$  and  $v$  are linearly dependent. This is called the **triangle inequality**.

(2)  $|u \cdot v| \leq \|u\| \|v\|$ . Equality holds if and only if  $u$  and  $v$  are linearly dependent. This property is called the **Cauchy inequality**.

(3) If  $(e_1, \dots, e_k)$  is an orthonormal system of vectors, then  $\|u\|^2 \geq |u \cdot e_1|^2 + \dots + |u \cdot e_k|^2$ .

This property is called the **Bessel inequality**.

(4) If  $(e_1, \dots, e_k)$  is an orthonormal system of vectors, then  $u \in \text{span}\{e_1, \dots, e_k\}$  if and only if

$$\|u\|^2 = |u \cdot e_1|^2 + \dots + |u \cdot e_k|^2.$$

This is called the **Parseval equality**.

(5) If  $(e_1, \dots, e_k)$  is an orthonormal system of vectors and  $u \in V$ , then the vector

$$w = (u \cdot e_1)e_1 + \dots + (u \cdot e_k)e_k$$

is the only vector which minimizes the norm  $\|u - v\|$  among all  $v \in \text{span}\{e_1, \dots, e_k\}$ .

where  $y^* := \bar{y}^T$ . Hence, we can equivalently express  $\langle \cdot, \cdot \rangle$  as

$$\langle x, y \rangle = x^T \bar{y} = y^* x.$$

By convention,  $\langle \cdot, \cdot \rangle$  is linear in the first argument but conjugate linear in the second one, in the sense that  $\langle ax, y \rangle = a \langle x, y \rangle$  but  $\langle x, ay \rangle = \bar{a} \langle x, y \rangle$ , for all  $x, y \in V$  and  $a \in \mathbb{F}$ .

The scalar product  $\langle \cdot, \cdot \rangle$  induces a norm on  $\mathbb{F}^n$  defined by  $\|x\|^2 = \langle x, x \rangle = \sum_{j=1}^n |x_j|^2$ .<sup>11</sup> Ensure that  $\|\cdot\|$  satisfies the defining properties of a norm, that is,

- $\|x\| \geq 0$  with  $\|x\| = 0$  if and only if  $x = 0$ ,
- $\|ax\| = |a| \|x\|$ , for any  $a \in \mathbb{F}$  and  $x \in \mathbb{F}^n$
- $\|x + y\| \leq \|x\| + \|y\|$ , for any  $x, y \in \mathbb{F}^n$ .

Next we will adopt the following terminology:

$$\langle \cdot, \cdot \rangle = \begin{cases} \text{standard dot product,} & \text{for } V = \mathbb{R}^n, \\ \text{standard Hermitian form,} & \text{for } V = \mathbb{C}^n, \end{cases}$$

This notation is consistent with what is used in Chapter 2 for the real case. Both spaces  $\mathbb{R}^n, \mathbb{C}^n$  endowed with  $\langle \cdot, \cdot \rangle$  provide examples of unitary spaces (also known as inner product spaces), as defined in 3.4.1. On the other hand, the distance map  $d : V \times V \rightarrow \mathbb{R}$ , defined by  $d(x, y) = \|x - y\|$ , establishes  $V = \mathbb{F}^n$  as a “metric space”, a fundamental concept in analysis which we will explore in Chapter 7

Next, we will see that unitary spaces extend beyond  $\mathbb{R}^n$  and  $\mathbb{C}^n$ , with many other examples existing. We begin with the following task, which is left as an easy challenge for you.

**3.D.1.** Consider the vector space  $\mathbb{C}^3$ , endowed with the standard Hermitian form  $\langle x, y \rangle = \sum_k x_k \bar{y}_k$  and the induced norm  $\|\cdot\|$ . Given the vectors  $x = (3 + 2i, 1 - i, -i)^T$  and  $y = (2 - 2i, 1 - i, 2 + i)^T$ , compute the inner product  $\langle x, y \rangle$ , the distance  $d(x, y) = \|x - y\|$ , and the normalized vectors  $\hat{x}, \hat{y}$  corresponding to  $x, y$ , with  $\|\hat{x}\| = 1 = \|\hat{y}\|$ .  $\circ$

**3.D.2.** When using Sage to compute scalar products of complex vectors, we need to be cautious. Sage permits the use of the standard command `x.dot_product(y)`, as discussed in Chapter 2 (see for example 2.C.45), to complex vectors as well. However, the handling of complex vectors may require special attention to ensure correct application and interpretation of the standard Hermitian scalar product.

For example, let us use the vectors  $x, y$  given in 3.D.1. Execute the cell

```
x = vector(CDF, [3+2*I, 1-I, -I])
y = vector(CDF, [2-2*I, 1-I, 2+I])
y.dot_product(x)
```

In this case Sage prints out the expression  $11.0 - 6.0 * I$ , which does not match the result obtained using the standard rule  $\langle x, y \rangle = \sum_i x_i \bar{y}_i$ . To obtain the correct result we should use the cell

<sup>11</sup>If  $z_j = x_j + iy_j \in \mathbb{C}$  recall that  $\bar{z}_j = x_j - iy_j$  and  $|z_j|^2 = x_j^2 + y_j^2$ .

**PROOF.** The verifications are all based on direct computations:

(2): The result is obvious if  $v = 0$ . Otherwise, define the vector  $w = u - \frac{u \cdot v}{v \cdot v} v$ , that is,  $w \perp v$  and compute

$$\begin{aligned} \|w\|^2 &= \|u\|^2 - \frac{(u \cdot v)^2}{\|v\|^2} - \frac{u \cdot v}{\|v\|^2} (v \cdot u) + \frac{(u \cdot v)(\overline{u \cdot v})}{\|v\|^4} \|v\|^2 \\ \|w\|^2 \|v\|^2 &= \|u\|^2 \|v\|^2 - 2(u \cdot v)(\overline{u \cdot v}) + (u \cdot v)(\overline{u \cdot v}) \end{aligned}$$

These are non-negative real values and thus,  $\|u\|^2 \|v\|^2 \geq |u \cdot v|^2$  and the equality holds if and only if  $w = 0$ , that is, whenever  $u$  and  $v$  are linearly dependent.

(1): It suffices to compute

$$\begin{aligned} \|u + v\|^2 &= \|u\|^2 + \|v\|^2 + u \cdot v + v \cdot u \\ &= \|u\|^2 + \|v\|^2 + 2 \operatorname{Re}(u \cdot v) \\ &\leq \|u\|^2 + \|v\|^2 + 2|u \cdot v| \leq \|u\|^2 + \|v\|^2 + 2\|u\| \|v\| \\ &= (\|u\| + \|v\|)^2 \end{aligned}$$

Since we deal with squares of non-negative real numbers, this means that  $\|u + v\| \leq \|u\| + \|v\|$ . Furthermore, equality implies that in all previous inequalities equality also holds. This is equivalent to the condition that  $u$  and  $v$  are linearly dependent (using the previous part).

(3), (4): Let  $(e_1, \dots, e_k)$  be an orthonormal system of vectors. We extend it to an orthonormal basis  $(e_1, \dots, e_n)$  (that is always possible by the previous theorem). Then, again using the previous theorem, we have for every vector  $u \in V$

$$\|u\|^2 = \sum_{i=1}^n (u \cdot e_i)(\overline{u \cdot e_i}) = \sum_{i=1}^n |u \cdot e_i|^2 \geq \sum_{i=1}^k |u \cdot e_i|^2$$

But that is the Bessel inequality. Furthermore, equality holds if and only if  $u \cdot e_i = 0$  for all  $i > k$ , which proves the Parseval equality.

(5): Choose an arbitrary  $v \in \operatorname{span}\{e_1, \dots, e_k\}$  and extend the given orthonormal system to the orthonormal basis  $(e_1, \dots, e_n)$ . Let  $(u_1, \dots, u_n)$  and  $(x_1, \dots, x_k, 0, \dots, 0)$  be coordinates of  $u$  and  $v$  under this basis. Then

$$\|u - v\|^2 = |u_1 - x_1|^2 + \dots + |u_k - x_k|^2 + |u_{k+1}|^2 + \dots + |u_n|^2$$

and this expression is clearly minimized when choosing the individual vectors to be  $x_1 = u_1, \dots, x_k = u_k$ .  $\square$

**3.4.4. Unitary and orthogonal mappings.** The properties of orthogonal mappings have direct analogues in the complex domain. We can easily formulate them and prove together:

**Proposition.** Consider the linear mapping (endomorphism)  $\varphi : V \rightarrow V$  on the (real or complex) space with scalar product. Then the following conditions are equivalent.

- (1)  $\varphi$  is unitary or orthogonal transformation,
- (2)  $\varphi$  is linear isomorphism and for every  $u, v \in V$

$$\varphi(u) \cdot v = u \cdot \varphi^{-1}(v),$$

- (3) the matrix  $A$  of the mapping  $\varphi$  in any orthonormal basis satisfies  $A^{-1} = \bar{A}^T$  (for Euclidean spaces this means that  $A^{-1} = A^T$ ),

```
x = vector(CDF, [3+2*I, 1-I, -I])
y = vector(CDF, [2-2*I, 1-I, 2+I])
y.hermitian_inner_product(x)
```

which returns  $3.0 + 8.0 * I$ .

**Remark.** It is important to note that in Sage the command `x.hermitian_inner_product(y)` prints out the expression  $3.0 - 8.0 * I$ . Therefore, Sage uses the rule  $\sum_i \bar{x}_i y_i$ , instead of our rule  $\sum_i x_i \bar{y}_i$ . In summary, when computing the standard Hermitian form of complex vectors  $x, y \in \mathbb{C}^n$ , to stay consistent with our conventions, we should use the rule

$$\langle x, y \rangle = y^* x = y.\text{hermitian\_inner\_product}(x).$$

An alternative is based on the `dot.product` function and goes as follows:

```
u.dot_product(v.conjugate())
```

This corresponds to  $\langle u, v \rangle$  for two complex vectors  $u, v$ .

**3.D.3.** Use the standard Hermitian form  $\langle v, w \rangle = \sum_i v_i \bar{w}_i$  to compute  $\langle v, w \rangle$ ,  $\|v\|^2$ ,  $\|w\|^2$  and the angle  $\theta$  between  $v, w$ , where these vectors are given as follows:

(a)  $v = (1 + i, 2 - i)^T, w = (3 - 2i, 1 + i)^T$  in  $\mathbb{C}^2$ ;

(b)  $v = (3, i)^T, w = (2 - i, 1 - i)^T$  in  $\mathbb{C}^2$ ;

(c)  $v = (-i, 0, 2)^T, w = (4, 1 - i, 1)^T$  in  $\mathbb{C}^3$ ;

Next verify your answers via Sage. ○

**3.D.4.** On  $V = \mathbb{F}^2$  for  $\mathbb{F} \in \{\mathbb{R}, \mathbb{C}\}$  consider the map

$$f((x_1, x_2)^T, (y_1, y_2)^T) = x_1 \bar{y}_1 + 4x_1 \bar{y}_2 + 4x_2 \bar{y}_1 + x_2 \bar{y}_2.$$

Does  $f$  define a scalar product on  $V$ ? ○

**3.D.5.** For  $x = (x_1, x_2)^T$  and  $y = (y_1, y_2)^T$  in  $\mathbb{R}^2$  set

$$g(x, y) := 2x_1 y_1 - x_1 y_2 - x_2 y_1 + 5x_2 y_2.$$

Show that  $g$  is a scalar product and compute its matrix relative to the standard basis of  $\mathbb{R}^2$ .

**Solution.** Linearity and symmetry can be easily proved. In addition, we see that

$$g(x, x) = 2x_1^2 - 2x_1 x_2 + 5x_2^2 = (x_1 + x_2)^2 + (x_1 - 2x_2)^2,$$

for all  $x \in \mathbb{R}$ . Thus  $g(x, x) \geq 0$ , in particular  $g(x, x) = 0$  if and only if  $x_1 + x_2 = 0$  and  $x_1 - 2x_2 = 0$ , which gives  $x = 0$ . Thus  $g$  is a scalar product. It is clearly different from the standard dot product. Its matrix with respect to the standard basis of  $\mathbb{R}^2$  is given by

$$A = \begin{pmatrix} g(e_1, e_1) & g(e_1, e_2) \\ g(e_2, e_1) & g(e_2, e_2) \end{pmatrix} = \begin{pmatrix} 2 & -1 \\ -1 & 5 \end{pmatrix},$$

such that  $g(x, y) = y^T A x$ . Observe, that  $A$  is symmetric and positive definite (recall that an element  $A \in \text{Mat}_n(\mathbb{R})$  is called a “positive definite matrix” when we have  $u^T A u > 0$  for any non-zero vector  $u \neq 0$  on  $\mathbb{R}^n$ ). □

**3.D.6.** Let  $a \neq b$  be some positive real numbers. Show that the rule  $\rho_{a,b}(u, v) := au_1 v_1 + bu_2 v_2$  defines a scalar product on  $\mathbb{R}^2$ , where  $u = (u_1, u_2)^T$  and  $v = (v_1, v_2)^T$ , respectively. Next, compute the angle between the vectors  $u = (1, 1)^T$  and

(4) the matrix  $A$  of a mapping  $\varphi$  in some orthonormal basis satisfies  $A^{-1} = \bar{A}^T$ ,

(5) the rows of the matrix  $A$  of the mapping  $\varphi$  in an orthonormal basis form an orthonormal basis of the space  $\mathbb{K}^n$  with standard scalar product,

(6) the columns of the matrix  $A$  of the mapping  $\varphi$  in an orthonormal basis form an orthonormal basis of the space  $\mathbb{K}^n$  with standard scalar product.

**PROOF.** (1)  $\Rightarrow$  (2): The mapping  $\varphi$  is injective, therefore it must be onto. Also  $\varphi(u) \cdot v = \varphi(u) \cdot \varphi(\varphi^{-1}(v)) = u \cdot \varphi^{-1}(v)$ .

(2)  $\Rightarrow$  (3): The standard scalar product is in  $\mathbb{K}^n$ . It is given for columns  $x, y$  of scalars by the expression  $x \cdot y = \bar{y}^T E x = \bar{y} x$ , where  $E$  is the unit matrix.

Property (2) thus means that the matrix  $A$  of the mapping  $\varphi$  is invertible and  $\bar{y}^T A x = (\bar{A}^{-1} y)^T x$ . This means that  $(\bar{y}^T A - (\bar{A}^{-1} y)^T) x = 0$  for all  $x \in \mathbb{K}^n$ . By substituting the complex conjugate of the expression in the parentheses for  $x$  we find that equality is possible only when  $\bar{A}^T = A^{-1}$ . (We may also rewrite the expression as  $\bar{y}^T (A - (\bar{A}^{-1})^T) x$  and see the conclusion by substituting the basis vectors for  $x$  and  $y$ .)

(3)  $\Rightarrow$  (4): This is an obvious implication.

(4)  $\Rightarrow$  (5) In the relevant basis, the claim is expressed via the matrix  $A$  of the mapping  $\varphi$  as the equation  $A \bar{A}^T = E$ , which is ensured by (4).

(5)  $\Rightarrow$  (6): We have  $|\bar{A}^T A| = |E| = |A \bar{A}^T| = |A| |\bar{A}| = 1$ , there exists the inverse matrix  $A^{-1}$ . But we also have  $A \bar{A}^T A = A$ , therefore also  $\bar{A}^T A = E$  which is expressed exactly by (6).

(6)  $\Rightarrow$  (1): In the chosen orthonormal basis

$$\varphi(u) \cdot \varphi(v) = (\overline{Ay})^T Ax = \bar{y}^T \bar{A}^T Ax = \bar{y}^T E x = \bar{y}^T x$$

where  $x$  and  $y$  are columns of coordinates of the vectors  $u$  and  $v$ . That ensures that the scalar product is preserved. □

Characterizations from the previous theorem deserve some notes. The matrices  $A \in \text{Mat}_n(\mathbb{K})$  with the property  $A^{-1} = \bar{A}^T$  are called *unitary matrices* for complex scalars (in the case  $\mathbb{R}$  we have already used the name *orthogonal matrices* for them). The definition itself immediately implies that a product of unitary (orthogonal) matrices is again unitary (orthogonal). The same is true for inverses. Unitary matrices thus form a subgroup  $U(n) \subset \text{GL}_n(\mathbb{C})$  in the group of all invertible complex matrices with the product operation. Orthogonal matrices form a subgroup  $O(n) \subset \text{GL}_n(\mathbb{R})$  in the group of real invertible matrices. We speak of a *unitary group* and of an *orthogonal group*.

The simple calculation

$$1 = \det E = \det(A \bar{A}^T) = \det A \overline{\det A} = |\det A|^2$$

shows that the determinant of a unitary matrix has norm equal to one. For real scalars the determinant is  $\pm 1$ . Furthermore, if  $Ax = \lambda x$  for a unitary or orthogonal matrix, then

$v = (1, -1)^T$  with respect to  $\rho_{2,1}$  and compare the result with the angle that occurs if we use the dot product on  $\mathbb{R}^2$ .  $\circ$

**3.D.7.** Suppose that  $A = (a_{ij})$  is a  $m \times n$  matrix over  $\mathbb{C}$ , whose column space has (complex) dimension  $n$ . Consider the mapping  $\rho_A : \mathbb{C}^n \times \mathbb{C}^n \rightarrow \mathbb{C}$  with  $\rho_A(x, y) = y^* A^* A x$ , where as usual  $A^* = \bar{A}^T$  denotes the transpose conjugate of a matrix  $A$ . Show that the pair  $(\mathbb{C}^n, \rho_A)$  is a unitary space.  $\circ$

**3.D.8.** Show that the rule  $\mathcal{B}(A, B) := \text{tr}(B^* A)$  defines a scalar product on the space  $\text{Mat}_{m,n}(\mathbb{F})$  of  $m \times n$  matrices with entries over  $\mathbb{F}$ , for  $\mathbb{F} \in \{\mathbb{R}, \mathbb{C}\}$ . This scalar product is known as the *Frobenius inner product*. 

**Solution.** For any  $A, B \in \text{Mat}_{m,n}(\mathbb{F})$ , the matrix  $B^* A$  is  $n \times n$ , and hence  $\mathcal{B}$  is well-defined. One can proceed by proving the axioms of a unitary space, as they are presented in 3.4.1. However, a direct calculation yields that

$$\mathcal{B}(A, B) = \sum_{i=1}^m \sum_{j=1}^n \bar{b}_{ij} a_{ij} = \sum_{i=1}^m \sum_{j=1}^n a_{ij} \bar{b}_{ij}$$

Hence, if we express  $A$  and  $B$  in terms of column vectors, say  $A = (A_1 \ \dots \ A_n)$  and  $B = (B_1 \ \dots \ B_n)$ , then  $\mathcal{B}(A, B) = \sum_{j=1}^n \langle A_j, B_j \rangle$ , which is the sum of the dot products of the vectors formed from the columns of the matrices  $A, B$ , respectively. Hence  $\mathcal{B}$  is a scalar product (as a sum of dot products). Otherwise, a direct proof is mainly based on the properties of the trace, described in 2.C.38 in Chapter 2. For instance, over the complex numbers we have  $\mathcal{B}(aA, B) = \text{tr}(B^*(aA)) = a \text{tr}(B^* A) = a\mathcal{B}(A, B)$  for any scalar  $a \in \mathbb{C}$  and any two elements  $A, B \in \text{Mat}_{m,n}(\mathbb{C})$ , and moreover, if  $C \in \text{Mat}_{m,n}(\mathbb{C})$  is another matrix, then

$$\begin{aligned} \mathcal{B}(A + C, B) &= \text{tr}(B^*(A + C)) = \text{tr}(B^* A) + \text{tr}(B^* C) \\ &= \mathcal{B}(A, B) + \mathcal{B}(C, B). \end{aligned}$$

Positive-definiteness occurs as follows: If  $A^* A$  has entries  $c_{ij}$ , then  $c_{ij} = \sum_{k=1}^n \bar{a}_{ki} a_{kj}$  and thus

$$\|A\|_{\mathcal{B}}^2 = \mathcal{B}(A, A) = \sum_{i=1}^n c_{ii} = \sum_{i,j} |a_{ij}|^2.$$

Hence, as soon as  $A \neq 0$ , we see that  $\mathcal{B}(A, A)$  is strictly positive,  $\mathcal{B}(A, A) > 0$ . We leave as an exercise a direct verification of the property  $\mathcal{B}(A, B) = \bar{\mathcal{B}}(B, A)$  for  $A, B \in \text{Mat}_{m,n}(\mathbb{C})$ .  $\square$

*In Chapter 7 we will encounter additional examples of unitary spaces. There, leveraging the concept of integration, which we will examine in Chapter 6, we will introduce inner products on spaces of polynomials and, more generally, on infinite-dimensional function spaces (see for example 7.1.1, 7.1.2 and see also the tasks 7.D.3, 7.D.4, 7.D.5, and 7.D.6). In this context, orthogonality becomes crucial, especially in Fourier analysis. For now, let us explore a few more elementary tasks related to orthogonality.*

$(Ax) \cdot (Ax) = x \cdot x = |\lambda|^2(x \cdot x)$ . Therefore the real eigenvalues of orthogonal matrices in the real domain are  $\pm 1$ . The eigenvalues of unitary matrices are always complex units in the complex plane.

The same argument as we have seen with the orthogonal mappings imply that orthogonal complements of invariant subspaces with respect to unitary mappings  $\varphi : V \rightarrow V$  are also invariant. Indeed, if  $\varphi(U) \subset U$ ,  $u \in U$  and  $v \in U^\perp$  are arbitrary, then

$$\varphi(v) \cdot \varphi(\varphi^{-1}(u)) = v \cdot \varphi^{-1}(u).$$

Because the restriction  $\varphi|_U$  is also unitary, it is a bijection. Notably  $\varphi^{-1}(u) \in U$ . But then  $\varphi(v) \cdot u = 0$ , because  $v \in U^\perp$ . Thus  $\varphi(v) \in U^\perp$ .

This leads to an immediate useful corollary in the complex domain

**Corollary.** *Let  $\varphi : V \rightarrow V$  be a unitary mapping of complex vector spaces. Then  $V$  is an orthogonal sum of one-dimensional eigensubspaces.*

**PROOF.** There exists at least one eigenvector  $v \in V$ , since complex eigenvalues always exist. Then the restriction of  $\varphi$  to the invariant subspace  $\langle v \rangle^\perp$  is again unitary and also has an eigenvector. After  $n$  such steps we obtain the desired orthogonal basis of eigenvectors. After normalising the vectors we obtain an orthonormal basis.  $\square$

Now it is possible to understand the details of the proof of the spectral decomposition of the orthogonal mapping from 2.4.7 at the end of the second chapter. The real matrix of an orthogonal mapping is interpreted as a matrix of a unitary mapping on a complex extension of Euclidean space. We observe the corollaries of the structure of the roots of the real characteristic polynomial over the complex domain. Automatically we obtain invariant two-dimensional subspaces given by pairs of complex conjugated eigenvalues and hence the corresponding rotation for restricted original real mapping.

**3.4.5. Dual and adjoint mappings.** When discussing vector spaces and linear mappings in the second chapter, we mentioned briefly the dual vector space  $V^*$  of all linear forms over the vector space  $V$ , see 2.3.17. This duality extends to mappings: 

DUAL MAPPINGS

For any linear mapping  $\psi : V \rightarrow W$ , the expression

$$(1) \quad \langle v, \psi^*(\alpha) \rangle = \langle \psi(v), \alpha \rangle,$$

where  $\langle \cdot, \cdot \rangle$  denotes the evaluation of the linear forms (the second argument) on the vectors (the first argument), while  $v \in V$  and  $\alpha \in W^*$  are arbitrary, defines the mapping  $\psi^* : W^* \rightarrow V^*$  called the *dual mapping* to  $\psi$ .

Choose bases  $\underline{v}$  in  $V$ ,  $\underline{w}$  in  $W$  and write  $A$  for the matrix of the mapping  $\psi$  in these bases. Then we compute the matrix of the mapping  $\psi^*$  in the corresponding dual bases in the

**3.D.9. (The Pythagorean theorem)** (a) In a real vector space  $V$  with a scalar product  $\langle \cdot, \cdot \rangle$  prove that two vectors  $u, w$  are orthogonal, i.e.,  $\langle u, w \rangle = 0$ , if and only if  $\|u+w\|^2 = \|u\|^2 + \|w\|^2$ .<sup>12</sup>

Next demonstrate with a counterexample that this property does not hold for a complex unitary vector space.

(b) If  $(V, \langle \cdot, \cdot \rangle)$  is a real scalar vector space, prove that the vectors  $u - w$  and  $u + w$  are orthogonal, if and only if  $\|u\| = \|w\|$ , where  $u, w \in V$  are two arbitrary vectors.  $\circ$

**3.D.10.** Let  $(V, \langle \cdot, \cdot \rangle)$  be a unitary space over  $\mathbb{F}$ , and  $u, v \in V$  two arbitrary vectors. Show that

(a)  $u \perp v$  if and only if  $\|u + av\| = \|u - av\|$  for all  $a \in \mathbb{F}$ .

(b)  $u \perp v$  if and only if  $\|u + av\| \geq \|u\|$  for all  $a \in \mathbb{F}$ .  $\circ$

**3.D.11.** Consider the space  $\text{Mat}_{m,n}(\mathbb{R})$  with the scalar product  $\mathcal{B}(A, B) = \text{tr}(B^T A)$ , introduced in 3.D.8. For the matrices

$$A = \begin{pmatrix} 1 & 3 & 5 \\ 0 & 2 & 2 \end{pmatrix} \quad \text{and} \quad B = \begin{pmatrix} 2 & 4 & 0 \\ 7 & 9 & 1 \end{pmatrix}$$

compute the following:

(a) the angle  $\theta$  between  $A, B$ ;

(b) the distance  $\|A - B\|_{\mathcal{B}}$  between  $A, B$ ;

(c) Verify the Cauchy-Schwarz inequality.

**Solution.** (a) By 3.D.8, for two real matrices  $A = (a_{ij})$  and  $B = (b_{ij})$ , both of size  $m \times n$ , we get  $\mathcal{B}(A, B) = \text{tr}(B^T A) = \sum_{i=1}^m \sum_{j=1}^n a_{ij} b_{ij}$  and  $\|A\|_{\mathcal{B}}^2 = \mathcal{B}(A, A) = \sum_{i=1}^m \sum_{j=1}^n a_{ij}^2$ . In particular, if  $A = \begin{pmatrix} a_{11} & a_{12} & a_{13} \\ a_{21} & a_{22} & a_{23} \end{pmatrix}$

and  $B = \begin{pmatrix} b_{11} & b_{12} & b_{13} \\ b_{21} & b_{22} & b_{23} \end{pmatrix}$  are two elements of  $\text{Mat}_{2,3}(\mathbb{R})$ ,

then we see that the product  $B^T A$  is given by

$$\begin{pmatrix} b_{11}a_{11} + b_{21}a_{21} & b_{11}a_{12} + b_{21}a_{22} & b_{11}a_{13} + b_{21}a_{23} \\ b_{12}a_{11} + b_{22}a_{21} & b_{12}a_{12} + b_{22}a_{22} & b_{12}a_{13} + b_{22}a_{23} \\ b_{13}a_{11} + b_{23}a_{21} & b_{13}a_{12} + b_{23}a_{22} & b_{13}a_{13} + b_{23}a_{23} \end{pmatrix}$$

such that

$$\begin{aligned} \mathcal{B}(A, B) &= \text{tr}(B^T A) = a_{11}b_{11} + a_{12}b_{12} + a_{13}b_{13} \\ &\quad + a_{21}b_{21} + a_{22}b_{22} + a_{23}b_{23}. \end{aligned}$$

Thus for the given  $A$  and  $B$  we compute

$$\begin{aligned} \mathcal{B}(A, B) &= 2 + 12 + 0 + 0 + 18 + 2 = 34, \\ \|A\|_{\mathcal{B}}^2 &= a_{11}^2 + a_{12}^2 + a_{13}^2 + a_{21}^2 + a_{22}^2 + a_{23}^2 = 43, \\ \|B\|_{\mathcal{B}}^2 &= b_{11}^2 + b_{12}^2 + b_{13}^2 + b_{21}^2 + b_{22}^2 + b_{23}^2 = 151. \end{aligned}$$

<sup>12</sup>Observe that this condition, known as the Pythagorean theorem, is not the same as the equality case in the triangle inequality  $\|u+w\| \leq \|u\| + \|w\|$ .

dual spaces. Indeed, the definition says that if we represent the vectors from  $W^*$  in the coordinates as rows of scalars, then the mapping  $\psi^*$  is given by the same matrix as  $\psi$ , if we multiply by it the row vectors from the right:

$$\langle \psi(v), \alpha \rangle = (\alpha_1, \dots, \alpha_n) \cdot A \cdot \begin{pmatrix} v_1 \\ \vdots \\ v_n \end{pmatrix} = \langle v, \psi^*(\alpha) \rangle.$$

This means that the matrix of the dual mapping  $\psi^*$  is the transpose  $A^T$ , because  $\alpha \cdot A = (A^T \cdot \alpha^T)^T$ .

Assume further that we have a vector space with scalar product. Then we can naturally identify  $V$  and  $V^*$  using the scalar product. Indeed, choosing one fixed vector  $w \in V$ , we substitute this vector into the second argument in the scalar product in order to obtain the identification  $V \simeq V^* = \text{Hom}(V, \mathbb{K})$

$$V \ni w \mapsto (v \mapsto \langle v, w \rangle) \in V^*.$$

The non-degeneracy condition on the scalar product ensures that this mapping is a bijection. Notice it is important to use  $w$  as the fixed second argument in the case  $\mathbb{K} = \mathbb{C}$  in order to obtain linear forms. Since factorizing complex multiples in the second argument yields complex conjugated scalars, the identification  $V \simeq V^*$  is linear over real scalars only.

It is clear that the vectors of an orthonormal basis are mapped to forms that constitute the dual basis, i.e. the orthonormal basis are selfdual under our identification. Moreover, every vector is automatically understood as a linear form, by means of the scalar product.

How does the above dual mapping  $W^* \rightarrow V^*$  look in terms of our identification? We use the same notation  $\psi^* : W \rightarrow V$  for the resulting mapping, which is uniquely given as follows:

ADJOINT MAPPING

For every linear mapping  $\psi : V \rightarrow W$  between spaces with scalar products, there is the *adjoint mapping*  $\psi^*$  uniquely determined by the formula

$$(2) \quad \langle \psi(u), v \rangle = \langle u, \psi^*(v) \rangle.$$

The parentheses means the scalar products on  $W$  or  $V$ , respectively.

Notice that the use of the same parenthesis for evaluation of one-forms and scalar products (which reflects the identification above) makes the defining formulae of dual and adjoint mappings look the same.

Equivalently we can understand the relation (2) to be the definition of the adjoint mapping  $\psi^*$ . By substituting all pairs of vectors from an orthonormal basis for the vectors  $u$  and  $v$  we obtain directly all the values of the matrix of the mapping  $\psi^*$ .

Hence  $\|A\|_{\mathcal{B}} = \sqrt{43}$ ,  $\|B\|_{\mathcal{B}} = \sqrt{151}$ , and

$$\cos \theta = \frac{\mathcal{B}(A, B)}{\|A\|_{\mathcal{B}}\|B\|_{\mathcal{B}}} = \frac{34}{\sqrt{43}\sqrt{151}}.$$

From this one can explicitly compute  $\theta$ , as before.

(b) We see that  $A - B = \begin{pmatrix} -1 & -1 & 5 \\ -7 & -7 & 1 \end{pmatrix}$ . Thus

$$\|A - B\|_{\mathcal{B}}^2 = \mathcal{B}(A - B, A - B) = 1 + 1 + 25 + 49 + 49 + 1 = 126$$

such that  $\|A - B\|_{\mathcal{B}} = \sqrt{126}$ .

(c) For the Cauchy inequality we refer to 3.4.3. This important inequality for the scalar product  $\mathcal{B}$  takes the form

$$|\mathcal{B}(A, B)| \leq \|A\|_{\mathcal{B}}\|B\|_{\mathcal{B}} = \sqrt{\mathcal{B}(A, A)}\sqrt{\mathcal{B}(B, B)} \iff |\text{tr}(B^* A)| \leq \sqrt{\text{tr}(A^* A)}\sqrt{\text{tr}(B^* B)}.$$

This gives us  $34 < \sqrt{43}\sqrt{151} \approx 80$ .  $\square$

We proceed with exercises related to orthonormal bases and orthogonal complements. Recall that we have already discussed these concepts in Chapter 2 (see for example 2.C.48, 2.C.50). There we introduced the Gram-Schmidt orthogonalization process, which transforms any basis  $\{E_1, \dots, E_n\}$  of a scalar product space  $(V, \langle \cdot, \cdot \rangle)$ , to an orthogonal basis  $\{w_1, \dots, w_n\}$  of  $V$ .

The process begins with  $w_1 = E_1$ , and constructs the  $j$ th member  $w_j$  as follows:

$$w_j = E_j - \frac{\langle E_j, w_1 \rangle}{\|w_1\|^2} w_1 - \dots - \frac{\langle E_j, w_{j-1} \rangle}{\|w_{j-1}\|^2} w_{j-1}.$$

This results to an orthonormal basis  $\{\frac{w_1}{\|w_1\|}, \dots, \frac{w_n}{\|w_n\|}\}$  of  $V$ .

This straightforward yet essential construction has a wide range of applications. We begin with an example that requires extending the method presented in Chapter 2 (cf. 2.C.50), to fit Sage's capabilities.

**3.D.12.** Consider the Euclidean space  $\mathbb{R}^3$  endowed with the scalar product  $\langle\langle u, v \rangle\rangle = v^T A u$ , where  $A$  is given by<sup>13</sup>

$$A = \begin{pmatrix} 2 & -1 & 0 \\ -1 & 2 & 1 \\ 0 & 1 & 2 \end{pmatrix}.$$

Applying the Gram-Schmidt procedure to obtain an  $\langle\langle \cdot, \cdot \rangle\rangle$ -orthogonal basis of  $\mathbb{R}^3$ , starting with the standard basis  $e = \{e_1, e_2, e_3\}$  of  $\mathbb{R}^3$ .

**Solution.** Let  $e_1 = (1, 0, 0)^T$ ,  $e_2 = (0, 1, 0)^T$  and  $e_3 = (0, 0, 1)^T$  be the vectors of the standard basis  $e$  of  $\mathbb{R}^3$ . According to the Gram-Schmidt method, an  $\langle\langle \cdot, \cdot \rangle\rangle$ -orthogonal basis of  $\mathbb{R}^3$  is given by  $\{w_1, w_2, w_3\}$ , with  $w_1 = e_1$  and

$$\begin{aligned} w_2 &= e_2 - \frac{\langle\langle e_2, w_1 \rangle\rangle}{\langle\langle w_1, w_1 \rangle\rangle} w_1, \\ w_3 &= e_3 - \frac{\langle\langle e_3, w_1 \rangle\rangle}{\langle\langle w_1, w_1 \rangle\rangle} w_1 - \frac{\langle\langle e_3, w_2 \rangle\rangle}{\langle\langle w_2, w_2 \rangle\rangle} w_2. \end{aligned}$$

<sup>13</sup>Verify yourselves that  $A$  is symmetric and positive definite (for the second claim show for example that all the eigenvalues of  $A$  are positive).

Using the coordinate expression for the scalar product, the formula (2) reveals the coordinate expression of the adjoint mapping:

$$\begin{aligned} \langle\psi(v), w\rangle &= \overline{(w_1, \dots, w_n)} \cdot A \cdot \begin{pmatrix} v_1 \\ \vdots \\ v_n \end{pmatrix} \\ &= \overline{\left(\bar{A}^T \cdot \begin{pmatrix} w_1 \\ \vdots \\ w_n \end{pmatrix}\right)^T} \cdot \begin{pmatrix} v_1 \\ \vdots \\ v_n \end{pmatrix} = \langle v, \psi^*(w) \rangle. \end{aligned}$$

It follows that if  $A$  is the matrix of the mapping  $\psi$  in an orthonormal basis, then the matrix of the adjoint mapping  $\psi^*$  is the transposed and conjugated matrix  $A$  – we denote this by  $A^* = \bar{A}^T$ .

The matrix  $A^*$  is called the *adjoint matrix* of the matrix  $A$ . Note that the adjoint matrix is well defined for any rectangular matrix. We should not confuse them with algebraic adjoints, which we used for square matrices when working with determinants.

We can summarise. For any linear mapping  $\psi : V \rightarrow W$  between unitary spaces, with matrix  $A$  in some bases on  $V$  and  $W$ , its dual mapping has the matrix  $A^T$  in the dual basis. If there are scalar products on  $V$  and  $W$ , we identify them (via the scalar products) with their duals. Then the dual mapping coincides with the adjoint mapping  $\psi^* : W \rightarrow V$ , which has the matrix  $A^*$ . The distinction between the matrix of the dual mapping and the matrix of the adjoint mapping is thus in the additional conjugation. This is of course a consequence of the fact that our identification of the unitary space with its dual is not a linear mapping over complex scalars.

**3.4.6. Self-adjoint mappings.** Those linear mappings which coincide with their adjoints:  $\psi^* = \psi$ , are of particular interest. They are called *self-adjoint mappings*. Equivalently we can say that they are the mappings whose matrix  $A$  satisfies  $A = A^*$  in some (and thus in all) orthonormal basis.

In the case of Euclidean spaces the self-adjoint mappings are those with symmetric matrices (in orthonormal basis). They are often called *symmetric mappings*.

In the complex domain the matrices that satisfy  $A = A^*$  are called *Hermitian matrices* or also *Hermitian symmetric matrices*. Sometimes they are also called *self-adjoint matrices*. Note that Hermitian matrices form a real vector subspace in the space of all complex matrices, but it is not a vector subspace in the complex domain.

**Remark.** The next observation is of special interest. If we multiply a Hermitian matrix  $A$  by the imaginary unit, we obtain the matrix  $B = i A$ , which has the property

$$B^* = \bar{i} \bar{A}^T = -B.$$

Such matrices are called *anti-Hermitian* or *Hermitian skew-symmetric*. Every real matrix can be written as a sum of its

We compute

$$\langle\langle e_2, w_1 \rangle\rangle = (1 \ 0 \ 0) \begin{pmatrix} 2 & -1 & 0 \\ -1 & 2 & 1 \\ 0 & 1 & 2 \end{pmatrix} \begin{pmatrix} 0 \\ 1 \\ 0 \end{pmatrix} = -1,$$

$$\langle\langle w_1, w_1 \rangle\rangle = (1 \ 0 \ 0) \begin{pmatrix} 2 & -1 & 0 \\ -1 & 2 & 1 \\ 0 & 1 & 2 \end{pmatrix} \begin{pmatrix} 1 \\ 0 \\ 0 \end{pmatrix} = 2.$$

Thus  $w_2 = e_2 + \frac{1}{2}e_1 = (\frac{1}{2}, 1, 0)^T$ . Next we compute

$$\begin{aligned} \langle\langle e_3, w_1 \rangle\rangle &= \langle\langle e_3, e_1 \rangle\rangle = e_1^T A e_3 \\ &= (1 \ 0 \ 0) \begin{pmatrix} 2 & -1 & 0 \\ -1 & 2 & 1 \\ 0 & 1 & 2 \end{pmatrix} \begin{pmatrix} 0 \\ 0 \\ 1 \end{pmatrix} = 0, \end{aligned}$$

that is,  $e_1$  and  $e_3$  are  $\langle\langle \cdot, \cdot \rangle\rangle$ -orthogonal, and hence

$$\begin{aligned} \langle\langle e_3, w_2 \rangle\rangle &= \langle\langle e_3, e_2 + \frac{1}{2}e_1 \rangle\rangle = \langle\langle e_3, e_2 \rangle\rangle + \frac{1}{2}\langle\langle e_3, e_1 \rangle\rangle \\ &= \langle\langle e_3, e_2 \rangle\rangle = e_2^T A e_3 \\ &= (0 \ 1 \ 0) \begin{pmatrix} 2 & -1 & 0 \\ -1 & 2 & 1 \\ 0 & 1 & 2 \end{pmatrix} \begin{pmatrix} 0 \\ 0 \\ 1 \end{pmatrix} = 1. \end{aligned}$$

Moreover,

$$\langle\langle w_2, w_2 \rangle\rangle = (\frac{1}{2} \ 1 \ 0) \begin{pmatrix} 2 & -1 & 0 \\ -1 & 2 & 1 \\ 0 & 1 & 2 \end{pmatrix} \begin{pmatrix} \frac{1}{2} \\ 1 \\ 0 \end{pmatrix} = \frac{3}{2}.$$

As an alternative, we know that  $\langle\langle e_1, e_1 \rangle\rangle = 2$ ,  $\langle\langle e_1, e_2 \rangle\rangle = -1$ , and we compute  $\langle\langle e_2, e_2 \rangle\rangle = 2$ . By linearity, we then have

$$\begin{aligned} \langle\langle w_2, w_2 \rangle\rangle &= \frac{1}{4}\langle\langle e_1, e_1 \rangle\rangle + \langle\langle e_1, e_2 \rangle\rangle + \langle\langle e_2, e_2 \rangle\rangle \\ &= \frac{1}{4} \cdot 2 + (-1) + 2 = \frac{3}{2}. \end{aligned}$$

Hence,  $w_3 = e_3 - \frac{2}{3}w_2 = (-\frac{1}{3}, -\frac{2}{3}, 1) = -\frac{1}{3}e_1 - \frac{2}{3}e_2 + e_3$ . To summarize, the desired basis has the form

$$\left\{ e_1, \frac{1}{2}e_1 + e_2, -\frac{1}{3}e_1 - \frac{2}{3}e_2 + e_3 \right\}.$$

To confirm this basis in Sage we may revise the method presented in Chapter 2 (see 2.C.50). This adjustment is necessary because we are now using a different scalar product than the standard one. The following cell includes the necessary explanations and performs the Gram-Schmidt orthogonalization with respect to the given inner product defined by the matrix  $A$ . Execute this block yourselves to read Sage's result.

symmetric part and its anti-symmetric part,

$$A = \frac{1}{2}(A + A^T) + \frac{1}{2}(A - A^T).$$

In the complex domain we have analogously

$$A = \frac{1}{2}(A + A^*) + i\frac{1}{2i}(A - A^*).$$

In particular, we may express every complex matrix in a unique way as a sum

$$A = B + iC$$

with Hermitian symmetric matrices  $B = \frac{1}{2}(A + A^*)$  and  $C = \frac{1}{2i}(A - A^*)$ . This is an analogy of the decomposition of a complex number into its real and purely imaginary component and in the literature we often encounter the notation

$$B = \operatorname{re} A = \frac{1}{2}(A + A^*), \quad C = \operatorname{im} A = \frac{1}{2i}(A - A^*).$$

In the language of linear mappings this means that every complex linear automorphism can be uniquely expressed by means of two self-adjoint mappings playing the role of the real and imaginary parts of the original mapping.

**3.4.7. Spectral decomposition.** Consider a self-adjoint mapping  $\psi : V \rightarrow V$  with the matrix  $A$  in some orthonormal basis. Proceed similarly as in 2.4.7 when we diagonalized the matrix of orthogonal mappings.

Again, consider arbitrary invariant subspaces of self-adjoint mappings and their orthogonal complements. If a self-adjoint mapping  $\psi : V \rightarrow V$  leaves a subspace  $W \subset V$  invariant, i.e.  $\psi(W) \subset W$ , then for every  $v \in W^\perp$ ,  $w \in W$

$$\langle\psi(v), w\rangle = \langle v, \psi(w)\rangle = 0.$$

Thus also,  $\psi(W^\perp) \subset W^\perp$ .

Next, consider the matrix  $A$  of a self-adjoint mapping in an orthonormal basis and an eigenvector  $x \in \mathbb{C}^n$ , i.e.  $A \cdot x = \lambda x$ . We obtain

$$\lambda \langle x, x \rangle = \langle Ax, x \rangle = \langle x, Ax \rangle = \bar{\lambda} \langle x, x \rangle.$$

The positive real number  $\langle x, x \rangle$  can be cancelled on both sides and thus  $\bar{\lambda} = \lambda$ , and we see that eigenvalues of Hermitian matrices are always real.

The characteristic polynomial  $\det(A - \lambda E)$  has as many complex roots as is the dimension of the square matrix  $A$  (including multiplicities), and all of them are actually real. Thus we have proved the important general result:

**Proposition.** *The orthogonal complements of invariant subspaces of self-adjoint mappings are also invariant. Furthermore, the eigenvalues of a Hermitian matrix  $A$  are always real.*

The very definition ensures that restriction of a self-adjoint mapping to an invariant subspace is again self-adjoint. Thus the latter proposition implies that there always exists an orthonormal basis of  $V$  composed of eigenvectors. Indeed, start with any eigenvector  $v_1$ , normalize it, consider its linear hull  $V_1$  and restrict the mapping to  $V_1^\perp$ . Consider next

```
A = Matrix([[2, -1, 0], [-1, 2, 1], [0, 1, 2]])
E1 = vector([1, 0, 0])
E2 = vector([0, 1, 0])
E3 = vector([0, 0, 1])
def proj(v, u):
    p = ((v*A*u) / (u*A*u)) * u
    return p
w1 = E1; w2 = E2 - proj(E2, w1)
w3 = E3 - proj(E3, w2) - proj(E3, w1)
```

another eigenvector  $v_1 \in V_2^\perp$ , take  $V_2 = \text{span}(V_1 \cup \{v_2\})$ , which is again invariant. Continue and construct the sequence of invariant subspaces  $V_1 \subset V_2 \subset \dots \subset V_n = V$ , building the orthonormal basis of eigenvectors, as expected.

Actually, it is easy to see directly that eigenvectors associated with different eigenvalues are perpendicular to each other. Indeed, if  $\psi(u) = \lambda u$ ,  $\psi(v) = \mu v$  then we obtain

$$\lambda \langle u, v \rangle = \langle \psi(u), v \rangle = \langle u, \psi(v) \rangle = \bar{\mu} \langle u, v \rangle = \mu \langle u, v \rangle.$$

Usually this result is formulated using projections onto eigensubspaces. Recall the properties of projections along subspaces, as discussed in 2.3.19. A projection  $P : V \rightarrow V$  is a linear mapping satisfying  $P^2 = P$ . This means that the restriction of  $P$  to its image is the identity and the projector is completely determined by choosing the subspaces  $\text{Im } P$  and  $\text{Ker } P$ .

A projection  $P : V \rightarrow V$  is called *orthogonal* if  $\text{Im } P \perp \text{Ker } P$ . Two orthogonal projections  $P, Q$  are called *mutually perpendicular* if  $\text{Im } P \perp \text{Im } Q$ .

SPECTRAL DECOMPOSITION OF SELF-ADJOINT MAPPINGS

**Theorem** (Spectral decomposition). *For every self-adjoint mapping  $\psi : V \rightarrow V$  on a vector space with scalar product there exists an orthonormal basis composed of eigenvectors. If  $\lambda_1, \dots, \lambda_k$  are all distinct eigenvalues of  $\psi$  and if  $P_1, \dots, P_k$  are the corresponding orthogonal and mutually perpendicular projectors onto the eigenspaces corresponding to the eigenvalues, then*

$$\psi = \lambda_1 P_1 + \dots + \lambda_k P_k.$$

*The dimensions of the images of these projections  $P_i$  equal the algebraic multiplicities of the eigenvalues  $\lambda_i$ .*

**3.4.8. Orthogonal diagonalization.** Linear mappings

which allow for orthonormal bases as in the latter theorem on spectral decomposition are called *orthogonally diagonalizable*. Of course, they are exactly the mappings for which we can find an orthonormal basis in which the matrix of the mapping is diagonal. We ask what they look like.

In the Euclidean case, this is simple: diagonal matrices are first of all symmetric, thus they are the self-adjoint mappings. As a corollary we note that an orthogonal mapping of an Euclidean space into itself is orthogonally diagonalizable if and only if it is self-adjoint. They are exactly the self-adjoint mappings with eigenvalues  $\pm 1$ .

The situation is much more interesting on unitary spaces. Consider any linear mapping  $\varphi : V \rightarrow V$  on a unitary space. Let  $\varphi = \psi + i\eta$  be the (unique) decomposition of  $\varphi$  into its Hermitian and anti-Hermitian part. If  $\varphi$  has diagonal matrix  $D$  in a suitable orthonormal basis, then  $D = \text{Re } D + i \text{Im } D$ , where the real and the imaginary parts are exactly the matrices of  $\psi$  and  $\eta$ . This follows from the uniqueness of the decomposition. Knowing this in the particular coordinates, we conclude the following computation relations at the level of

```
g = [w1, w2, w3]
show(g)
```

□

**3.D.13.** Let  $(V, \langle \cdot, \cdot \rangle)$  be a (finite-dimensional) unitary vector space and let  $\{E_j\}_{j=1}^n$  be an  $\langle \cdot, \cdot \rangle$ -orthonormal basis of  $V$ , i.e.,  $\langle E_i, E_j \rangle = \delta_{ij}$ . Show that any two vectors  $x, y \in V$  satisfy  $\langle x, y \rangle = \sum_{j=1}^n \langle x, E_j \rangle \langle y, E_j \rangle$ . ○

**3.D.14.** Show that the vectors  $E_1 = (-1, 1, 2)$ ,  $E_2 = (2, 0, 1)$  and  $E_3 = (1, 5, -2)$  form an orthogonal basis of  $\mathbb{R}^3$  (with respect to the usual dot product). Next express the vector  $u = (6, 2, -4)$  as a linear combination of this basis. ○

**3.D.15.** Based on the Cauchy-Schwarz inequality, show that any triple  $(a, b, c)$  of positive real numbers satisfies the following inequality:

$$\sqrt{\frac{a+2b}{a+b+c}} + \sqrt{\frac{b+2c}{a+b+c}} + \sqrt{\frac{c+2a}{a+b+c}} \leq 3.$$

○

**3.D.16.** Consider  $\mathbb{C}^3$  endowed with the standard Hermitian form  $\langle u, v \rangle = \sum_{i=1}^3 u_i \bar{v}_i$  and the standard basis  $\underline{e} = \{e_1, e_2, e_3\}$ . Verify Parseval's equality for the vector  $u = (2+i, -1+2i, 3-i) \in \mathbb{C}^3$ . ○

**3.D.17.** In Problem 3.D.11 use the isomorphism  $\text{Mat}_{2,3}(\mathbb{R}) \cong \mathbb{R}^6$  established in Problem 2.C.31 to show that the matrices  $A, B$  are linearly independent. Then consider the subspace  $W$  of  $\text{Mat}_{2,3}(\mathbb{R})$  spanned by the matrices  $A, B$ . Find a basis of the orthogonal complement  $W^\perp$  of  $W$  with respect to the Frobenius scalar product  $\mathcal{B}$  (introduced in 3.D.8).

**Solution.** Under the isomorphism  $\varphi : \text{Mat}_{2,3}(\mathbb{R}) \cong \mathbb{R}^6$  discussed in Problem 2.C.31, we may view the matrices  $A$  and  $B$  as the following vectors on  $\mathbb{R}^6$ :  $\varphi(A) = v_1 = (1, 3, 5, 0, 2, 2)^T$  and  $\varphi(B) = v_2 = (2, 4, 0, 7, 9, 1)^T$ , respectively. We now treat their linear independence via Sage by the cell

```
V = RR^6
v1 = vector(RR, [1, 3, 5, 0, 2, 2])
v2 = vector(RR, [2, 4, 0, 7, 9, 1])
V.linear_dependence([v1, v2]) == []
```

Sage prints out True, so  $v_1, v_2$  are linearly independent. Consider the subspace  $W = \text{span}_{\mathbb{R}}\{A, B\} \cong \text{span}_{\mathbb{R}}\{v_1, v_2\}$  of  $\text{Mat}_{2,3}(\mathbb{R}) \cong \mathbb{R}^6$  spanned by  $A, B$ . We need to determine  $W^\perp$  with respect to  $\mathcal{B}$ , that is,

$$W^\perp = \{C \in \text{Mat}_{2,3}(\mathbb{R}) : \mathcal{B}(C, A) = 0 = \mathcal{B}(C, B)\}.$$

Let us express  $C \in \text{Mat}_{2,3}(\mathbb{R})$  as  $C = \begin{pmatrix} a & b & c \\ d & e & f \end{pmatrix}$ , for some reals  $a, \dots, f$ . Then  $C \in W^\perp$  if and only if  $\text{tr}(A^T C) = 0 = \text{tr}(B^T C)$ , that is

$$\{a + 3b + 5c + 2e + 2f = 0, 2a + 4b + 7d + 9e + f = 0\}.$$

mappings  $\psi \circ \eta = \eta \circ \psi$  (i.e. the real and imaginary parts of  $\varphi$  commute), and  $\varphi \circ \varphi^* = \varphi^* \circ \varphi$  (since this clearly holds for all diagonal metrics). The mappings  $\varphi : V \rightarrow V$  with the latter property are called the *normal mappings*.

A detailed characterization is given by the following theorem (stated in the notation of this paragraph):

**Theorem.** The following conditions on a mapping  $\varphi : V \rightarrow V$  on a unitary space  $V$  are equivalent:

- (1)  $\varphi$  is orthogonally diagonalizable,
- (2)  $\varphi^* \circ \varphi = \varphi \circ \varphi^*$  ( $\varphi$  is a normal mapping),
- (3)  $\psi \circ \eta = \eta \circ \psi$  (the Hermitian and anti-Hermitian parts commute),
- (4) if  $A = (a_{ij})$  is the matrix of  $\varphi$  in some orthonormal basis, and  $\lambda_i$  are the  $m = \dim V$  eigenvalues of  $A$ , then

$$\sum_{i,j=1}^m |a_{ij}|^2 = \sum_{i=1}^m |\lambda_i|^2.$$

**PROOF.** The implication (1)  $\Rightarrow$  (2) was discussed above.

(2)  $\Leftrightarrow$  (3): it suffices to calculate

$$\varphi \circ \varphi^* = (\psi + i\eta)(\psi - i\eta) = \psi^2 + \eta^2 + i(\eta\psi - \psi\eta)$$

$$\varphi^* \circ \varphi = (\psi - i\eta)(\psi + i\eta) = \psi^2 + \eta^2 + i(\psi\eta - \eta\psi)$$

Subtraction of the two lines yields

$$\varphi\varphi^* - \varphi^*\varphi = 2i(\eta\psi - \psi\eta).$$

(2)  $\Rightarrow$  (1): If  $\varphi$  is normal, then

$$\begin{aligned} \langle \varphi(u), \varphi(u) \rangle &= \langle \varphi^* \varphi(u), u \rangle = \langle \varphi \varphi^*(u), u \rangle \\ &= \langle \varphi^*(u), \varphi^*(u) \rangle \end{aligned}$$

thus  $|\varphi(u)| = |\varphi^*(u)|$ .

Next, notice  $(\varphi - \lambda \text{id } V)^* = (\varphi^* - \bar{\lambda} \text{id } V)$ . Thus, if  $\varphi$  is normal, then  $(\varphi - \lambda \text{id } V)$  is normal too.

If  $\varphi(u) = \lambda u$ , then  $u$  is in the kernel of  $\varphi - \lambda \text{id } V$ . Thus the latter equality of norms of values for normal mappings and their adjoints ensures that  $u$  is also in the kernel of  $\varphi^* - \bar{\lambda} \text{id } V$ . It follows that  $\varphi^*(u) = \bar{\lambda}u$ . We have proved, under the assumption (2), that  $\varphi$  and  $\varphi^*$  have the same eigenvectors and that they are associated to conjugated eigenvalues.

Similarly to our procedure with self-adjoint mappings, we now prove orthogonal diagonalizability. The latter procedure is based on the fact that the orthogonal complements to sums of eigenspaces are invariant subspaces.

Consider an eigenvector  $u \in V$  with eigenvalue  $\lambda$ , and any  $v \in \langle u \rangle^\perp$ . We have

$$\langle \varphi(v), u \rangle = \langle v, \varphi^*(u) \rangle = \langle v, \bar{\lambda}u \rangle = \lambda \langle u, v \rangle = 0.$$

Thus  $\varphi(v) \in \langle u \rangle^\perp$ . The same occurs if  $u$  is replaced by a sum of eigenvectors instead.

(1)  $\Rightarrow$  (4): the expression  $\sum_{i,j} |a_{ij}|^2$  is the trace of the matrix  $AA^*$ , which is the matrix of the mapping  $\varphi \circ \varphi^*$ . Therefore its value does not depend on the choice of the orthonormal basis. Thus if  $\varphi$  is diagonalizable, this expression equals exactly  $\sum_i |\lambda_i|^2$ .

(4)  $\Rightarrow$  (1): This part of the proof is a direct corollary of the Schur theorem on unitary triangulation of an arbitrary

This is a system of two equations with six unknowns. Let  $c, d, e, f \in \mathbb{R}$  be the free variables. Then we get the solution

$$a = 10c - \frac{21}{2}d - \frac{19}{2}e + \frac{5}{2}f, \quad b = -5c + \frac{7}{2}d + \frac{5}{2}e - \frac{3}{2}f.$$

Hence  $W^\perp$  consists of matrices of the form

$$C = \begin{pmatrix} 10c - \frac{21}{2}d - \frac{19}{2}e + \frac{5}{2}f & -5c + \frac{7}{2}d + \frac{5}{2}e - \frac{3}{2}f & c \\ & d & e \\ & & f \end{pmatrix}$$

with  $c, d, e, f \in \mathbb{R}$ . We see that

$$\begin{aligned} C &= c \begin{pmatrix} 10 & -5 & 1 \\ 0 & 0 & 0 \end{pmatrix} + d \begin{pmatrix} -21/2 & 7/2 & 0 \\ 1 & 0 & 0 \end{pmatrix} \\ &\quad + e \begin{pmatrix} -19/2 & 5/2 & 0 \\ 0 & 1 & 0 \end{pmatrix} + f \begin{pmatrix} 5/2 & -3/2 & 0 \\ 0 & 0 & 1 \end{pmatrix} \\ &= cW_1 + dW_2 + eW_3 + fW_4, \end{aligned}$$

where we denote the matrices appearing above by  $W_1, W_2, W_3, W_4$ , respectively. This shows that  $W_1, \dots, W_4$  generate  $W^\perp$ . Actually, they provide a basis of  $W^\perp$ . For a quick verification of their linear independence, we use again the isomorphism  $\text{Mat}_{2,3}(\mathbb{R}) \cong \mathbb{R}^6$  and proceed with Sage, as before:

```
V = RR^6
w1 = vector(RR, [10, -5, 1, 0, 0, 0])
w2 = vector(RR, [-21/2, 7/2, 0, 1, 0, 0])
w3 = vector(RR, [-19/2, 5/2, 0, 0, 1, 0])
w4 = vector(RR, [5/2, -3/2, 0, 0, 0, 1])
V.linear_dependence([w1, w2, w3, w4]) == []
```

□

*Invertible linear transformations naturally intersect with group theory, a topic that we briefly introduced in Chapter 1 and will explore in greater detail in Chapter 12. This intersection forms the basis of “matrix groups”, which are of particular interest in this context. Next we will focus on the group of all invertible linear mappings from  $\mathbb{R}^n$  to  $\mathbb{R}^n$ , known as the “real general linear group”, denoted by  $\text{GL}_n(\mathbb{R})$ .*

*The operation that defines this group is the composition of linear mappings. Equivalently,  $\text{GL}_n(\mathbb{R})$  can be described as the group of all invertible  $n \times n$  matrices with real entries, where the group operation is the matrix multiplication, i.e.,*

$$\text{GL}_n(\mathbb{R}) = \{A \in \text{Mat}_n(\mathbb{R}) : \det(A) \neq 0\}.$$

*On the other hand, a “matrix group” is defined as a closed subgroup of  $\text{GL}_n(\mathbb{R})$ .<sup>14</sup> An example of a matrix group*

<sup>14</sup>Matrix groups are special cases of the well-known “Lie groups”. In simple terms, a Lie group is a group equipped with a compatible differentiable structure, also known as a smooth manifold. Lie groups were introduced by the Norwegian mathematician Sophus Lie (1842-1899) during the late 19th century, shortly after the discovery of non-Euclidean geometries. Lie referred to them as “continuous symmetry groups”. During this period, Lie collaborated with F. Klein, and together they significantly altered perspectives in geometry and the theory of differential equations. Today, the theory of Lie groups and Lie algebras has become a fundamental area in differential geometry with a wide range of applications. It’s worth noting that not all Lie groups are matrix groups, indicating the potential complexity of these structures.

linear mapping  $V \rightarrow V$ , which we prove later in 3.4.15. This theorem says that for every linear mapping  $\varphi : V \rightarrow V$  there exists an orthonormal basis under which  $\varphi$  has an upper triangular matrix. Then all the eigenvalues of  $\varphi$  appear on its diagonal. Since we have already shown that the expression  $\sum_{i,j} |a_{ij}|^2$  does not depend on the choice of the orthonormal bases, all elements in the upper triangular matrix, which are not on the diagonal must be zero. □

**Remark.** We can rephrase the main statement of the latter theorem in terms of matrices. A mapping is normal if and only if its matrix  $A$  satisfies  $AA^* = A^*A$  in some orthonormal basis (and equivalently in any orthonormal basis). Such matrices are called *normal*. Moreover, we can consider the last theorem as a generalization of standard calculations with complex numbers. The linear mappings appear similar to complex numbers in their algebraic form. The role of real numbers is played by self-adjoint mappings, and the unitary mappings play the role of the complex units  $\cos t + i \sin t \in \mathbb{C}$ . The following consequence of the theorem shows the link to the property  $\cos^2 t + \sin^2 t = 1$ .

**Corollary.** *The unitary mappings on a unitary space  $V$  are exactly those normal mappings  $\varphi$  on  $V$  for which the unique decomposition  $\varphi = \psi + i\eta$  into Hermitian and anti-Hermitian parts satisfies  $\psi^2 + \eta^2 = \text{id}_V$ .*

**PROOF.** If  $\varphi$  is unitary, then  $\varphi\varphi^* = \text{id}_V = \varphi^*\varphi$  and thus  $\varphi\varphi^* = (\psi + i\eta)(\psi - i\eta) = \psi^2 + 0 + \eta^2 = \text{id}_V$ . On the other hand, if  $\varphi$  is normal, we can read the latter computation backwards which proves the other implication. □

**3.4.9. Roots of matrices.** Non-negative real numbers are exactly those which are squares of real numbers (and thus we may find their square roots). At the same time, their positive square roots are uniquely defined. Now we observe a similar behaviour of matrices of the form  $B = A^*A$ . Of course, these are the matrices of the compositions of mappings  $\varphi$  with their adjoints.

By definition,

$$(1) \quad \langle Bx, x \rangle = \langle A^*Ax, x \rangle = \langle Ax, Ax \rangle \geq 0$$

for all vectors  $x$ . Furthermore, we clearly have

$$B^* = (A^*A)^* = A^*A = B.$$

Hermitian matrices  $B$  with the property  $\langle Bx, x \rangle \geq 0$  for all  $x$  are called *positive semidefinite* matrices. If the zero value is attained only for  $x = 0$ , they are called *positive definite*. Analogously, we speak of *positive definite* and *positive semidefinite* (self-adjoint) mappings  $\varphi : V \rightarrow V$ .

For every mapping  $\varphi : V \rightarrow V$  we can define its *square root* as a mapping  $\psi$  such that  $\psi \circ \psi = \varphi$ . The next theorem completely describes the situation when restricting to positive semidefinite mappings.

is the “orthogonal group”  $O(n)$ , which consists of all linear transformations  $\varphi : \mathbb{R}^n \rightarrow \mathbb{R}^n$  of  $\mathbb{R}^n$  preserving the standard Euclidean product, i.e.,  $\langle \varphi(u), \varphi(v) \rangle = \langle u, v \rangle$ , for all  $u, v \in \mathbb{R}^n$ . We studied such endomorphisms in the end of Chapter 2 and we learned that they correspond to orthogonal matrices (see 2.4.6 and 2.D.11). Hence, in terms of matrices,  $O(n)$  consists of all  $n \times n$  orthogonal matrices, i.e.,  $O(n) = \{A \in \text{Gl}_n(\mathbb{R}) : A^{-1} = A^T\}$ .

**3.D.18.** Prove that  $O(n)$  is a group and a subgroup of  $\text{Gl}_n(\mathbb{R})$ . Additionally, demonstrate that the determinant of any matrix  $A \in O(n)$  is either 1 or  $-1$ .

**Solution.** Obviously, the  $n \times n$  identity matrix  $E$  belongs to  $O(n)$  and this is the corresponding identity element of the group. Thus, to verify that  $O(n)$  is a group it remains to prove that the composition of two orthogonal transformations is orthogonal, and that the inverse of an orthogonal transformation is again orthogonal. By the conclusion in Problem 2.D.11, one can equivalently work with orthogonal matrices. Let  $A, B \in O(n)$ . Then we see that

$$\begin{aligned} (AB)^T AB &= B^T A^T AB = B^T B = E, \\ AB(AB)^T &= ABB^T A^T = AA^T = E, \\ (A^{-1})^T A^{-1} &= (A^T)^{-1} A^{-1} = (AA^T)^{-1} = E^{-1} = E, \\ A^{-1}(A^{-1})^T &= A^{-1}(A^T)^{-1} = (A^T A)^{-1} = E^{-1} = E, \end{aligned}$$

and these relations certify our claim. Finally recall that the matrix multiplication is associative.

Now, given a group  $(G, \circ)$ , a non-empty subset  $K$  of  $G$  which is closed under composition and taking inverses (with respect to the restriction of the group operation  $\circ$  to  $K$ ), is called a *subgroup* of  $G$ , see also 12.4.1 for more details. To demonstrate that a (non-empty) subset  $K \subset G$  of  $G$  is a subgroup of  $G$ , we need to show that  $a \circ b^{-1} \in K$ , for any two elements  $a, b \in K$ . Let  $A, B \in O(n)$  be two orthogonal matrices. By the previous assertion we know that  $B^{-1} \in O(n)$  as well, and hence  $AB^{-1} \in O(n)$ . Since  $O(n)$  is also a subset of  $\text{Gl}_n(\mathbb{R})$ , our claim follows. For the determinant, let  $A \in \text{Mat}_n(\mathbb{R})$  be an orthogonal matrix, i.e.,  $AA^T = E = A^T A$ . Hence  $\det(AA^T) = \det(E) = 1$ . However,  $\det(AA^T) = \det(A) \det(A^T) = \det(A)^2$ , thus  $\det(A)^2 = 1$ , i.e.,  $\det(A) = \pm 1$ .  $\square$

The special orthogonal group  $\text{SO}(n)$  is the subgroup of  $O(n)$  consisting of orthogonal matrices with determinant one,  $\text{SO}(n) = \{A \in O(n) : \det(A) = 1\}$ . Obviously, for  $n = 1$  we have  $O(1) \cong \mathbb{Z}_2$  and the group  $\text{SO}(1)$  is trivial. For  $n = 2$  it is not hard to prove that the group  $\text{SO}(2)$  is isomorphic (as a group) to the unit circle  $S^1 = \{z \in \mathbb{C} : |z| = 1\}$ . For  $n = 3$  we have already described examples of special orthogonal matrices in Chapter 2, e.g., rotations on  $\mathbb{R}^3$  about an axis through the origin, which indeed have matrices lying in the special orthogonal group  $\text{SO}(3)$  (see 2.D.13). Let us further emphasize on rotations on the 3-dimensional Euclidean

POSITIVE SEMIDEFINITE SQUARE ROOTS

**Theorem.** For each positive semidefinite square matrix  $B$ , there is the uniquely defined positive semidefinite square root  $\sqrt{B}$ .

If  $P$  is any matrix such that  $P^{-1}BP = D$  is diagonal, then  $\sqrt{B} = P\sqrt{D}P^{-1}$ , where  $D$  has got the (non-negative) eigenvalues of  $B$  on its diagonal and  $\sqrt{D}$  is the matrix with the positive square roots of these values on its diagonal.

**PROOF.** Since  $B$  is a matrix of a self-adjoint mapping  $\varphi$ , there is even an orthonormal  $P$  as in the theorem (cf. Theorem 3.4.7) with all eigenvalues in the diagonal of  $D$  non-negative. Consider  $C = \sqrt{B}$  as defined in the second claim and notice that indeed

$$C^2 = P\sqrt{D}P^{-1}P\sqrt{D}P^{-1} = PDP^{-1} = B.$$

Thus the mapping  $\psi$  given by  $C$  must have the same eigenvectors as  $\varphi$  and thus these two mappings share the decompositions of  $\mathbb{K}^n$  into mutually orthogonal eigenspaces. In particular, both of them will share the bases in which they have diagonal matrices and thus the definition of  $\sqrt{D}$  must be unique in each such basis. This proves that the definition of  $\sqrt{B}$  does not depend on our particular choice of the diagonalization of  $\varphi$ .  $\square$

Notice there could be a lot of different roots, if we relax the positivity condition on  $\sqrt{B}$  (e.g., we may choose the signs in the diagonal matrix  $D$ ).

**3.4.10. Spectra and nilpotent mappings.** We return to the behavior of linear mappings in full generality. We continue to work with real or complex vector spaces, but without necessarily fixing a scalar product there.

Recall that the *spectrum of a linear mapping*  $f : V \rightarrow V$  is a sequence of roots of the characteristic polynomial of the mapping  $f$ , counting multiplicities. The *algebraic multiplicity* of an eigenvalue is its multiplicity as a root of the characteristic polynomial. The *geometric multiplicity* of an eigenvalue is the dimension of the corresponding subspace of eigenvectors.

A linear mapping  $f : V \rightarrow V$  is called *nilpotent*, if there exists an integer  $k \geq 1$  such that the iterated mapping  $f^k$  is identically zero. The smallest  $k$  with such a property is called the *degree of nilpotency* of the mapping  $f$ . The mapping  $f : V \rightarrow V$  is called *cyclic*, if there exists the basis  $(u_1, \dots, u_n)$  of the space  $V$  such that  $f(u_1) = 0$  and  $f(u_i) = u_{i-1}$  for all  $i = 2, \dots, n$ . In other words, the matrix of  $f$  in this basis is of the form

$$A = \begin{pmatrix} 0 & 1 & 0 & \dots \\ 0 & 0 & 1 & \dots \\ \vdots & \vdots & \ddots & \ddots \end{pmatrix}.$$

space, by presenting some addition exercises, see also in Section F for further material (cf. 3.F.35, 3.F.37).

**3.D.19.** Write down the matrices of rotations by the angle  $\theta$ , about the (oriented) axes  $x$ ,  $y$  and  $z$  in  $\mathbb{R}^3$ .<sup>15</sup> ○

The concept of linear transformations on real vector spaces naturally extends to complex vector spaces. In particular, the groups  $O(n)$  and  $SO(n)$  have counterparts in the complex case, known as the “unitary group”  $U(n)$  and the “special unitary group”  $SU(n)$ . These groups are closed subgroups of the complex general linear group  $GL_n(\mathbb{C})$ , which serves as the starting point in this context, replacing  $GL_n(\mathbb{R})$ . As a result, they are also matrix groups (note that when identifying  $\mathbb{C}^n \cong \mathbb{R}^{2n}$ , the group  $GL_n(\mathbb{C})$  can be viewed as a subgroup of  $GL_{2n}(\mathbb{R})$ ).

The unitary group consists of all complex linear mappings  $\psi : \mathbb{C}^n \rightarrow \mathbb{C}^n$ , preserving the standard Hermitian form  $\langle \cdot, \cdot \rangle$  on  $\mathbb{C}^n$ . Equivalently, it can be viewed as the matrix group  $U(n) = \{U \in GL_n(\mathbb{C}) : U^{-1} = U^* = \bar{U}^T\}$ . Just as  $SO(n)$  is defined as a subgroup of  $O(n)$ , the special unitary group  $SU(n)$  is defined as the subgroup of  $U(n)$  consisting of unitary matrices with determinant one.

**3.D.20.** As we said above, over  $\mathbb{C}$  a  $n \times n$  unitary matrix  $U$  is defined as the one preserving the standard Hermitian form  $\langle \cdot, \cdot \rangle$  on  $\mathbb{C}^n$ , i.e.,  $\langle Ux, Uy \rangle = \langle x, y \rangle$  for any  $x, y \in \mathbb{C}^n$ . Show that this is equivalent to say that  $U^*U = UU^* = E$ . Next prove that  $U(n)$  is a group, and that the determinant of any unitary matrix is a complex unit. ○

**3.D.21. Unitary matrices.** Determine which of the matrices listed below is unitary:

$$A = \begin{pmatrix} \frac{1}{\sqrt{2}} & \frac{1}{\sqrt{2}} \\ \frac{i}{\sqrt{2}} & -\frac{i}{\sqrt{2}} \end{pmatrix}, B = \frac{1}{2} \begin{pmatrix} 1+i & \sqrt{2} \\ 1-i & \sqrt{2}i \end{pmatrix}, C = \begin{pmatrix} 1 & -i \\ -1 & i \end{pmatrix}.$$

**Solution.** Let us use Sage to analyze the matrix  $A$ . We want to determine whether the products  $A^*A$  and  $AA^*$  yield the identity matrix. We this goal in mind, we type:

```
A=matrix(SR, [[(1/sqrt(2)), (1/sqrt(2))],
[(1/sqrt(2))*I, (-1/sqrt(2))*I]])
show(A)
A_her=A.conjugate_transpose()
show(A_her)
bool(A_her*A==A*A_her)
```

The command `A.conjugate_transpose()` returns the conjugate transpose of  $A$ , and has as shortcut the rule `A.H`. Executing this block we confirm that  $A$  is a unitary matrix. As mentioned before, a more direct method uses the command

<sup>15</sup>The matrices presented in the solution are well-known and are commonly used in 3D graphics, robotics, and other fields involving three-dimensional transformations.

If  $f(v) = av$ , then  $f^k(v) = a^k \cdot v$  for every natural  $k$ . Note that, the spectrum of nilpotent mapping can contain only the zero scalar (and this is always present).

By the definition, every cyclic mapping is nilpotent. Moreover, its degree of nilpotency equals the dimension of the space  $V$ . The derivative operator on polynomials,  $D(x^k) = kx^{k-1}$ , is an example of a cyclic mapping on the spaces  $\mathbb{K}_n[x]$  of all polynomials of degree at most  $n$  over the scalars  $\mathbb{K}$ .

Perhaps surprisingly, this is also true the other way round – every nilpotent mapping is a direct sum of cyclic mappings. A proof of this claim takes much work. So we formulate first the results we are aiming at, and only then come back to the technical work.

In the resulting theorem describing the *Jordan decomposition*, the crucial role is played by vector (sub)spaces and linear mappings with a single eigenvalue  $\lambda$  given by the matrix

$$(1) \quad J = \begin{pmatrix} \lambda & 1 & 0 & \dots & 0 \\ 0 & \lambda & 1 & \dots & 0 \\ \vdots & \vdots & \ddots & & \vdots \\ 0 & 0 & 0 & \dots & \lambda \end{pmatrix}.$$

These matrices (and the corresponding invariant subspaces) are called *Jordan blocks*.<sup>5</sup>

JORDAN CANONICAL FORM

**Theorem.** Let  $V$  be a real or complex vector space of dimension  $n$ . Let  $f : V \rightarrow V$  be a linear mapping with  $n$  eigenvalues (in the chosen domain of scalars), counting algebraic multiplicities. Then there exists a unique decomposition of the space  $V$  into the direct sum of subspaces

$$V = V_1 \oplus \dots \oplus V_k$$

where not only  $f(V_i) \subset V_i$ , but the restriction of  $f$  to each  $V_i$  has a single eigenvalue  $\lambda_i$  and the restriction  $f - \lambda_i \text{id}_{V_i}$  on  $V_i$  is either cyclic or is the zero mapping. In particular, there is a suitable basis in which  $f$  has a block-diagonal matrix  $J$  with Jordan blocks along the diagonal.

We say that the matrix  $J$  from the theorem is in Jordan canonical form. In the language of matrices, we can rephrase the theorem as follows:

**Corollary.** For each square matrix  $A$  over complex scalars, there is an invertible matrix  $P$  such that  $A = P^{-1}JP$  and  $J$  is in canonical Jordan form.

The matrix  $P$  is the transition matrix to the basis from the theorem above. Notice that the total number of ones over the diagonal in  $J$  equals the difference between the total algebraic and geometric multiplicity of the eigenvalues. The ordering of the blocks in the matrix corresponds to the chosen ordering

<sup>5</sup>Camille Jordan was a famous French Mathematician working in Analysis and Algebra at the end of the 19th and the beginning of the 20th centuries.

`A.is_unitary()`, which for our cases returns True. Alternatively, we can assess the orthonormality of the matrix's columns (or rows) with respect to the standard Hermitian form on  $\mathbb{C}^n$  (for a  $n \times n$  matrix). This is analogous to evaluating orthogonality in real matrices. These arguments enable us to conclude that the matrices  $B$  is unitary, while the matrix  $C$  is not (although the scaled matrix  $\frac{1}{2}C$  is unitary). We will demonstrate the verification process for the matrix  $B$ , and leave the other case for practise.

For the matrix  $B$ , the column vectors are given by  $u_1 = (\frac{1+i}{2}, \frac{1-i}{2})^T$ ,  $u_2 = (\frac{\sqrt{2}}{2}, \frac{i\sqrt{2}}{2})^T$ . Thus

$$\begin{aligned} \|u_1\| &= \sqrt{\frac{1+i}{2} \cdot \frac{1-i}{2} + \frac{1-i}{2} \cdot \frac{1+i}{2}} = 1, \\ \|u_2\| &= \sqrt{\frac{\sqrt{2}}{2} \cdot \frac{\sqrt{2}}{2} - i^2 \cdot \frac{\sqrt{2}}{2} \cdot \frac{\sqrt{2}}{2}} = 1, \\ \langle u_1, u_2 \rangle &= \frac{1+i}{2} \cdot \frac{\sqrt{2}}{2} - \frac{1-i}{2} \cdot \frac{i\sqrt{2}}{2} = 0. \end{aligned}$$

Hence  $B$  is unitary. Let us also proceed with Sage, by applying one of the methods described above. For example, executing the command

```
B = matrix(SR, [[(1+I)/2, sqrt(2)/2],
[(1-I)/2, sqrt(2)*I/2]])
B.is_unitary()
```

Sage returns True. □

Let  $V, W$  be two unitary spaces. Given a linear map  $\psi : V \rightarrow W$  its “adjoint” is the linear map  $\psi^* : W \rightarrow V$  defined by  $\langle \psi(u), w \rangle_W = \langle u, \psi^*(w) \rangle_V$ , for all  $u \in V$ , and  $w \in W$ . By the discussion in 3.4.5 we know that if  $A$  is the matrix of  $\psi$  in an orthonormal basis of  $V$ , then the conjugate transpose  $A^*$  is the matrix of  $\psi^*$ .

When  $f = f^*$ , or equivalently when  $A$  is Hermitian, i.e.,  $A = A^*$ , then  $f$  is called “self-adjoint”, see 3.4.6.<sup>16</sup> The following series of exercises will explore these objects, starting with the properties of the adjoint operator.

**3.D.22.** Consider two linear mappings  $\varphi, \psi : V \rightarrow V$  on a complex unitary space  $(V, \langle \cdot, \cdot \rangle)$ . Show that the adjoint operators of  $\varphi$  and  $\psi$  satisfy the following properties:

- $(c\varphi)^* = \bar{c}\varphi^*$ , for any  $c \in \mathbb{C}$ ;
- $(\varphi + \psi)^* = \varphi^* + \psi^*$ ;
- $(\varphi \circ \psi)^* = \psi^* \circ \varphi^*$ ;
- $(\varphi^*)^* = \varphi$ ;
- If  $\varphi$  is invertible, so is  $\varphi^*$  with  $(\varphi^*)^{-1} = (\varphi^{-1})^*$ . ○

<sup>16</sup>Self-adjoint operators and Hermitian matrices are fundamental in various scientific and engineering disciplines. In quantum mechanics, they represent observable quantities such as energy, momentum, and position with their real eigenvalues being of special importance. In numerical analysis, self-adjoint operators are used to solve eigenvalue problems, which are essential for simulations and modeling in engineering and physics. In computer science, Hermitian matrices find applications in machine learning, where they help in dimensionality reduction and data analysis by identifying important features in large datasets.

of the subspaces  $V_i$  in the direct sum. Thus, the uniqueness of the matrix  $J$  is true up to the ordering of the Jordan blocks. There is therefore freedom in the choice of the basis for such a Jordan canonical form.

**3.4.11. Remarks.** The existence of the Jordan canonical form is clear for the cases when all eigenvalues are either distinct or when the geometric and algebraic multiplicities of the eigenvalues are the same. In particular, this is the case for all unitary and self-adjoint mappings on unitary vector spaces, while the definition of normal mappings requires exactly this behavior. In particular, the Jordan canonical form of a mapping is diagonal if and only if the mapping is normal.

A consequence of the Jordan canonical form theorem is that for every linear mapping  $f$ , every eigenvalue of  $f$  uniquely determines an invariant subspace that corresponds to all Jordan blocks with this particular eigenvalue. We shall call this subspace the *root subspace* corresponding to the given eigenvalue.

We mention one useful corollary of the Jordan theorem (which is already used in the discussion about the behavior of Markov chains). Assume that the eigenvalues of our mapping  $f$  are all of absolute value less than one. Then repeated application of the linear mapping on every vector  $v \in V$  leads to a decrease of all coordinates of  $f^k(v)$  towards zero, without bounds.

Indeed, assume  $f$  has only one eigenvalue  $\lambda$  on all the complex space  $V$  and that  $f - \lambda \text{id}_V$  is cyclic (that is, we consider only one Jordan block separately). Let  $v_1, \dots, v_\ell$  be the corresponding basis. Then the theorem says that  $f(v_2) = \lambda v_2 + v_1$ ,  $f^2(v_2) = \lambda^2 v_2 + \lambda v_1 + \lambda v_1 = \lambda^2 v_2 + 2\lambda v_1$ , and similarly for other  $v_i$ 's and higher powers. In any case, the iteration of  $f$  results in higher and higher powers of  $\lambda$  for all non-zero components. The smallest of them can differ from the largest one only by less than the dimension of  $V$ . The coefficients are bounded too.

This proves the claim. The same argument can be used to prove that for the mapping with all eigenvalues with absolute value strictly greater than one leads to unbounded growth of all coordinates for the iterations  $f^k(v)$ .

The remainder of this part of the third chapter is devoted to the proof of the Jordan theorem and a few necessary lemmas. It is much more difficult than anything so far. The reader can skip it, until the beginning of the fifth part of this chapter in case of any problems with reading it.

**3.4.12. Root spaces.** We have already seen by explicit examples that the eigensubspaces completely describe geometric properties for some linear mappings only. Thus we now introduce a more subtle tool, the root subspaces.

**Definition.** A non-zero vector  $u \in V$  is called a *root vector* of the linear mapping  $\varphi : V \rightarrow V$ , if there exists an  $a \in \mathbb{K}$  and an integer  $k > 0$  such that  $(\varphi - a \text{id}_V)^k(u) = 0$ . This means that the  $k$ -th iteration of the given mapping sends  $u$

**3.D.23.** Let  $\varphi : \mathbb{C}^2 \rightarrow \mathbb{C}^2$  the linear mapping given by

$$\varphi \left( \begin{pmatrix} z_1 \\ z_2 \end{pmatrix} \right) = \begin{pmatrix} iz_1 + 2z_2 \\ z_1 - iz_2 \end{pmatrix}.$$

Determine the matrix of  $\varphi$  with respect to the standard basis of  $\mathbb{C}^2$  and find its adjoint operator  $\varphi^*$ . Deduce that  $\varphi$  is *not* self-adjoint. Next solve the task in Sage.

**Solution.** Consider the standard orthonormal basis  $\underline{e} = \{e_1, e_2\}$  of  $\mathbb{C}^2$  (with respect to the standard Hermitian form  $\langle \cdot, \cdot \rangle$ ). Recall that if  $A = [\varphi]_{\underline{e}}$  is the matrix of  $\varphi$  with respect to  $\underline{e}$  and  $A = (a_{ij})$ , then we have  $a_{ij} = \langle \varphi(u_j), u_i \rangle$ . We compute  $\varphi(e_1) = (i, 1)^T$ ,  $\varphi(e_2) = (2, -i)^T$  and hence  $a_{11} = \langle \varphi(e_1), e_1 \rangle = i$ ,  $a_{12} = \langle \varphi(e_2), e_1 \rangle = 2$ ,  $a_{21} = \langle \varphi(e_1), e_2 \rangle = 1$  and  $a_{22} = \langle \varphi(e_2), e_2 \rangle = -i$ . Directly

$$A = [\varphi]_{\underline{e}} = \begin{pmatrix} \varphi(e_1) & \varphi(e_2) \end{pmatrix} = \begin{pmatrix} i & 2 \\ 1 & -i \end{pmatrix}.$$

Then, for the matrix  $A^* = \bar{A}^T$  we compute  $A^* = \begin{pmatrix} -i & 1 \\ 2 & i \end{pmatrix}$ .

Consequently, the adjoint of  $\varphi$  is given by

$$\varphi^* \left( \begin{pmatrix} z_1 \\ z_2 \end{pmatrix} \right) = \begin{pmatrix} -iz_1 + z_2 \\ 2z_1 + iz_2 \end{pmatrix}.$$

To verify this result we will use defining equation of  $\varphi^*$ , that is,  $\langle \varphi(u), v \rangle = \langle u, \varphi^*(v) \rangle$ , for any two vectors  $u = (z_1, z_2)^T$  and  $v = (z_3, z_4)^T$  of  $\mathbb{C}^2$ . We compute

$$\begin{aligned} \left\langle \begin{pmatrix} iz_1 + 2z_2 \\ z_1 - iz_2 \end{pmatrix}, \begin{pmatrix} z_3 \\ z_4 \end{pmatrix} \right\rangle &= (iz_1 + 2z_2)\bar{z}_3 + (z_1 - iz_2)\bar{z}_4 \\ &= iz_1\bar{z}_3 + 2z_2\bar{z}_3 + z_1\bar{z}_4 - iz_2\bar{z}_4, \\ \left\langle \begin{pmatrix} z_1 \\ z_2 \end{pmatrix}, \begin{pmatrix} -iz_3 + z_4 \\ 2z_3 + iz_4 \end{pmatrix} \right\rangle &= z_1\overline{(-iz_3 + z_4)} + z_2\overline{(2z_3 + iz_4)} \\ &= z_1(i\bar{z}_3 + \bar{z}_4) + z_2(2\bar{z}_3 - i\bar{z}_4) \\ &= iz_1\bar{z}_3 + z_1\bar{z}_4 + 2z_2\bar{z}_3 - iz_2\bar{z}_4. \end{aligned}$$

Finally, since  $A \neq A^*$  it follows that  $\varphi$  is not self-adjoint.

In Sage a solution goes as follows:

```
# Define the matrix A of the linear map phi
A = Matrix(QQbar, [[I, 2], [1, -I]])
# Display the matrix A
show("Matrix A of phi:")
show(A)
# Compute the adjoint of A
A_adjoint = A.H
# Display the adjoint matrix
show("Adjoint matrix A*:")
show(A_adjoint)
# Check if A is self-adjoint
is_self_adjoint = (A == A_adjoint)
# Display whether A is self-adjoint
show("Is A self-adjoint?")
show(is_self_adjoint)
```

□

**3.D.24. The numerical system QQbar in Sage.** Observe that the Sage solution presented in 3.D.23 uses the option QQbar to define the matrix A. This represents the numerical system of algebraic complex numbers. The field of algebraic

to zero. The set of all root vectors corresponding to a fixed scalar  $\lambda$  along with the zero vector is called the *root subspace* associated with the scalar  $\lambda \in \mathbb{K}$ . We denote it by  $\mathcal{R}_\lambda$ .

If  $u$  is a root vector and the integer  $k$  from the definition is chosen as the smallest possible one for  $u$ , then  $(\varphi - a \text{id}_V)^{k-1}(u)$  is an eigenvector with the eigenvalue  $a$ . Thus we have  $\mathcal{R}_\lambda = \{0\}$  for all scalars  $\lambda$  which are not in the spectrum of the mapping  $\varphi$ .

**Proposition.** Let  $\varphi : V \rightarrow V$  be a linear mapping. Then

- (1)  $\mathcal{R}_\lambda \subset V$  is a vector subspace for every  $\lambda \in \mathbb{K}$ ,
- (2) for every  $\lambda, \mu \in \mathbb{K}$ , the subspace  $\mathcal{R}_\lambda$  is invariant with respect to the linear mapping  $(\varphi - \mu \text{id}_V)$ . In particular  $\mathcal{R}_\lambda$  is invariant with respect to  $\varphi$ ,
- (3) if  $\mu \neq \lambda$ , then  $(\varphi - \mu \text{id}_V)|_{\mathcal{R}_\lambda}$  is invertible,
- (4) the mapping  $(\varphi - \lambda \text{id}_V)|_{\mathcal{R}_\lambda}$  is nilpotent.

**PROOF.** (1) Checking the properties of the vector subspace is easy and is left to the reader.

(2) Assume that  $(\varphi - \lambda \text{id}_V)^k(u) = 0$  and put  $v = (\varphi - \mu \text{id}_V)(u)$ . Then

$$\begin{aligned} (\varphi - \lambda \text{id}_V)^k(v) &= (\varphi - \lambda \text{id}_V)^k((\varphi - \lambda \text{id}_V) + (\lambda - \mu) \text{id}_V)(u) \\ &= (\varphi - \lambda \text{id}_V)^{k+1}(u) + (\lambda - \mu) \cdot (\varphi - \lambda \text{id}_V)^k(u) = 0 \end{aligned}$$

(3) If  $u \in \text{Ker}(\varphi - \mu \text{id}_V)|_{\mathcal{R}_\lambda}$ , then

$$\begin{aligned} (\varphi - \lambda \text{id}_V)(u) &= (\varphi - \mu \text{id}_V)(u) + (\mu - \lambda)u = (\mu - \lambda)u. \\ \text{This implies } 0 &= (\varphi - \lambda \text{id}_V)^k(u) = (\mu - \lambda)^k u \text{ and thus } \\ \text{also } u &= 0 \text{ for } \lambda \neq \mu. \end{aligned}$$

(4) Choose a basis  $e_1, \dots, e_p$  of the subspace  $\mathcal{R}_\lambda$ . By definition, there exist integers  $k_i$  such that  $(\varphi - \lambda \text{id}_V)^{k_i}(e_i) = 0$ . In particular, the entire mapping  $(\varphi - \lambda \text{id}_V)|_{\mathcal{R}_\lambda}$  must be nilpotent. □

**3.4.13. Quotient spaces.** Our next aim is to show that the dimension of the root spaces always equals the algebraic multiplicity of the corresponding eigenvalues. First, we introduce some general useful technical tools.

#### QUOTIENT SPACES

**Definition.** Let  $U \subset V$  be a vector subspace. Define an equivalence relation on the set of all vectors in  $V$  by  $v_1 \sim v_2$  if and only if  $v_1 - v_2 \in U$ . Axioms of equivalence are easy to check. The set  $V/U$  of the classes of this equivalence is equipped by the operations defined by using representatives. That is, for classes  $[u]$  and  $[v]$  determined by the vectors  $u$  and  $v$ , set  $[v] + [w] = [v + w]$ ,  $a[u] = [au]$ . This is a well defined vector space called the *quotient vector space* of the space  $V$  by the subspace  $U$ .

Check the correctness of the definition of the operations and verify all axioms of the vector space in detail!

The classes (vectors) in the quotient space  $V/U$  will often be denoted as formal sums of one representative with all

numbers, usually denoted by  $\bar{\mathbb{Q}}$ , is formed by adjoining the rational numbers  $\mathbb{Q}$  with the roots of all polynomial equations with rational coefficients. In other words, an algebraic number is a complex number that is a root of a non-zero polynomial equation with rational coefficients. Thus, in Sage QQbar is an extension of the numerical system QQ, enabling exact computations with algebraic numbers. However, the result would be the same if we used CC, instead of QQbar, as both numerical systems approximate complex numbers.

Note however that QQbar allows for exact algebraic computations, while CC uses floating-point arithmetic for complex numbers. In particular, when displaying complex matrices with QQbar, then each element is shown in its exact algebraic form, preserving the precision of computations. In contrast, CC displays complex matrices using floating-point approximations, which can introduce rounding errors but are generally more efficient for large-scale computations.

**3.D.25.** Use Sage to determine which of the following matrices is Hermitian:

$$A = \begin{pmatrix} \sqrt{2} & i & 1-i \\ -i & 10 & \sqrt{2}+i \\ 1+i & \sqrt{2}-i & 0 \end{pmatrix},$$

$$B = \begin{pmatrix} a & i+b \\ -i+b & \sqrt{|a|} \end{pmatrix}, \text{ where } a, b \in \mathbb{R},$$

$$C = \begin{pmatrix} 1 & 8i & 1-i\sqrt{5} \\ -8i & 4z & 0 \\ 1+i\sqrt{5} & 0 & 1 \end{pmatrix}, \text{ where } z \in \mathbb{C} \text{ with } \text{Im}(z) = 0,$$

$$D = \begin{pmatrix} i\sqrt{2} & i & 1-i \\ -i & 0 & 4+i \\ 1+i & 4-i & 0 \end{pmatrix}.$$

**3.D.26.** Prove that with respect to the Frobenius inner product  $B(A, B) = \text{tr}(B^* A)$  on  $\text{Mat}_n(\mathbb{C})$  the following statement is true: Two matrices  $A, B \in \text{Mat}_n(\mathbb{C})$  satisfying  $B = U^* A U$  for some  $n \times n$  unitary matrix  $U$ , are such that  $\|A\|_B^2 = \|B\|_B^2$ .

**3.D.27.** Consider the linear map  $\varphi : \mathbb{R}^2 \rightarrow \mathbb{R}^3$  defined by

$$\varphi \left( \begin{pmatrix} x \\ y \end{pmatrix} \right) = \begin{pmatrix} \sqrt{2}x + y \\ x - y \\ 2y \end{pmatrix}.$$

Compute its adjoint operator  $\varphi^* : \mathbb{R}^3 \rightarrow \mathbb{R}^2$ . Next examine the linear operator  $\psi : \mathbb{C}^3 \rightarrow \mathbb{C}^3$  whose matrix with respect to the standard basis of  $\mathbb{C}^3$  is given by

$$B = \begin{pmatrix} 10 & 5+5i & 3+2i \\ 5-5i & 5 & \sqrt{2}i \\ 3-2i & -\sqrt{2}i & 0 \end{pmatrix}.$$

vectors in the subspace  $U$ , for instance  $u + U \in V/U, u \in V$ . The class  $0 + U$  is the zero vector in  $V/U$ , i.e. the vector  $u \in V$  represents the zero element in  $V/U$  if and only if  $u \in U$ .

Trivial examples are  $V/\{0\} \cong V, V/V \cong \{0\}$ . Another example is the quotient space of the plane  $\mathbb{R}^2$  factored by any one-dimensional subspace (here, every one-dimensional subspace  $U \subset \mathbb{R}^2$  is a line passing through the origin). Then the equivalence classes are all the lines parallel to this line.

**Proposition.** Let  $U \subset V$  be a vector subspace and  $(u_1, \dots, u_n)$  be a basis of  $V$ , such that  $(u_1, \dots, u_k)$  is a basis of  $U$ . Then  $\dim V/U = n - k$  and the vectors

$$u_{k+1} + U, \dots, u_n + U$$

form a basis of  $V/U$ .

**PROOF.**  $V = \text{span}\{u_1, \dots, u_n\}$ , so  $V/U = \text{span}\{u_1 + U, \dots, u_n + U\}$ . But the first  $k$  generators are zero, thus  $V/U = \text{span}\{u_{k+1} + U, \dots, u_n + U\}$ . Assume that the linear combination  $a_{k+1}(u_{k+1} + U) + \dots + a_n(u_n + U) = (a_{k+1}u_{k+1} + \dots + a_nu_n) + U = 0 \in V/U$  vanishes. Equivalently, this linear combination of the vectors  $u_{k+1}, \dots, u_n$  belongs to the subspace  $U$ . Since  $U$  is generated by the remaining vectors in the basis of  $V$ , the latter linear combination is necessarily zero, and so all coefficients  $a_i$  are zero. This proves the linear independence of the generators of  $V/U$ .  $\square$

**3.4.14. Induced mappings on quotient spaces.** Assume that  $U \subset V$  is an invariant subspace with respect to linear mapping  $\varphi : V \rightarrow V$  and choose basis  $u_1, \dots, u_n$  of the space  $V$  such that the first  $k$  vectors of this basis is a basis of  $U$ . With

this basis,  $\varphi$  has block matrix  $A = \begin{pmatrix} B & C \\ 0 & D \end{pmatrix}$ . Then we can prove the following lemma:

**Lemma.** (1) the mapping  $\varphi$  induces a linear mapping  $\varphi_{V/U} : V/U \rightarrow V/U, \varphi_{V/U}(v+U) = \varphi(v)+U$  with the matrix  $D$  under the induced basis  $u_{k+1} + U, \dots, u_n + U$  on  $V/U$ ,  
 (2) the characteristic polynomial of  $\varphi_{V/U}$  divides the characteristic polynomial of  $\varphi$ .

**PROOF.** For  $v, w \in V, u \in U, a \in \mathbb{K}$  we have  $\varphi(v+u) \in \varphi(v)+U$  (because  $U$  is invariant),  $(\varphi(v)+U) + (\varphi(w)+U) = \varphi(v+w)+U$  and  $a(\varphi(v)+U) = a\varphi(v)+U = \varphi(av)+U$  (because  $\varphi$  is linear), thus the mapping  $\varphi_{V/U}$  is well-defined and linear. Moreover the very definition of the matrix of a mapping in a basis implies that the matrix of  $\varphi_{V/U}$  in the induced basis on  $V/U$  is exactly the matrix  $D$  (when counting the images of the basis elements the coefficients of the matrix  $C$  add only to the class  $U$ ).

The characteristic polynomial of the induced mapping  $\varphi_{V/U}$  is thus  $|D - \lambda E|$ , while characteristic polynomial of the original mapping  $\varphi$  is  $|A - \lambda E| = |B - \lambda E||D - \lambda E|$ .  $\square$

Demonstrate that this operator is self-adjoint. ○

**3.D.28.** Derive the adjoint of the trace  $\text{tr} : \text{Mat}_m(\mathbb{F}) \rightarrow \mathbb{F}$  with respect to the Frobenius inner product  $\mathcal{B}(A, B) = \text{tr}(B^* A)$ , for  $\mathbb{F} \in \{\mathbb{R}, \mathbb{C}\}$ . ○

**3.D.29.** Let  $(V, \langle \cdot, \cdot \rangle)$  be an inner product space and let  $W \subset V$  be a subspace of  $W$ . Show that the orthogonal projection  $\text{proj}_W : V \rightarrow V$  on  $W$  is self-adjoint. ○

Recall that a linear endomorphism  $f : V \rightarrow V$  on a (finite-dimensional) vector space  $V$  is diagonalizable if and only if  $V$  admits a basis  $B$ , consisting of eigenvectors of  $f$ . When  $V$  is equipped with a scalar product  $\langle \cdot, \cdot \rangle$  and given an endomorphism  $f$ , it is natural to ask whether there exists an orthonormal basis of eigenvectors for  $f$ . If such a basis exists, the matrix  $[f]_B$  of  $f$  with respect to  $B$  is diagonal, and the same holds true for the matrix associated with the adjoint  $f^*$  of  $f$ . Since diagonal matrices commute, this implies  $f \circ f^* = f^* \circ f$ . Linear operators (or matrices) satisfying this relation are called “normal”. For instance, orthogonal or unitary matrices are normal, but there are many other types of normal matrices as well, see below.

It turns out that on a complex scalar vector space  $(V, \langle \cdot, \cdot \rangle)$  an endomorphism  $f : V \rightarrow V$  is normal if and only if  $V$  has an orthonormal basis consisting of eigenvectors of  $f$ . It is important to note that this result does not hold for real vector spaces. In the case of a real unitary space the existence of an orthonormal basis of eigenvectors for a linear operator  $f$  is equivalent to  $f$  being self-adjoint, i.e.,  $f = f^*$ .

**3.D.30.** Prove that orthogonal and unitary matrices are normal. Next demonstrate that not all normal matrices (or transformations) are orthogonal or unitary, by providing a counterexample, that is, a normal matrix that is neither orthogonal nor unitary. ○

Let  $\varphi : V \rightarrow V$  be a normal operator on a unitary space  $(V, \langle \cdot, \cdot \rangle)$ . By 3.4.8 and the proof given in the main theorem of this paragraph, we know that eigenvectors corresponding to distinct eigenvalues of  $\varphi$  are orthogonal with respect to  $\langle \cdot, \cdot \rangle$ . Let us illustrate this important situation by examples.

**3.D.31.** Suppose that  $\varphi : V \rightarrow V$  is a normal operator on a (finite-dimensional) unitary space  $(V, \langle \cdot, \cdot \rangle)$ , having two distinct eigenvalues, namely,  $\lambda_1 = 3$  and  $\lambda_2 = 5$ . Assume also that the corresponding eigenvectors are of unit length. Use the Pythagorean theorem to prove that there exist a vector  $u \in V$  with  $\|u\| = 2$  and  $\|\varphi(u)\| = 6$ , where  $\|\cdot\|$  is the norm induced by  $\langle \cdot, \cdot \rangle$ .

**Solution.** Suppose that  $v, w \in V$  are the eigenvectors of  $\varphi$  corresponding to  $\lambda_1$  and  $\lambda_2$ , that is  $\varphi(v) = 3v$  and  $\varphi(w) = 5w$ , respectively. By assumption  $\varphi$  is normal, hence eigenvectors corresponding to distinct eigenvalues are orthogonal,  $\langle v, w \rangle = 0$ . Then, for the vector  $u = v + w$  by the

**Corollary.** Let  $V$  be a vector space over  $\mathbb{K}$  of dimension  $n$  and let  $\varphi : V \rightarrow V$  be a linear mapping whose spectrum contains  $n$  elements (that is, all roots of the characteristic polynomial lie in  $\mathbb{K}$  and we count their multiplicities). Then there exists a sequence of invariant subspaces  $\{0\} = V_0 \subset V_1 \subset \dots \subset V_n = V$  with dimensions  $\dim V_i = i$ . Consider a basis  $u_1, \dots, u_n$  of the space  $V$  such that  $V_i = \text{span}\{u_1, \dots, u_i\}$ . In this basis, the matrix of the mapping  $\varphi$  is an upper triangular matrix:

$$\begin{pmatrix} \lambda_1 & \dots & * \\ \vdots & \ddots & \vdots \\ 0 & \dots & \lambda_n \end{pmatrix},$$

with the spectrum  $\lambda_1, \dots, \lambda_n$  on the diagonal.

**PROOF.** The subspaces  $V_i$  are constructed inductively. Let  $\{\lambda_1, \dots, \lambda_n\}$  be the spectrum of the mapping  $\varphi$ . Thus the characteristic polynomial of the mapping  $\varphi$  is of the form  $\pm(\lambda - \lambda_1) \cdots (\lambda - \lambda_n)$ . We choose  $V_0 = \{0\}$ ,  $V_1 = \text{span}\{u_1\}$ , where  $u_1$  is an eigenvector with eigenvalue  $\lambda_1$ . According to the previous theorem, the characteristic polynomial of the mapping  $\varphi_{V/V_1}$  is of the form  $\pm(\lambda - \lambda_2) \cdots (\lambda - \lambda_n)$ . Assume that we have already constructed linearly independent vectors  $u_1, \dots, u_k$  and invariant subspaces  $V_i = \text{span}\{u_1, \dots, u_i\}$ ,  $i = 1, \dots, k < n$  such that the characteristic polynomial of  $\varphi_{V/V_k}$  is of the form  $\pm(\lambda - \lambda_{k+1}) \cdots (\lambda - \lambda_n)$  and  $\varphi(u_i) \in (\lambda_i \cdot u_i + V_{i-1})$  for all  $i = 1, \dots, k$ .

We want to add one more vector  $u_{k+1}$  with analogous properties. There exists an eigenvector  $u_{k+1} + V_k \in V/V_k$  of the mapping  $\varphi_{V/V_k}$  with the eigenvalue  $\lambda_{k+1}$ . Consider the space  $V_{k+1} = \text{span}\{u_1, \dots, u_{k+1}\}$ . If the vector  $u_{k+1}$  is a linear combination of the vectors  $u_1, \dots, u_k$  then  $u_{k+1} + V_k$  would be the zero class in  $V/V_k$ . But this is not possible. Thus  $\dim V_{k+1} = k + 1$ . It remains to study the induced mapping  $\varphi_{V/V_{k+1}}$ . The characteristic polynomial of this mapping is of degree  $n - k - 1$  and divides the characteristic polynomial of the mapping  $\varphi$ . But completing the vectors  $u_1, \dots, u_{k+1}$  to the basis of  $V$  yields a block matrix of the mapping  $\varphi$  with an upper triangular submatrix  $B$  in the left upper corner and zero in the left lower corner. The diagonal elements are exactly the scalars  $\lambda_1, \dots, \lambda_{k+1}$ . Therefore the roots of the characteristic polynomial of the induced mapping have the required properties. □

**Remark.** If  $V$  decomposes into the direct sum of eigensubspaces for  $\varphi$ , the latter results do not say anything new. But their significance consists in the fact, that only the existence of  $\dim V$  roots of the characteristic polynomial (counting multiplicities) is assumed. This is ensured whenever the field  $\mathbb{K}$  is algebraically closed, for instance the complex numbers  $\mathbb{C}$ . As a direct consequence we see that the determinant and the trace of the mapping  $\varphi$  are always the product and the sum of the elements in the spectrum, respectively.

This can be also used for all real matrices. Just consider them to be complex, calculate the determinant or the trace as

Pythagorean theorem we have  $\|u\|^2 = \|v\|^2 + \|w\|^2$ , that is  $\|u\| = \sqrt{2}$ . On the other hand, again by the Pythagorean theorem we obtain

$$\begin{aligned} \|\varphi(u)\| &= \|\varphi(v+w)\| = \|\varphi(v) + \varphi(w)\| \\ &= \|3v + 5w\| = \sqrt{9 + 25} = 6. \end{aligned}$$

□

**3.D.32.** Consider the normal operator  $\varphi : \mathbb{C}^3 \rightarrow \mathbb{C}^3$  whose matrix with respect to the standard basis of  $\mathbb{C}^3$  is given by

$$A = \begin{pmatrix} 2 & 1+i & 0 \\ 1-i & 3 & 0 \\ 0 & 0 & 1 \end{pmatrix}.$$

Use Sage to illustrate the orthogonality of eigenvectors corresponding to distinct eigenvalues of  $\varphi$ . Next present a formal solution. ○

**3.D.33. Skew-Hermitian matrices.** Recall that a complex matrix  $A = (a_{ij})$  is called skew-Hermitian if  $A = -A^*$ , or equivalently  $a_{ij} = -\bar{a}_{ji}$ . Prove that:

- (i) Every skew-Hermitian matrix  $A$  is normal.
- (ii) The eigenvalues of a skew-Hermitian matrix  $A$  are purely imaginary, that is, they are of the form  $i\mu$  with  $\mu \in \mathbb{R}$ .

**Solution.** (i) The first claim is obvious: If  $A^* = -A$ , then  $A^*A = -A^2 = AA^*$ . Hence  $A$  is normal.

(ii) Suppose that  $\lambda$  is an eigenvalue of  $A$  with corresponding eigenvector  $u$ , that is  $Au = \lambda u$ . It is sufficient to prove that  $\lambda = -\bar{\lambda}$ . First we see that

$$u^*Au = u^*(\lambda u) = \lambda u^*u = \lambda \|u\|^2,$$

and since  $\|u\| \in \mathbb{R}$  the r.h.s belongs to  $\mathbb{C}$ . Thus  $(u^*Au)^* = \bar{\lambda} \|u\|^2$ . Now, because  $\|u\| \in \mathbb{R}$ , taking conjugates we obtain

$$\begin{aligned} \bar{\lambda} \|u\|^2 &= \overline{\lambda \|u\|^2} = (u^*Au)^* = u^*A^*u = -u^*Au \\ &= -u^*\lambda u = -\lambda \|u\|^2. \end{aligned}$$

This final relation yields the desired  $\lambda = -\bar{\lambda}$ . □

**3.D.34.** Present an example of a normal matrix which is neither Hermitian nor skew-Hermitian. Moreover, use Sage to verify your answer. ○

Recall that a  $n \times n$  matrix  $A$  is diagonalizable if and only if it has  $n$  linearly independent eigenvectors, and in this case  $A$  is similar to the diagonal matrix  $D$  consisting of the eigenvalues of  $A$ , i.e.,  $P^{-1}AP = D$ . Here,  $P$  is the matrix obtained from the eigenvectors of  $A$  (as column vectors). A square matrix  $A$  is said to be orthogonally diagonalizable when an orthogonal matrix  $P$  can be found such that  $P^{-1}AP = P^TAP$  is diagonal.

To clarify the concept, we provide an example, and additional tasks on orthogonal diagonalization are discussed in Section F (see for example 3.F.46 for an implementation of orthogonal diagonalization using Sage).

the product or sum of eigenvalues and because both determinant and the trace are algebraic expressions in terms of the elements of the matrix, the results will be correct.

**3.4.15. Orthogonal triangulation.** If we are given a scalar product on a vector space  $V$  and  $U \subset V$  is a subspace, then clearly  $V/U \simeq U^\perp$  where  $v \in U^\perp$  is identified with  $v + U$ . Moreover, each class of the quotient space  $V/U$  contains exactly one vector from  $U^\perp$  (the difference of two such vector is in  $U \cap U^\perp$ ). We can exploit this observation in every inductive step of the proof of the theorem above. Choose the representative  $u_{k+1} \in V_k^\perp$  of the eigenvector of  $\varphi_{V/V_k}$ . This modification leads to the orthogonal basis with the properties required in the claim about triangulation in the corollary above. Therefore there exists such an orthonormal basis, and we arrive at a very important theorem:

SCHUR'S ORTHOGONAL TRIANGULATION THEOREM

**Theorem.** Let  $\varphi : V \rightarrow V$  be a linear mapping on a vector space with scalar product. Let there be  $m = \dim V$  eigenvalues, counting multiplicities. Then there exists an orthonormal basis of the space  $V$  such that the matrix of  $\varphi$  in this basis is upper triangular with eigenvalues  $\lambda_1, \dots, \lambda_m$  on the diagonal.

**3.4.16. Theorem.** Let  $\varphi : V \rightarrow V$  be a linear mapping and  $\lambda_1, \dots, \lambda_k$  be all distinct eigenvalues. Then the sum of the root spaces  $\mathcal{R}_{\lambda_1}, \dots, \mathcal{R}_{\lambda_k}$  is direct. Furthermore, for every eigenvalue  $\lambda$  the dimension of the subspace  $\mathcal{R}_\lambda$  equals the algebraic multiplicity of  $\lambda$ .

**PROOF.** We prove first the independence of nonzero vectors from different root spaces. We proceed by induction over the number  $k$  of root spaces. The claim is obvious if  $k = 1$ . Assume that the theorem holds for cases with less than  $k > 1$  root spaces and assume that vectors  $u_1 \in \mathcal{R}_{\lambda_1}, \dots, u_k \in \mathcal{R}_{\lambda_k}$  satisfy  $u_1 + \dots + u_k = 0$ . Then,  $(\varphi - \lambda_k \text{id}_V)^j(u_k) = 0$  for suitable  $j$ , and moreover all  $y_i = (\varphi - \lambda_k \text{id}_V)^j(u_i)$  are non-zero vectors in  $\mathcal{R}_{\lambda_i}$ ,  $i = 1, \dots, k-1$ , whenever  $u_i$  are non-zero by Proposition 3.4.12. But at the same time

$$y_1 + \dots + y_{k-1} = (\varphi - \lambda_k \cdot \text{id}_V)^j \left( \sum_{i=1}^k u_i \right) = 0$$

and, according to the inductive assumption, all  $y_i$  are zero. But then also all  $u_i$ ,  $1 \leq i < k$  must vanish and thus  $u_k = 0$ , too. This proves the first claim.

It remains consider the dimensions of the root spaces  $\mathcal{R}_\lambda$ . Consider an eigenvalue  $\lambda$  of  $\varphi$ , use the same notation  $\varphi$  for the restriction  $\varphi|_{\mathcal{R}_\lambda}$  and write  $\psi : V/\mathcal{R}_\lambda \rightarrow V/\mathcal{R}_\lambda$  for the mapping induced by  $\varphi$  on the quotient space.

Assume that the dimension  $\mathcal{R}_\lambda$  is strictly smaller than the algebraic multiplicity of the root  $\lambda$  of the characteristic polynomial. In view of lemma 3.4.14,  $\lambda$  is also an eigenvalue

**3.D.35. (Orthogonal diagonalization)** Consider the symmetric matrix  $A$  given below. Find a matrix  $P \in \text{Mat}_3(\mathbb{R})$  such that  $P^{-1}AP = P^T AP$  is diagonal:

$$A = \begin{pmatrix} 1 & 2 & 6 \\ 2 & 0 & 2 \\ 6 & 2 & 1 \end{pmatrix}.$$

A real  $n \times n$  symmetric matrix has real eigenvalues, and the same holds true for Hermitian matrices, see 3.4.7. However, the converse is not necessarily true, as demonstrated by the counterexample given by the matrix  $A = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}$ . Moreover, by the spectral decomposition theorem of self-adjoint operators (see the theorem in ??), the eigenvectors corresponding to distinct eigenvalues of a symmetric or a Hermitian matrix  $A$  are orthogonal. Leveraging these properties, one can derive the following fundamental result which is further motivated by the result in 3.D.35, mentioned above.

**3.D.36.** Prove that a real  $n \times n$  matrix  $A$  is orthogonally diagonalizable if and only if is symmetric, i.e.,  $A = A^T$ .

In a similar vein, a complex square matrix  $A \in \text{Mat}_n(\mathbb{C})$  is said to be “unitary diagonalizable”, if there exists a unitary matrix  $U$  such that  $U^*AU$  is diagonal. By the spectral theorem (see 3.4.7) we know that any Hermitian matrix  $A$  is unitary diagonalizable. Conversely, the following holds.

**3.D.37.** Suppose that  $A$  is a complex matrix with real eigenvalues, which can be diagonalizable by a unitary matrix  $U$ . Show that  $A$  is Hermitian.

**Solution.** By assumption, we have  $U^*AU = D$ , where  $D$  is the diagonal matrix having diagonal entries the eigenvalues of  $A$ . However, the hypothesis states that  $A$  has real eigenvalues, so  $D$  is a real diagonal matrix, which implies that  $D^* = D$ . Now, since  $U$  is unitary from the relation  $U^*AU = D$  we get  $A = (U^*)^{-1}DU^{-1} = UDU^*$ . Then we see that

$$A^* = (UDU^*)^* = UD^*U^* = UDU^* = A.$$

**3.D.38. (Unitary diagonalization)** Consider the matrices  $A, B$  given below. For each case demonstrate that the corresponding eigenvectors are orthogonal each other (with respect to the standard Hermitian form  $\langle \cdot, \cdot \rangle$  on  $\mathbb{C}^3$ ). Next demonstrate that both matrices are unitarily diagonalizable and illustrate the conditions necessary for unitary diagonalization:

$$A = \begin{pmatrix} -1 & 0 & i \\ 0 & 1 & 0 \\ -i & 0 & 1 \end{pmatrix}, \quad B = \begin{pmatrix} 3 & i \\ -i & 3 \end{pmatrix}.$$

**3.D.39.** Prove that a normal matrix  $A$  having all its eigenvalues purely imaginary is skew-Hermitian.

of the mapping  $\psi$ . Let  $(v + \mathcal{R}_\lambda) \in V/\mathcal{R}_\lambda$  be the corresponding eigenvector, that is,  $\psi(v + \mathcal{R}_\lambda) = \lambda(v + \mathcal{R}_\lambda)$ . Then  $v \notin \mathcal{R}_\lambda$  and  $\varphi(v) = \lambda v + w$  for suitable  $w \in \mathcal{R}_\lambda$ . Thus  $w = (\varphi - \lambda \text{id}_V)(v)$  and  $(\varphi - \lambda \text{id}_V)^j(w) = 0$  for suitable  $j$ . We conclude that  $(\varphi - \lambda \text{id}_V)^{j+1}(v) = 0$ , which contradicts the choice  $v \notin \mathcal{R}_\lambda$ .

It follows that the dimension of  $\mathcal{R}_\lambda$  equals the algebraic multiplicity of the root  $\lambda$  of the characteristic polynomial of the mapping  $\varphi : V \rightarrow V$ .  $\square$

Combining the latter theorem with the triangulation result from Corollary 3.4.14, we can formulate:

**Corollary.** Consider a linear mapping  $\varphi : V \rightarrow V$  on a vector space  $V$  over scalars  $\mathbb{K}$ , whose entire spectrum is in  $\mathbb{K}$ . Then  $V = \mathcal{R}_{\lambda_1} \oplus \dots \oplus \mathcal{R}_{\lambda_n}$  is the direct sum of the root subspaces. If we choose suitable bases for these subspaces, then under this basis  $\varphi$  has block-diagonal form with upper triangular matrices in the blocks and eigenvalues  $\lambda_i$  on the diagonal.

**3.4.17. Nilpotent and cyclic mappings.** Now almost everything is prepared for the discussion about canonical forms of matrices. It only remains to clear the relation between cyclic and nilpotent mappings and combine already proved results.

**Theorem.** Let  $\varphi : V \rightarrow V$  be a nilpotent linear mapping. Then there exists a decomposition of  $V$  into a direct sum of subspaces  $V = V_1 \oplus \dots \oplus V_k$  such that the restriction of  $\varphi$  to each summand  $V_i$  is cyclic.

**PROOF.** We provide a straightforward construction of a basis of the space  $V$  such that the action of the mapping  $\varphi$  on the basis vectors directly shows the decomposition into the cyclic mappings.

Let  $k$  be the degree of nilpotency of the mapping  $\varphi$  and write  $P_i = \text{Im}(\varphi^i)$ ,  $i = 0, \dots, k$ . Thus,

$$\{0\} = P_k \subset P_{k-1} \subset \dots \subset P_1 \subset P_0 = V.$$

Choose a basis  $e_1^{k-1}, \dots, e_{p_{k-1}}^{k-1}$  of the space  $P_{k-1}$ , where  $p_{k-1} > 0$  is the dimension of  $P_{k-1}$ . By definition,  $P_{k-1} \subset \text{Ker } \varphi$ , i.e.  $\varphi(e_j^{k-1}) = 0$  for all  $j$ .

Assume that  $P_{k-1} \neq V$ . Since  $P_{k-1} = \varphi(P_{k-2})$ , there necessarily exist the vectors  $e_j^{k-2}$ ,  $j = 1, \dots, p_{k-1}$  in  $P_{k-2}$ , such that  $\varphi(e_j^{k-2}) = e_j^{k-1}$ . Assume

$$a_1 e_1^{k-1} + \dots + a_{p_{k-1}} e_{p_{k-1}}^{k-1} + b_1 e_1^{k-2} + \dots + b_{p_{k-1}} e_{p_{k-1}}^{k-2} = 0.$$

Applying  $\varphi$  on this linear combination yields  $b_1 e_1^{k-1} + \dots + b_{p_{k-1}} e_{p_{k-1}}^{k-1} = 0$ . This is a linear combination of independent vectors, therefore all  $b_j = 0$ . But then also  $a_j = 0$ . Thus the linear independence of all  $2p_{k-1}$  chosen vectors is established. Next, extend them to a basis

$$(1) \quad \begin{matrix} e_1^{k-1}, \dots, e_{p_{k-1}}^{k-1} \\ e_1^{k-2}, \dots, e_{p_{k-1}}^{k-2}, e_{p_{k-1}+1}^{k-2}, \dots, e_{p_{k-2}}^{k-2} \end{matrix}$$

of the space  $P_{k-2}$ . The images of the added basis vectors are in  $P_{k-1}$ . Necessarily they must be linear combinations of

We have seen that working with diagonalizable matrices significantly simplifies many computations, such as matrix powers. When  $A$  is not diagonalizable, it is still useful to have a simplified form of  $A$  with respect to some ordered basis.

In fact, for any linear transformation  $f : V \rightarrow V$  on a finite-dimensional complex vector space  $V$ , there exists a particular simple matrix representation. If  $A$  is a complex square matrix, this means that we can find a matrix  $J$  such that  $A = PJP^{-1}$  for some invertible matrix  $P$ .

The matrix  $J$  is known as the Jordan normal form (or Jordan canonical form) and is typically represented as:

$$J = \begin{pmatrix} J_1 & & & 0 \\ & J_2 & & \\ & & \ddots & \\ 0 & & & J_k \end{pmatrix}.$$

In this expression,  $J_i$  ( $i = 1, \dots, k$ ) are the so called Jordan blocks, which are upper triangular matrices whose form is explained below. The Jordan canonical form  $J$  will be a diagonal matrix if and only if  $A$  is diagonalizable, see 3.4.10.

Let us briefly outline the procedure for computing the Jordan canonical form of a given  $n \times n$  matrix  $A$ :

- Step 1: Compute the eigenvalues  $\lambda_1, \dots, \lambda_k$  of  $A$  and their algebraic multiplicities, which we denote by  $\alpha(\lambda_i)$ .
- Step 2: Compute the geometric multiplicity  $\gamma(\lambda_i)$  of each eigenvalue  $\lambda_i$  of  $A$ . Recall that  $\gamma(\lambda_i) = \dim \text{Ker}(A - \lambda_i E)$ , where  $E$  is the  $n \times n$  identity matrix (we have  $\gamma(\lambda_i) \leq \alpha(\lambda_i)$  for all  $i = 1, \dots, k$ ).
- Step 3: For each eigenvalue  $\lambda_i$  determine the root subspace (also known as generalized eigenspace)

$$\mathcal{R}_{\lambda_i} = \text{Ker}((A - \lambda_i E)^j),$$

where  $j = \alpha(\lambda_i)$  is the algebraic multiplicity of  $\lambda_i$ . Note the null spaces  $\text{Ker}((A - \lambda_i E)^\ell)$  for  $\ell < j = \alpha(\lambda_i)$  are included in  $\mathcal{R}_{\lambda_i}$ , for any eigenvalues  $\lambda_i$ , as  $\mathcal{R}_{\lambda_i}$  captures all the necessary vectors. In particular, the dimension of  $\mathcal{R}_{\lambda_i}$  coincides with the algebraic multiplicity  $j = \alpha(\lambda_i)$  of  $\lambda_i$ , for all  $i = 1, \dots, k$ .

- Step 4: Construct the Jordan block  $J_i \equiv J_{\lambda_i}$  for all  $i = 1, \dots, k$ , which has necessarily  $\lambda_i$  on the diagonal and 1s on the superdiagonal, while other elements are 0. To determine the size of  $J_i$  we start from the highest power  $j$  for which the dimension  $\dim \text{Ker}((A - \lambda_i E)^j)$  is non-zero (this highest power is typically the algebraic multiplicity, i.e.,  $j = \alpha(\lambda_i)$ ), and move downwards to  $j = 1$ . For example, a Jordan block of size  $m \times m$  corresponding to the eigenvalue  $\lambda_i$  has the form

$$J_i = \begin{pmatrix} \lambda_i & 1 & 0 & \dots & 0 \\ 0 & \lambda_i & 1 & \dots & 0 \\ 0 & 0 & \lambda_i & \dots & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & 0 & \dots & \lambda_i \end{pmatrix} \in \text{Mat}_m(\mathbb{C}).$$

the basis elements  $e_1^{k-1}, \dots, e_{p_{k-1}}^{k-1}$ . We can thus adjust the chosen vectors  $e_{p_{k-1}+1}^{k-2}, \dots, e_{p_{k-2}}^{k-2}$  by adding the appropriate linear combinations of the vectors  $e_1^{k-2}, \dots, e_{p_{k-1}}^{k-2}$  with the result that they are in the kernel of  $\varphi$ . Thus we may assume our choice in the scheme (1) has this property.

Assume that we have already constructed a basis of the subspace  $P_{k-\ell}$  such that we can directly arrange it into the scheme similar to (1)

$$\begin{matrix} e_1^{k-1}, \dots, e_{p_{k-1}}^{k-1} \\ e_1^{k-2}, \dots, e_{p_{k-1}}^{k-2}, e_{p_{k-1}+1}^{k-2}, \dots, e_{p_{k-2}}^{k-2} \\ e_1^{k-3}, \dots, e_{p_{k-1}}^{k-3}, e_{p_{k-1}+1}^{k-3}, \dots, e_{p_{k-2}}^{k-3}, e_{p_{k-2}+1}^{k-3}, \dots, e_{p_{k-3}}^{k-3} \\ \vdots \\ e_1^{k-\ell}, \dots, e_{p_{k-1}}^{k-\ell}, e_{p_{k-1}+1}^{k-\ell}, \dots, e_{p_{k-2}}^{k-\ell}, e_{p_{k-2}+1}^{k-\ell}, \dots, e_{p_{k-\ell}}^{k-\ell} \end{matrix}$$

where the value of the mapping  $\varphi$  on any basis vector is located above it. The value is zero if there is nothing above that basis vector.

If  $P_{k-\ell} \neq V$ , then again there must exist vectors  $e_1^{k-\ell-1}, \dots, e_{p_{k-\ell}}^{k-\ell-1}$  which map to  $e_1^{k-\ell}, \dots, e_{p_{k-\ell}}^{k-\ell}$ . We can extend them to a basis  $P_{k-\ell-1}$ , say, by the vectors

$$e_{p_{k-\ell}+1}^{k-\ell-1}, \dots, e_{p_{k-\ell-1}}^{k-\ell-1}.$$

Again, exactly as when adjusting (1) above, we choose the additional basis vectors from the kernel of  $\varphi$ . and analogically as before we verify that we indeed obtain a basis for  $P_{k-\ell-1}$ .

After  $k$  steps we obtain a basis for the whole  $V$ , which has the properties given for the basis of the subspace  $P_{k-\ell}$ . Individual columns of the resulting scheme then generate the subspaces  $V_i$ . Additionally we have found the bases of these subspaces which show that corresponding restrictions of  $\varphi$  are cyclic mappings.  $\square$

**3.4.18. Proof of the Jordan theorem.** Let  $\lambda_1, \dots, \lambda_k$  be all the distinct eigenvalues of the mapping  $\varphi$ . From the assumptions of the Jordan theorem it follows that  $V = \mathcal{R}_{\lambda_1} \oplus \dots \oplus \mathcal{R}_{\lambda_k}$ .

The mappings  $\varphi_i = (\varphi|_{\mathcal{R}_{\lambda_i}} - \lambda_i \text{id}_{\mathcal{R}_{\lambda_i}})$  are nilpotent and thus each of the root spaces is a direct sum

$$\mathcal{R}_{\lambda_i} = P_{1,\lambda_i} \oplus \dots \oplus P_{j_i,\lambda_i}$$

of spaces on which the restriction of the mapping  $\varphi - \lambda_i \text{id}_V$  is cyclic. Matrices of these restricted mappings on  $P_{r,s}$  are Jordan blocks corresponding to the zero eigenvalue, the restricted mapping  $\varphi|_{P_{r,s}}$  has thus for its matrix the Jordan block with the eigenvalue  $\lambda_i$ .

For the proof of Jordan theorem it remains to verify the claim about uniqueness (up to reordering the blocks). Because the diagonal values  $\lambda_i$  are given as roots of the characteristic polynomial, their uniqueness is immediate. The decomposition to root spaces is unique as well. Thus, without loss of generality we may assume that there is just one eigenvalue  $\lambda$  and we are going to express the dimensions of

Later we will see that each Jordan block corresponds to a size which represents the length of a so-called chain of generalized eigenvectors associated with  $\lambda_i$ . The increase in dimension between the kernel of  $(A - \lambda_i E)^{j-1}$  and  $(A - \lambda_i E)^j$  is the number of blocks of size  $j$  or more.

We finally form the matrix  $J$  as posed above, i.e.,  $J$  consists of the Jordan blocks  $J_i$  which all lie along the diagonal, while the blank off-diagonal blocks are all zero. Therefore, in a Jordan matrix  $J$  the only possibly non-zero entries are those on the diagonal, which can attain any complex value (including 0), and those on the superdiagonal, which are either 0 or 1.

**3.D.40.** Let  $A$  be a matrix with characteristic polynomial  $\chi_A(\lambda) = (\lambda - \sqrt{2})^3$ . Illustrate all possible configurations for the Jordan canonical form of  $A$ .

**Solution.** Since the characteristic polynomial is of degree three, the matrix  $A$  should be  $3 \times 3$ . Since  $\chi_A(\lambda) = (\lambda - \sqrt{2})^3$ , the unique eigenvalue  $\lambda = \sqrt{2}$  has algebraic multiplicity 3. Now, the geometric multiplicity  $\gamma(\lambda)$  of  $\lambda$  satisfies  $1 \leq \gamma(\lambda) \leq 3$ . Hence there are three possible configurations (up to the ordering of the Jordan blocks):

- If  $\gamma(\lambda) = 1$ , then the Jordan canonical form will consist of a single Jordan block of size 3:

$$J = \begin{pmatrix} \sqrt{2} & 1 & 0 \\ 0 & \sqrt{2} & 1 \\ 0 & 0 & \sqrt{2} \end{pmatrix}.$$

- If  $\gamma(\lambda) = 2$ , then the Jordan canonical form will consist of one Jordan block of size 2 and one Jordan block of size 1:

$$J = \left( \begin{array}{cc|c} \sqrt{2} & 1 & 0 \\ 0 & \sqrt{2} & 0 \\ \hline 0 & 0 & \sqrt{2} \end{array} \right).$$

- If  $\gamma(\lambda) = 3$ , then the Jordan canonical form will consist of three Jordan blocks of size 1 each (in this case there exist three linearly independent eigenvectors, hence  $A$  is diagonalizable and  $J$  is diagonal):

$$J = \begin{pmatrix} \sqrt{2} & 0 & 0 \\ 0 & \sqrt{2} & 0 \\ 0 & 0 & \sqrt{2} \end{pmatrix}.$$

□

**3.D.41.** Which of the following matrices represents a Jordan canonical form? Explain your answer.

$$G_1 = \begin{pmatrix} 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 2 & 0 \\ 0 & 0 & 0 & 2 \end{pmatrix}, G_2 = \begin{pmatrix} 3 & 0 & 0 \\ 0 & 1 & 1 \\ 0 & 0 & 1 \end{pmatrix},$$

$$G_3 = \begin{pmatrix} 5 & 1 \\ 0 & 1 \end{pmatrix}, G_4 = \begin{pmatrix} -2 & 1 & 0 \\ 0 & -1 & 0 \\ 0 & 0 & -2 \end{pmatrix}, G_5 = (\pi),$$

individual Jordan blocks using the ranks  $r_k$  of the mapping  $(\varphi - \lambda \text{id}_V)^k$ . This will show that the blocks are uniquely determined (up to their order). On the other hand, changing the order of the blocks corresponds to renumbering the vectors of basis, thus we can obtain them in any order.

If  $\psi$  is a cyclic operator on an  $m$ -dimensional space, then the defect of the iterated mapping  $\psi^k$  is  $k$  for  $0 \leq k \leq m$ , while the defect is  $m$  for all  $k \geq m$ . This implies that if our matrix  $J$  of the mapping  $\varphi$  on the  $n$ -dimensional space  $V$  (remind we assume  $V = \mathcal{R}_\lambda$ ) contains  $d_k$  Jordan blocks of the order  $k$ , then the defect  $D_\ell = n - r_\ell$  of the matrix  $(J - \lambda E)^\ell$  is

$$D_\ell = d_1 + 2d_2 + \cdots + \ell d_\ell + \ell d_{\ell+1} + \cdots.$$

Now, taking the combination  $2D_k - D_{k-1} - D_{k+1}$  we cancel all those terms in the latter expression which coincide for  $\ell = k - 1, k, k + 1$  and we are left with

$$2D_k - D_{k-1} - D_{k+1} = d_k.$$

Substituting for  $D_\ell$ 's, we finally arrive at

$$d_k = 2n - 2r_k - n + r_{k-1} - n + r_{k+1} = r_{k-1} - 2r_k + r_{k+1}.$$

This is the requested expression for the sizes of the Jordan blocks and the theorem is proved.

**3.4.19. Remarks.** The proof of the theorem about the existence of the Jordan canonical form was constructive, but it does not give an efficient algorithmic approach for the construction. Now we show how our results can be used for explicit computation of the basis in which the given mapping  $\varphi : V \rightarrow V$  has its matrix in the canonical Jordan form.<sup>6</sup>

- (1) Find the roots of the characteristic polynomial.
- (2) If there are less than  $n = \dim V$  roots (counting multiplicities), then there is no canonical form.
- (3) If there are  $n$  linearly independent eigenvectors, there is a basis of  $V$  composed of eigenvectors under which  $\varphi$  has diagonal matrix.
- (4) Let  $\lambda$  be the eigenvalue with geometric multiplicity strictly smaller than the algebraic multiplicity and  $v_1, \dots, v_k$  be the corresponding eigenvectors. They should be the vectors on the upper boundary of the scheme from the proof of the theorem 3.4.17. We need to complete the basis by application of iterations  $\varphi - \lambda \text{id}_V$ . By doing this we also find in which row the vectors should be located. Hence we find the linearly independent solutions  $w_i$  of the equations  $(\varphi - \lambda \text{id})(w_i) = v_i$  from the rows below it. Repeat the procedure iteratively (that is, for  $w_i$  and so on). In this way, we find the “chains” of basis vectors that give invariant subspaces, where  $\varphi - \lambda \text{id}$  is cyclic (the columns from the scheme in the proof).

<sup>6</sup>There is a beautiful purely algebraic approach to compute the Jordan canonical form efficiently, but it does not give any direct information about the right basis. This algebraic approach is based on polynomial matrices and Weierstrass divisors. We shall not go into details in this textbook.

$$G_6 = \begin{pmatrix} 2 & 1 & 0 & 0 & 0 & 0 \\ 0 & 2 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 1 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & 0 & 0 & 0 \end{pmatrix}.$$

○

**3.D.42.** Find the Jordan canonical form of the matrix

$$A = \begin{pmatrix} 5 & 4 & 2 \\ 0 & 1 & -1 \\ -1 & -1 & 3 \end{pmatrix}.$$

**Solution.** *Step 1:* The characteristic polynomial is given by

$$\begin{aligned} \chi_A(\lambda) &= \begin{vmatrix} 5-\lambda & 4 & 2 \\ 0 & 1-\lambda & -1 \\ -1 & -1 & 3-\lambda \end{vmatrix} = (5-\lambda) \begin{vmatrix} 1-\lambda & -1 \\ -1 & 3-\lambda \end{vmatrix} \\ &\quad - 4 \begin{vmatrix} 0 & -1 \\ -1 & 3-\lambda \end{vmatrix} + 2 \begin{vmatrix} 0 & 1-\lambda \\ -1 & -1 \end{vmatrix} \\ &= -\lambda^3 + 9\lambda^2 - 24\lambda + 16. \end{aligned}$$

We see that 1 is a root of  $\chi_A(\lambda)$ . To find all roots we can apply the Horner's scheme:

$$\begin{array}{r|rrrr} 1 & -1 & 9 & -24 & 16 \\ & & -1 & 8 & -16 \\ \hline & -1 & 8 & -16 & 0 \end{array}$$

Thus,

$$\begin{aligned} \chi_A(\lambda) &= -\lambda^3 + 9\lambda^2 - 24\lambda + 16 \\ &= (\lambda - 1)(-\lambda^2 + 8\lambda - 16) = (\lambda - 1)(\lambda - 4)^2, \end{aligned}$$

and  $A$  has two eigenvalues:  $\lambda_1 = 1$  with  $\alpha(\lambda_1) = 1$  and  $\lambda_2 = 4$  with  $\alpha(\lambda_2) = 2$ .

*Step 2:* Let us now compute the geometric multiplicities. For  $\lambda_1 = 1$  we need to solve the matrix equation  $(A - E)u = 0$  for some vector  $u = (x_1, x_2, x_3)^T \in \mathbb{R}^3$ . Since

$$A - E = \begin{pmatrix} 4 & 4 & 2 \\ 0 & 0 & -1 \\ -1 & -1 & 2 \end{pmatrix},$$

we obtain the linear system

$$\{4x_1 + 4x_2 + 2x_3 = 0, x_3 = 0, -x_1 - x_2 + 2x_3 = 0\}.$$

The solution space of this system is 1-dimensional:

$$\left\{ \begin{pmatrix} x_1 \\ x_2 \\ x_3 \end{pmatrix} = \begin{pmatrix} r \\ -r \\ 0 \end{pmatrix} : r \in \mathbb{R} \right\}.$$

Thus  $\gamma(\lambda_1) = \dim \text{Ker}(A - I) = 1$ , in particular we may assume that  $V_1$  is generated by the eigenvector  $u_1 = (1, -1, 0)^T$ . For the second eigenvalue  $\lambda_2 = 4$  we have the matrix equation  $(A - 4E)v = 0$  for some vector  $v = (y_1, y_2, y_3)^T \in \mathbb{R}^3$ . Since

$$A - 4E = \begin{pmatrix} 1 & 4 & 2 \\ 0 & -3 & -1 \\ -1 & -1 & -1 \end{pmatrix},$$

The procedure is practical for matrices when the multiplicities of the eigenvalues are small, or at least when the degrees of nilpotency are small. For instance, for the matrix

$$A = \begin{pmatrix} 2 & 0 & 1 \\ 0 & 2 & 1 \\ 0 & 0 & 2 \end{pmatrix}$$

we obtain the two-dimensional subspace of eigenvectors

$$\text{span}\{(1, 0, 0)^T, (0, 1, 0)^T\},$$

but we still do not know, which of them are the “ends of the chains”. We need to solve the equations  $(A - 2E)x = (a, b, 0)^T$  for (yet unknown) constants  $a, b$ . This system is solvable if and only if  $a = b$ , and one of the possible solutions is  $x = (0, 0, 1)^T$ ,  $a = b = 1$ . The entire basis is then composed of  $(1, 1, 0)^T$ ,  $(0, 0, 1)^T$ ,  $(1, 0, 0)^T$ . Note that we have free choices on the way and thus there are many such bases.

### 5. Decompositions of the matrices and pseudoinversions

Previously we concentrated on the geometric description of the structure of a linear mapping. Now we translate our results into the language of matrix decomposition. This is an important topic for numerical methods and matrix calculus in general.

Even when computing effectively with real numbers we use decompositions into products. The simplest one is the unique expression of every real number in the form

$$a = \text{sgn}(a) \cdot |a|,$$

that is, as a product of the sign and the absolute value. Proceeding in the same way with complex numbers, we obtain their polar form. That is, we write  $z = (\cos \varphi + i \sin \varphi)|z|$ . Here the complex unit plays the role of the sign and the other factor is a non-negative real multiple.

In the following paragraphs we list briefly some useful decompositions for distinct types of matrices. Remind, we met suitable decompositions earlier, for instance for positive semidefinite matrices in paragraph 3.4.9 when finding the square roots. We shall start with similar simple examples.

**3.5.1. LU-decomposition.** In paragraphs 2.1.7 and 2.1.8 we transformed matrices over scalars from any field into row echelon form. For this we used elementary row transformations, based on successive multiplication of our matrix by invertible lower triangular matrices  $P_i$ . In this way we added multiples of the rows above the currently transformed one.

Sometimes we also interchanged the rows, which corresponded to multiplication by a *permutation matrix*. That is a square matrix in which all elements are zero except exactly one value 1 in each row and column. To imagine why, consider a matrix with just one non-zero element in the first column but not in the first row. When we used the backwards

we obtain the linear system

$$\{y_1 + 4y_2 + 2y_3 = 0, 3y_2 + y_3 = 0, y_1 + y_2 + y_3 = 0\}.$$

Using Sage via the cell

```
A1=matrix([[1, 4, 2], [0, -3, -1], [-1, -1, -1]])
show(A1)
show(A1.rref())
```

we obtain the following reduced row echelon form

$$A - 4E = \begin{pmatrix} 1 & 4 & 2 \\ 0 & -3 & -1 \\ -1 & -1 & -1 \end{pmatrix} \sim \begin{pmatrix} 1 & 0 & 2/3 \\ 0 & 1 & 1/3 \\ 0 & 0 & 0 \end{pmatrix},$$

which can be verified by hand in a few steps. Therefore, the solution space is given by

$$\left\{ \begin{pmatrix} y_1 \\ y_2 \\ y_3 \end{pmatrix} = \begin{pmatrix} -\frac{2}{3}s \\ -\frac{1}{3}s \\ s \end{pmatrix} : s \in \mathbb{R} \right\}.$$

Consequently, we may assume that the eigenspace  $V_4$  is generated by the eigenvector  $u_2 = (2, 1, -3)^T$  (this corresponds to the choice  $s = -3$ ). In particular,  $\gamma(\lambda_2) = 1$ .

*Step 3:* Since the eigenvalue  $\lambda_2 = 4$  satisfies  $\gamma(\lambda_2) = 1 < \alpha(\lambda_2) = 2$ , the matrix  $A$  is not diagonalizable, and we should proceed with Step 3. In particular, for  $\lambda_2 = 4$  we have  $j = \alpha(\lambda_2)$ , and this algebraic multiplicity coincides with the dimension of the generalized eigenspace  $\mathcal{R}_{\lambda_2} = \text{Ker}((A - 4E)^2)$ , i.e.,  $\dim \text{Ker}((A - 4E)^2) = 2$  (see below in 3.D.44 for a description of  $\mathcal{R}_{\lambda_2}$ ). Thus, according to our algorithm, for the eigenvalue  $\lambda_2 = 4$  exists a unique Jordan block of size  $2 \times 2$  or larger, since

$$\dim \text{Ker}((A - 4E)^2) - \dim \text{Ker}((A - 4E)) = 2 - 1 = 1.$$

Counting dimensions we see that this has necessarily the form  $J_2 = \begin{pmatrix} 4 & 1 \\ 0 & 4 \end{pmatrix}$ , since for  $\lambda_1 = 1$  the corresponding Jordan block  $J_1$  is just a scale,  $J_1 = (1)$ .

*Step 4:* We are now able to describe the Jordan canonical form:

$$J = (1) \oplus \begin{pmatrix} 4 & 1 \\ 0 & 4 \end{pmatrix} = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 4 & 1 \\ 0 & 0 & 4 \end{pmatrix}. \quad \square$$

*Having the Jordan canonical form  $J$  of a squared matrix  $A$ , we can derive a similarity matrix  $P$  such that  $P^{-1}AP = J$ , or, equivalently,  $A = PJP^{-1}$ . Such a matrix  $P$  is composed of columns that are eigenvectors and generalized eigenvectors of  $A$ . To understand how  $P$  is constructed, recall that for an eigenvalue  $\lambda_i$  of  $A$ , a generalized eigenvector  $u$  is defined as a non-zero vector such that  $(A - \lambda_i E)^j u = 0$  for some integer  $j > 0$ . If  $j$  is the smallest positive integer with this property, the set*

$$\{(A - \lambda_i)^{j-1}u, (A - \lambda_i)^{j-2}u, \dots, (A - \lambda_i)u, u\}$$

*is known as a “(Jordan) chain of length  $j$ ”, see also the discussion in 3.4.19.*

*The structure of these chains reflects the sizes and arrangements of the Jordan blocks in the Jordan form  $J$ . In*

elimination to transform the matrix into the blockwise form

$$\begin{pmatrix} E_h & 0 \\ 0 & 0 \end{pmatrix}$$

(*remind  $E_h$  stays for the unit matrix of rank  $h$* ) then we potentially needed to interchange columns as well. This was achieved by multiplying by a permutation matrix from the right hand side.

For simplicity, assume we have a square matrix  $A$  of size  $m$  and that Gaussian elimination does not force a row interchange. Thus all matrices  $P_i$  can be lower triangular with ones on diagonal. Finally we note that inverses of such  $P_i$  are again lower triangular with ones on the diagonal (either remember the algorithm 2.1.10 or the formula in 2.2.11). We obtain

$$U = P \cdot A = P_k \cdots P_1 \cdot A$$

where  $U$  is an upper triangular matrix. Thus

$$A = L \cdot U$$

where  $L$  is lower triangular matrix with ones on diagonal and  $U$  is upper triangular. This decomposition is called *LU-decomposition* of the matrix  $A$ . We can also absorb the diagonal values of  $U$  into a diagonal matrix  $D$  and obtain the *LDU-decomposition* where both  $U$  and  $L$  have just ones along the diagonal,  $A = LDU$ .

For a general matrix  $A$ , we need to add the potential permutations of rows during Gaussian elimination. Then we obtain the general result. (Think why we can always put the necessary permutation matrices to the most left and most right positions!)

#### LU-DECOMPOSITION

Let  $A$  be any square matrix of size  $m$  over a field of scalars. Then we can find lower triangular matrix  $L$  with ones on its diagonal, upper triangular matrix  $U$  and permutation matrices  $P$  and  $Q$ , all of size  $m$ , such that

$$A = P \cdot L \cdot U \cdot Q.$$

**3.5.2. Remarks.** As one direct corollary of the Gaussian elimination we can observe that, up to a choice of suitable bases on the domain and codomain, every linear mapping  $f : V \rightarrow W$  is given by a matrix in block-diagonal form with unit matrix of the size equal to the dimension of the image of  $f$ , and with zero blocks all around. This can be reformulated as follows: every matrix  $A$  of the type  $m/n$  over a field of scalars  $\mathbb{K}$  can be decomposed into the product

$$A = P \cdot \begin{pmatrix} E & 0 \\ 0 & 0 \end{pmatrix} \cdot Q,$$

where  $P$  and  $Q$  are suitable invertible matrices.

Previously (in 3.4.10) we discussed properties of linear mappings  $f : V \rightarrow V$  over complex vector spaces. We

particular, each chain corresponds to a block, and the number of vectors in the chain indicates the block's size. Now each column in  $P$  corresponds to a vector in a Jordan chain. For a Jordan block of size  $j$  associated with  $\lambda_i$ , the matrix  $P$  will include  $j$  columns from the Jordan chain of a generalized eigenvector associated with  $\lambda_i$ .

Let us illustrate these facts with examples and for further exercises on the Jordan canonical form see Section F.

**3.D.43.** Using the matrices  $G_1, \dots, G_6$  given in 3.D.41, derive the characteristic polynomial of the corresponding matrix  $A$  for those cases that represent a Jordan canonical form.  $\circ$

**3.D.44.** For the matrix  $A$  provided in 3.D.42, determine a similarity matrix  $P$  such that  $P^{-1}AP = J$ , where  $J$  is Jordan canonical form of  $A$ , as obtained in 3.D.42.

**Solution.** We know that  $\mathcal{R}_{\lambda_2} = \text{Ker}((A - 4E)^2)$  is 2-dimensional. This is because the homogeneous linear system induced by the matrix equation  $(A - 4E)^2w = 0$ , i.e.,

$$\begin{pmatrix} -1 & -10 & -4 \\ 1 & 10 & 4 \\ 0 & 0 & 0 \end{pmatrix} \begin{pmatrix} w_1 \\ w_2 \\ w_3 \end{pmatrix} = \begin{pmatrix} 0 \\ 0 \\ 0 \end{pmatrix}$$

has a 2-dimensional solution space, given by

$$\left\{ \begin{pmatrix} w_1 \\ w_2 \\ w_3 \end{pmatrix} = \begin{pmatrix} -10t - 4s \\ t \\ s \end{pmatrix} : t, s \in \mathbb{R} \right\}.$$

To derive that matrix  $P$  we first need to solve the matrix equation  $(A - 4E)w = u_2$ , where  $v_2 = (2, 1, -3)^T$  is the eigenvector corresponding to  $\lambda_2 = 4$  (see 3.4.19). Then, the vector  $w$  should be an element of  $\mathcal{R}_{\lambda_2}$  and the set  $\{(A - 4E)w, w\} = \{u_2, w\}$  will give rise to a Jordan chain for  $w$ . Moreover, the columns of  $P$  will be the vectors  $u_1, u_2$  and  $w$ , i.e.,  $P = (u_1 \mid u_2 \mid w)$ .

Let us find  $w$ . The augmented matrix of the linear system induced by the equation  $(A - 4E)w = u_2$ , is given by

$$B := (A - 4E \mid u_2) = \left( \begin{array}{ccc|c} 1 & 4 & 2 & 2 \\ 0 & -3 & -1 & 1 \\ -1 & -1 & -1 & -3 \end{array} \right),$$

and we can apply elementary row operations to obtain the corresponding RREF. Successively one obtains

$$\begin{aligned} B &\xrightarrow{R_3 \rightarrow R_1 + R_3} \left( \begin{array}{ccc|c} 1 & 4 & 2 & 2 \\ 0 & -3 & -1 & 1 \\ 0 & 3 & 1 & -1 \end{array} \right) \xrightarrow{R_3 \rightarrow R_2 + R_3} \\ &\left( \begin{array}{ccc|c} 1 & 4 & 2 & 2 \\ 0 & -3 & -1 & 1 \\ 0 & 0 & 0 & 0 \end{array} \right) \xrightarrow{R_2 \rightarrow -\frac{1}{3}R_2} \left( \begin{array}{ccc|c} 1 & 4 & 2 & 2 \\ 0 & 1 & 1/3 & -1/3 \\ 0 & 0 & 0 & 0 \end{array} \right) \\ &\xrightarrow{R_1 \rightarrow R_1 - 4R_2} \left( \begin{array}{ccc|c} 1 & 0 & 2/3 & 10/3 \\ 0 & 1 & 1/3 & -1/3 \\ 0 & 0 & 0 & 0 \end{array} \right). \end{aligned}$$

You can verify this expression in Sage by the `rref()`-method, as we learned in Chapter 2.

showed that every square matrix  $A$  of dimension  $m$  can be decomposed into the product

$$A = P \cdot J \cdot P^{-1},$$

where  $J$  is a block-diagonal with Jordan blocks associated with the eigenvalues of  $A$  on the diagonal. Indeed, this is just a reformulation of the Jordan theorem, because multiplying by the matrix  $P$  and by its inverse from the other side corresponds in this case just to the change of the basis on the vector space  $V$  (with transition matrix  $P$ ). The quoted theorem says that every mapping has Jordan canonical form in a suitable basis.

Analogously, when discussing the self-adjoint mappings we proved that for real symmetric matrices or for complex Hermitian matrices there exists a decomposition into the product

$$A = P \cdot D \cdot P^*,$$

where  $D$  is the diagonal matrix with all (always real) eigenvalues on the diagonal, counting multiplicities. Indeed, we proved that there is an orthonormal basis consisting of eigenvectors. Thus the transition matrix  $P$  reflecting the appropriate change of the basis must be orthogonal. In particular,  $P^{-1} = P^*$ .

For real orthogonal mappings we derived analogous expression as for the symmetric ones, i.e.  $A = P \cdot B \cdot P^*$ . But in this case the matrix  $B$  is block-diagonal with blocks of size two or one, expressing rotations, mirror symmetry and identities with respect to the corresponding subspaces.

**3.5.3. Singular decomposition theorem.** We return to general linear mappings  $f : V \rightarrow W$  between vector spaces (generally distinct). We assume that scalar products are defined on both spaces and we restrict ourselves to orthonormal bases only.

If we want a similar decomposition result as above, we must proceed in a more refined way than in the case of arbitrary bases. But the result is surprisingly similar and strong:

#### SINGULAR DECOMPOSITION

**Theorem.** Let  $A$  be a matrix of the type  $m/n$  over real or complex scalars. Then there exist square unitary matrices  $U$  and  $V$  of dimensions  $m$  and  $n$ , and a real diagonal matrix  $D$  with non-negative elements of dimension  $r$ ,  $r \leq \min\{m, n\}$ , such that

$$A = U S V^*, \quad S = \begin{pmatrix} D & 0 \\ 0 & 0 \end{pmatrix}$$

and  $r$  is the rank of the matrix  $AA^*$ .

The matrix  $S$  is determined uniquely up to the order of the diagonal elements  $s_i$  in  $D$ . Moreover,  $s_i$  are the square roots of the positive eigenvalues  $d_i$  of the matrix  $AA^*$ .

If  $A$  is a real matrix, then the matrices  $U$  and  $V$  are orthogonal.

```
A=matrix([[5, 4, 2], [0, 1, -1],
[-1, -1, 3]])
E=identity_matrix(3)
AA=A-4*E
print(bool(AA==
matrix([[1, 4, 2], [0, -3, -1],
[-1, -1, -1]])))
b=vector([2, 1, -3])
B=AA.augment(b)
B.rref()
```

Therefore, we obtain the system (we assume that  $w$  has the form  $w = (x, y, z)^T$ )

$$\left\{x + \frac{2}{3}z = \frac{10}{3}, y + \frac{1}{3}z = -\frac{1}{3}, z \in \mathbb{R}\right\}$$

with solution space

$$\left\{\begin{pmatrix} x \\ y \\ z \end{pmatrix} = \begin{pmatrix} -\frac{2}{3}s + \frac{10}{3} \\ -\frac{1}{2}s - \frac{1}{3} \\ s \end{pmatrix} : s \in \mathbb{R}\right\}.$$

To obtain a representative we may set  $s = 0$  which gives the generalized eigenvector  $w = (10/3, -1/3, 0)^T$ . Let us use Sage to verify that  $w$  is indeed a generalized eigenvector. To do so, we can simply run the following code block:

```
w=vector([10/3, -1/3, 0])
A=matrix([[5, 4, 2], [0, 1, -1], [-1, -1, 3]])
E=identity_matrix(3)
BB=(A-4*E)^2
bool(BB*w==0)
```

Sage's output is True and we can present the matrix  $P$ :

$$P = (u_1 \mid u_2 \mid w) = \begin{pmatrix} 1 & 2 & \frac{10}{3} \\ -1 & 1 & -\frac{1}{3} \\ 0 & -3 & 0 \end{pmatrix}.$$

To verify the correctness of this result, first compute  $P^{-1}$  and next check that  $P^{-1}AP = J$ . For convenience, we will use Sage to perform these computations promptly.

```
A=matrix([[5, 4, 2], [0, 1, -1],
[-1, -1, 3]])
J=matrix([[1, 0, 0], [0, 4, 1],
[0, 0, 4]])
P=matrix([[1, 2, 10/3], [-1, 1, -1/3],
[0, -3, 0]])
show(A, P, J, P.inverse())
print(P.inverse()*A*P==J)
```

We mention that Sage provides a built-in method to obtain the Jordan canonical form of a matrix, using the command `A.jordan_form()`. For instance, for our matrix  $A$  give the cell

```
A=matrix([[5, 4, 2], [0, 1, -1],
[-1, -1, 3]])
J,P=A.jordan_form(transformation=True)
show(J, P)
```

**PROOF.** Assume first that  $m \leq n$ . Denote by  $\varphi : \mathbb{K}^n \rightarrow \mathbb{K}^m$  the mapping between real or complex spaces with standard scalar products, given by the matrix  $A$  in the standard bases.

We can reformulate the statement of the theorem as follows: there exists orthonormal bases on  $\mathbb{K}^n$  and  $\mathbb{K}^m$  in which the mapping  $\varphi$  is given by the matrix  $S$  from the statement of the theorem.

As noted before, the matrix  $A^*A$  is positive semidefinite. Therefore it has only real non-negative eigenvalues and there exists an orthonormal basis  $\underline{u}$  of  $\mathbb{K}^n$  in which the corresponding mapping  $\varphi^* \circ \varphi$  is given by a diagonal matrix with eigenvalues on the diagonal. In other words, there exists a unitary matrix  $V$  such that  $A^*A = VBV^*$  for a real diagonal matrix  $B$  with non-negative eigenvalues  $(d_1, d_2, \dots, d_r, 0, \dots, 0)$  on the diagonal,  $d_i \neq 0$  for all  $i = 1, \dots, r$ . Thus

$$B = V^*A^*AV = (AV)^*(AV).$$

This is equivalent to the claim that the first  $r$  columns of the matrix  $AV$  are orthogonal, while the remaining columns vanish because they have zero norm.

Next, we denote the first  $r$  columns of  $AV$  as  $v_1, \dots, v_r \in \mathbb{K}^m$ . Thus,  $\langle v_i, v_i \rangle = d_i$ ,  $i = 1, \dots, r$ , and the normalized vectors  $u_i = \frac{1}{\sqrt{d_i}}v_i$  form an orthonormal system of non-zero vectors. Extend them to an orthonormal basis  $\underline{u} = u_1, \dots, u_m$  for the entire  $\mathbb{K}^m$ . Expressing the original mapping  $\varphi$  in the bases  $\underline{u}$  of  $\mathbb{K}^n$  and  $\underline{u}$  of  $\mathbb{K}^m$ , yields the matrix  $\sqrt{B}$ . The transformations from the standard bases to the newly chosen ones correspond to the multiplication from the left by a unitary (orthogonal) matrix  $U$  and from the right by  $V^{-1} = V^*$ . This is the claim of the theorem.

If  $m > n$ , we can apply the previous part of the proof to the matrix  $A^*$  which implies the desired result.

All the previous steps in the proof are also valid in the real domain with real scalars.  $\square$

This proof of the theorem about singular decomposition is constructive and we can indeed use it for computing the unitary (orthogonal) matrices  $U$  and  $V$  and the non-zero diagonal elements of the matrix  $S$ .

The diagonal values of the matrix  $D$  from the previous theorem are called *singular values of the matrix  $A$* .

**3.5.4. Further comments.** When dealing with real scalars, the singular values of a linear mapping  $\varphi : \mathbb{R}^n \rightarrow \mathbb{R}^m$  have a simple geometric meaning:

Let  $K \subset \mathbb{R}^n$  be the unit ball in the standard scalar product. The image  $\varphi(K)$  is always an  $m$ -dimensional ellipsoid (possibly degenerate). The singular values of the matrix  $A$  are then the norms of the main half-axes. The theorem says further that the original ball allows an orthogonal set of diameters, whose images are exactly the half-axes of this ellipsoid.

For square matrices it can be seen that  $A$  is invertible if and only if all singular values are non-zero. The ratio of the

Sage's output has the form

$$\left( \begin{array}{ccc|ccc} 1 & 0 & 0 & & & \\ \hline 0 & 4 & 1 & & & \\ 0 & 0 & 4 & & & \end{array} \right), \quad \left( \begin{array}{ccc} 1 & \frac{1}{2} & 1 \\ -1 & \frac{1}{4} & 0 \\ 0 & -\frac{3}{4} & -\frac{1}{4} \end{array} \right).$$

This verifies the expression of the matrix  $J$  derived in 3.D.42 and presents a similarity matrix  $P$ , such that  $P^{-1}AP = J$ . However, be aware that  $P$  is not uniquely determined, which is why Sage's candidate for  $P$  may differ from ours.  $\square$

**3.D.45.** Consider the matrix  $A = \begin{pmatrix} 3 & 1 \\ -1 & 1 \end{pmatrix}$ .

(a) Show that  $A$  is not diagonalizable and find the associated Jordan canonical form. Moreover, find a similarity matrix  $P$  such that  $P^{-1}AP = J$  and verify the results using Sage.

(b) Compute the 4th power  $A^4$  of  $A$  using the Jordan canonical form  $J$  and the matrices  $P, P^{-1}$ , derived in (a).  $\circ$

**3.D.46.** Consider the matrix  $A = \begin{pmatrix} 5 & 4 & 2 & 1 \\ 0 & 5 & 1 & 1 \\ 0 & 0 & 5 & 2 \\ 0 & 0 & 0 & 5 \end{pmatrix}$ . De-

termine the eigenvectors and generalized eigenvectors of  $A$  and find generators of the subspaces  $\text{Ker}((A - 5E)^2)$ ,  $\text{Ker}((A - 5E)^3)$  and  $\text{Ker}((A - 5E)^4)$ . Next determine the Jordan canonical form  $J$  of  $A$  and present a matrix  $P$  such that  $P^{-1}AP = J$ . Moreover show that the generalized eigenspace  $\mathcal{R}_\lambda$  of the unique eigenvalue  $\lambda$  of  $A$  satisfies  $\mathcal{R}_\lambda = \text{Ker}((A - 5E)^4) \cong \mathbb{R}^4$ .  $\circ$

### E. Matrix decompositions

*Matrices with some special property, such as diagonal matrices, triangular matrices, or unitary matrices, are simpler to work with than general matrices. The final part of this chapter focuses on matrix decompositions, which involving techniques expressing a given matrix as a product of "simpler" matrices, as those mentioned above, see the paragraphs 3.5.1 – 3.5.6. Matrix decompositions are essential for tasks like solving linear systems of equations and performing many complex matrix operations.*

We begin with the LU-decomposition, which is essentially the matrix form of the Gauss elimination method, described in paragraphs 2.1.7-2.1.9. The LU-decomposition exists for squared matrices  $A$  which can be reduced to a row-echelon form through a series of row operations without requiring row exchanges. In such a situation we can arrive to a factorization of the form  $A = LU$ , where  $U$  is the upper triangular matrix whose diagonal entries are the pivots, and  $L = (\ell_{ij})$  is a lower triangular matrix having units in the diagonal and nonzero off-diagonal entries  $\ell_{ij}$  encoding the elementary row operations that we applied to find  $U$ . Thus,  $\ell_{ij}$  represents the times that we subtracted the row  $j$  from row  $i$ , during the specific step of the Gaussian elimination.

greatest to the smallest singular value is an important parameter for the robustness of many numerical computations with matrices, for instance the computation of the inverse matrix. Note that there are fast methods of computation (approximations) for eigenvalues. Thus the singular decomposition is a very effective tool to work with.

**3.5.5. Polar decomposition theorem.** The singular decomposition theorem is the starting point for many other useful tools. We present several direct corollaries (which by themselves are non-trivial and important).

The statement of the singular decomposition theorem saying that for any matrix  $A$ , real or complex,  $A = USW^*$  with  $S$  diagonal with non-negative real numbers on the diagonal and  $U$  and  $W$  unitary, can be rephrased as

$$A = USU^*UW^*$$

and let us denote  $P = USU^*$ ,  $V = UW^*$ . The first of the matrices,  $P$ , is Hermitian (in the real case, symmetric) and positive semidefinite (because  $P$  and  $S$  are matrices of the the same mapping in different orthonormal bases). At the same time,  $V$  is the product of two unitary matrices and thus again is unitary (in the real case orthogonal).

Next, assume that  $A = PV = QZ$  are two such decompositions of the matrix  $A$  into the product of a positive semidefinite Hermitian matrix and a unitary matrix. Clearly,  $A^* = WSU^*$ . Thus  $AA^* = USSU^* = P^2$ , and the matrix  $P$  is actually the square root of the easily computable Hermitian matrix  $AA^*$ . In particular, this proves that  $P$  is uniquely determined, cf. 3.4.9.

Further, assume that  $A$  is invertible. Then also  $P$  is invertible and  $Z = V = P^{-1}A$ .

We have derived a very useful analogy of the decomposition of a real number into a sign and the absolute value:

#### POLAR DECOMPOSITION

**Theorem.** Every square complex matrix  $A$  of dimension  $n$  can be expressed in the form  $A = PV$ , where  $P$  is a Hermitian positive semi-definite square matrix of the same dimension while  $V$  is unitary.

The matrix  $P = \sqrt{AA^*}$  is uniquely given, and if  $A$  is invertible, the decomposition is unique and  $V = (\sqrt{AA^*})^{-1}A$ .

If  $A$  is a matrix of real scalars, then  $P$  is symmetric and  $V$  is orthogonal.

If we apply the same theorem to  $A^*$  instead of  $A$ , we obtain the same result, but with the order of the Hermitian and unitary matrices is reversed. This means  $A = VP$  with  $V$  unitary and  $P = \sqrt{A^*A}$  positive semidefinite. The matrices in the corresponding right and left polar decompositions will in general be different.

**3.E.1.** Find a  $LU$ -decomposition of the matrix

$$A = \begin{pmatrix} -2 & 1 & 0 \\ -4 & 4 & 2 \\ -6 & 1 & -1 \end{pmatrix}.$$

**Solution.** The desired decomposition is given by

$$A = LU = \begin{pmatrix} 1 & 0 & 0 \\ 2 & 1 & 0 \\ 3 & -1 & 1 \end{pmatrix} \begin{pmatrix} -2 & 1 & 0 \\ 0 & 2 & 2 \\ 0 & 0 & 1 \end{pmatrix}.$$

To obtain to this result, let us denote by  $R_1, R_2, R_3$  the rows of  $A$ , during any step of the Gaussian elimination. Then  $U$  (the row-echelon form of  $A$ ) occurs by the following elementary row operations

$$\begin{pmatrix} -2 & 1 & 0 \\ -4 & 4 & 2 \\ -6 & 1 & -1 \end{pmatrix} \begin{matrix} R_2 - \textcircled{2}R_1 \\ R_3 - \textcircled{3}R_1 \\ \Rightarrow \end{matrix} \begin{pmatrix} -2 & 1 & 0 \\ 0 & 2 & 2 \\ 0 & -2 & -1 \end{pmatrix} \\ R_3 - \textcircled{-1}R_2 \Rightarrow \begin{pmatrix} -2 & 1 & 0 \\ 0 & 2 & 2 \\ 0 & 0 & 1 \end{pmatrix} = U.$$

Recall from Chapter 2 (cf. 2.A.9) that in Sage one can compute a row echelon form of a matrix  $A$  using the `echelon_form()` command. However, Sage's output may differ from the expected result, and some caution is required when choosing the numerical system. For instance, consider the matrix  $A$  with entries over  $\mathbb{Z}$ . Executing in Sage the cell given below, we will obtain the matrix  $\begin{pmatrix} 2 & 1 & 0 \\ 0 & 2 & 0 \\ 0 & 0 & 1 \end{pmatrix}$ , which is clearly not the desired result.

```
A = matrix(ZZ, [[-2, 1, 0], [-4, 4, 2], [-6, 1, -1]])
A.echelon_form()
```

On the other hand, you can verify on your own that by replacing `ZZ` with `RR`, `RDF`, `QQbar` or the symbolic ring `SR`, the resulting matrix will be the  $3 \times 3$  identity matrix. Hence, in this case, Sage returns the reduced row-echelon form of  $A$ , which is not useful for our task.

Now, for the lower triangular matrix

$$L = \begin{pmatrix} 1 & 0 & 0 \\ \ell_{21} & 1 & 0 \\ \ell_{31} & \ell_{32} & 1 \end{pmatrix}$$

we see that the entries  $\ell_{21}, \ell_{31}, \ell_{32}$  are given by the circled numbers 2, 3 and  $-1$ , appearing in the row operations mentioned above. In 3.E.5 below, you will be asked to derive the expression of  $L$  in terms of elementary matrices. Finally, a verification in Sage can be done manually, as follows:

Actually, if  $A$  is invertible, it is easy to check, that the matrices in the left are polar decomposition coincide if and only if  $A$  is normal. Look at theorem 3.4.8 and verify it yourself.

In the complex case the analogy with the decomposition of numbers is even more entertaining. The positive semidefinite  $P$  again plays the role of the absolute value of the complex number. The unitary matrix  $V$  uniquely allows the expression as a sum  $V = \operatorname{re} V + i \operatorname{im} V$  with Hermitian real and imaginary parts and the property  $(\operatorname{re} V)^2 + (\operatorname{im} V)^2 = E$ . We obtain a full analogy for the polar form for the complex numbers (see the final remark and corollary in 3.4.8). But note that in the higher dimensional case, it is important in which order this “polar form” of matrix is written. It is possible in both ways, but the results differ in general.

**3.5.6. QR decomposition.** For many practical applications it is faster to use another decomposition of matrices, which is an analogy of the Schur orthogonal triangulation theorem:

QR DECOMPOSITION

**Theorem.** For every complex matrix  $A$  of the type  $m/n$  there exists a unitary matrix  $Q$  and an upper triangular matrix  $R$  such that  $A = QR$ .

If all the scalars are real, then both  $Q$  and  $R$  are real (i.e.  $Q$  orthogonal).

**PROOF.** In the geometric formulation we need to prove that for every mapping  $\varphi : \mathbb{K}^n \rightarrow \mathbb{K}^m$  with the matrix  $A$  in the standard bases we can choose a new orthonormal basis on  $\mathbb{K}^m$  for which  $\varphi$  has upper triangular matrix.

Consider the images  $\varphi(e_1), \dots, \varphi(e_n) \in \mathbb{K}^m$  of the vectors of the standard orthonormal basis of  $\mathbb{K}^n$ . Choose from them a maximal linearly independent system  $v_1, \dots, v_k$  in such a way that the removed dependent vectors are always a linear combination of the previous vectors. Extend it into a basis  $v_1, \dots, v_m$ . Let  $u_1, \dots, u_m$  be an orthonormal basis  $\mathbb{K}^m$  obtained by the Gram-Schmidt orthogonalization of this system of vectors.

For every  $e_i$ ,  $\varphi(e_i)$  is either one of  $v_j$ ,  $j \leq i$ , or it is a linear combination of  $v_1, \dots, v_{i-1}$ . Therefore in the expression of  $\varphi(e_i)$  in the basis  $\underline{u}$  only the vectors  $u_1, \dots, u_i$  appear. Thus, in the standard basis on  $\mathbb{K}^n$  and  $\underline{u}$  on  $\mathbb{K}^m$ , the mapping  $\varphi$  has an upper triangular matrix  $R$ . The change of the basis  $\underline{u}$  on  $\mathbb{R}^m$  corresponds to the multiplication by a unitary matrix  $Q^*$  from the left. That is,  $R = Q^*A$ , equivalently  $A = QR$ .

The last claim is clear from the construction.  $\square$

**3.5.7. Pseudoinversions.** Finally, we discuss an especially useful and important extension of the inversion concept, which is of great importance for numerical procedures and also in Statistics.

```
A = matrix(RR, [[-2, 1, 0], [-4, 4, 2],
[-6, 1, -1]])
L = matrix(RR, [[1, 0, 0], [2, 1, 0],
[3, -1, 1]])
U = matrix(RR, [[-2, 1, 0], [0, 2, 2],
[0, 0, 1]])
L*U==A
```

Sage returns True. Note in this block we could use RDF or SR instead of RR, or even omit specifying a numerical system altogether.  $\square$

**3.E.2. Permuted LU-decomposition via Sage.** If partial pivoting (row exchanges) is allowed, then for any squared matrix  $A$  we have a decomposition of the form  $PA = LU$ , where  $P$  is a permutation matrix. This is known as the *LU-decomposition with partial pivoting*, or *permuted LU-decomposition*. Note that Sage provides the command `A.LU()`, which corresponds to a built-in method to obtain the permuted LU-decomposition. In particular, for a  $m \times n$  matrix  $A$  this command returns a triple of matrices  $P$ ,  $L$  and  $U$ , such that  $A = PLU$ , satisfying the following properties:  $P$  is a  $m \times m$  permutation matrix,  $L$  is a lower triangular  $m \times m$  matrix with units in the diagonal, and  $U$  is an upper triangular  $m \times n$  matrix. Notice in this case  $U$  is *not* in general a row-echelon form of  $A$ .

For example, using the matrix  $A$  from 3.E.1 and running the cell

```
A = matrix([[ -2, 1, 0], [-4, 4, 2], [-6, 1, -1]])
A.LU()
```

we obtain the following answer:

```
(
[0 0 1] [ 1 0 0] [ -6 1 -1]
[0 1 0] [2/3 1 0] [ 0 10/3 8/3]
[1 0 0], [1/3 1/5 1], [ 0 0 -1/5]
)
```

Notice that the matrices  $L$  and  $U$  that Sage prints out here, differ from those obtained in 3.E.1.

*The LU-decomposition is an effective method for solving linear systems. Given that  $A = LU$  is the LU-factorization of a squared matrix  $A$ , the equation  $Ax = b$  can be written as  $LUx = b$ . Introducing  $Ux = y$ , this gives us  $Ly = b$ . Typically, we first solve  $Ly = b$  with respect to  $y$  and then use this result to solve  $Ux = y$  for  $x$ .*

**3.E.3.** Solve  $Ax = b$  using a LU-decomposition of the matrix  $A$ , where  $A$  and  $b$  are respectively given by

$$A = \begin{pmatrix} 3 & -6 & 2 & -2 \\ -3 & 4 & 1 & 0 \\ 6 & -4 & 0 & -4 \\ -9 & 6 & -2 & 12 \end{pmatrix}, \quad b = \begin{pmatrix} -7 \\ 4 \\ 6 \\ -3 \end{pmatrix}.$$

**Solution.** One can verify that

Technically, the following quite straightforward application of singular decompositions of matrices allows us to define the pseudoinverse. However, we should beware that the singular decomposition is not unique and thus we must verify that such a definition is consistent. We shall see that in the next theorem.

PSEUDOINVERSE MATRICES

Let  $A$  be a real or complex matrix of the type  $m/n$ . Let

$$A = USV^*, \quad S = \begin{pmatrix} D & 0 \\ 0 & 0 \end{pmatrix}$$

be its singular decomposition (in particular,  $D$  is invertible). The matrix

$$A^\dagger := VS^\dagger U^*, \quad S^\dagger = \begin{pmatrix} D^{-1} & 0 \\ 0 & 0 \end{pmatrix}$$

is called the *pseudoinverse matrix* of the matrix  $A$ .

In geometric terms, we may view the linear mapping  $\varphi$  given by the matrix  $A$  in the two special orthonormal basis, where  $\varphi$  has got the matrix  $S$  with non-negative diagonal entries. We take the inverse of the “invertible part” of  $\varphi$  and complete it trivially to the pseudoinverse<sup>7</sup> mapping  $\varphi^\dagger$ . The result is then viewed in the original basis and yields  $A^\dagger$ .

As the following theorem shows, the pseudoinverse is an important generalization of the notion of inverse matrix, together with direct applications. At the same time, property (3), together with property (2), verifies the appropriateness of the definition.

<sup>7</sup>This concept was introduced by Eliakim Hastings Moore, an American mathematician, around 1920. It was reinvented by Roger Penrose and others later. In the literature, it is often called the *Moore-Penrose pseudoinverse*. Roger Penrose is an extremely influential mathematical physicist and philosopher of science working in Oxford, known also for his many best-selling popular books such as *The Emperor’s New Mind: Concerning Computers, Minds, and The Laws of Physics* (1989); *Shadows of the Mind: A Search for the Missing Science of Consciousness* (1994); *The Road to Reality: A Complete Guide to the Laws of the Universe* (2004); *Cycles of Time: An Extraordinary New View of the Universe* (2010).

$$A = LU = \begin{pmatrix} 1 & 0 & 0 & 0 \\ -1 & 1 & 0 & 0 \\ 2 & -4 & 1 & 0 \\ -3 & 6 & -14/8 & 1 \end{pmatrix} \begin{pmatrix} 3 & -6 & 2 & -2 \\ 0 & -2 & 3 & -2 \\ 0 & 0 & 8 & -8 \\ 0 & 0 & 0 & 4 \end{pmatrix}.$$

For example, use Sage via the block

```
A=matrix(RDF, [[3, -6, 2, -2], [-3, 4, 1, 0],
[6, -4, 0, -4], [-9, 6, -2, 12]])
L=matrix(RDF, [[1, 0, 0, 0], [-1, 1, 0, 0],
[2, -4, 1, 0], [-3, 6, -14/8, 1]])
U=matrix(RDF, [[3, -6, 2, -2], [0, -2, 3, -2],
[0, 0, 8, -8], [0, 0, 0, 4]])
L*U == A
```

Sage prints out True. Now we solve the equation  $Ly = b$ , which is given by

$$\begin{pmatrix} 1 & 0 & 0 & 0 \\ -1 & 1 & 0 & 0 \\ 2 & -4 & 1 & 0 \\ -3 & 6 & -14/8 & 1 \end{pmatrix} \begin{pmatrix} y_1 \\ y_2 \\ y_3 \\ y_4 \end{pmatrix} = \begin{pmatrix} -7 \\ 4 \\ 6 \\ -3 \end{pmatrix}.$$

From this we obtain

$$\begin{aligned} y_1 &= -7, & y_2 &= 4 + y_1 = -3, \\ y_3 &= 6 - 2y_1 + 4y_2 = 8, \\ y_4 &= -3 + 3y_1 - 6y_2 + \frac{14}{8}y_3 = 8. \end{aligned}$$

Next we solve  $Ux = y$ , which is given by

$$\begin{pmatrix} 3 & -6 & 2 & -2 \\ 0 & -2 & 3 & -2 \\ 0 & 0 & 8 & -8 \\ 0 & 0 & 0 & 4 \end{pmatrix} \begin{pmatrix} x_1 \\ x_2 \\ x_3 \\ x_4 \end{pmatrix} = \begin{pmatrix} -7 \\ -3 \\ 8 \\ 8 \end{pmatrix}.$$

By back substitution we get the desired solution:

$$\begin{aligned} x_4 &= \frac{8}{4} = 2, & x_3 &= \frac{8 + 8x_4}{8} = 3, \\ x_2 &= \frac{-3 - 3x_3 + 2x_4}{-2} = \frac{-8}{-2} = 4, \\ x_1 &= \frac{-7 + 6x_2 - 2x_3 + 2x_4}{3} = \frac{15}{3} = 5. \end{aligned}$$

□

Given a  $n \times n$  matrix  $A$  with a LU-decomposition  $A = LU$ , the efficiency of solving the linear equation  $Ax = b$  can be analyzed by counting the number of multiplications and divisions required.<sup>17</sup> As we saw before, to solve  $Ax = b$  using LU-factorization, the process involves solving  $Ly = b$  and  $Ux = y$ . It can be proved that approximately  $n^2$  multiplications and divisions are needed for these steps. For instance, in the case of a  $4 \times 4$  matrix  $A$  as in 3.E.3, you can count exactly 16 multiplications and divisions for these steps. For instance, in the case of a  $4 \times 4$  matrix  $A$  as in 3.E.3, you can count exactly 16 multiplications and divisions, 6 for solving the equation  $Ly = b$  and 10 for solving the equation  $Ux = y$ .

<sup>17</sup>Additions are typically ignored in this analysis due to their lower computational “cost”.

PROPERTIES OF PSEUDOINVERSE MATRICES

**Theorem.** Let  $A$  be a real or complex matrix of the type  $m/n$  and let  $A^\dagger$  be its pseudoinverse. Then:

- (1) if  $A$  is invertible (necessarily square), then
 
$$A^\dagger = A^{-1},$$
- (2)  $A^\dagger A$  and  $AA^\dagger$  are Hermitian (in real case symmetric) and
 
$$AA^\dagger A = A, \quad A^\dagger AA^\dagger = A^\dagger.$$
- (3) the pseudoinverse matrices  $A^\dagger$  are uniquely defined by the four properties from (2). Thus if some matrix  $B$  of the type  $n \times m$  has the properties that  $BA$  and  $AB$  are both Hermitian,  $ABA = A$  and  $BAB = B$ , then  $B = A^\dagger$ .
- (4) if  $A$  is a matrix of the system of linear equations  $Ax = b$  with  $b \in \mathbb{K}^m$ , then the vector  $y = A^\dagger b \in \mathbb{K}^n$  minimizes the norm  $\|Ax - b\|$  for all vectors  $x \in \mathbb{K}^n$ .
- (5) the system of linear equations  $Ax = b$  with  $b \in \mathbb{K}^m$  is solvable if and only if  $AA^\dagger b = b$ . In this case all solutions are given by the expression

$$x = A^\dagger b + (E - A^\dagger A)u,$$

where  $u \in \mathbb{K}^n$  is arbitrary.

PROOF. (1): If  $A$  is invertible, then the matrix  $S = U^*AV$  is also invertible and directly from the definition  $S^\dagger = S^{-1}$ . Consequently,  $A^\dagger A = AA^\dagger = E$ .

(2): Direct computation yields  $SS^\dagger S = S$  and  $S^\dagger SS^\dagger = S^\dagger$ , therefore

$$AA^\dagger A = USV^*V S^\dagger U^*USV^* = USS^\dagger SV^* = USV^* = A$$

and analogically for the second equation. Furthermore,

$$\begin{aligned} (AA^\dagger)^* &= (USS^\dagger U^*)^* = U(S^\dagger)^* S^* U^* \\ &= U(SS^\dagger)^* U^* = USS^\dagger U^* = AA^\dagger. \end{aligned}$$

It can be proved similarly that  $(A^\dagger A)^* = A^\dagger A$ .

(3) The claim can be proved by direct computation. Of course we can consider the matrices  $A, A^\dagger, B$  as the matrices of the mappings  $\varphi, \varphi^\dagger$ , and  $\psi$  in the standard bases on  $\mathbb{K}^n$  and  $\mathbb{K}^m$ , or any other pair of orthonormal bases. The requested equality is equivalent to the equality  $\varphi^\dagger = \psi$  independently of the choice of the bases. We choose a couple of orthogonal bases from the singular decomposition of  $A$ . Then the mapping  $\varphi$  has the matrix  $S$  from the definition of the pseudoinverse  $A^\dagger$ , so we write directly

$$A = \begin{pmatrix} D & 0 \\ 0 & 0 \end{pmatrix}, \quad A^\dagger = \begin{pmatrix} D^{-1} & 0 \\ 0 & 0 \end{pmatrix},$$

with the diagonal matrix  $D$  consisting of all non-zero singular values. We write again  $B$  for the matrix of  $\psi$  in these bases. Clearly  $B$  and  $A$  satisfy the assumptions of the claim (3). Thus

$$A^\dagger A = \begin{pmatrix} E & 0 \\ 0 & 0 \end{pmatrix}, \quad ABA = A$$

On the other hand, performing row reduction directly on the augmented matrix  $(A \mid b)$  to transform it to  $(U \mid y)$  requires about  $n^3/3$  arithmetic operations (as multiplications and divisions), which is significantly more time-consuming. Even worse, computing the inverse of  $A$  demands about  $n^3$  operations, and multiplying  $b$  by  $A^{-1}$  to obtain  $x = A^{-1}b$  requires another  $n^2$  operations.

**3.E.4. How are determinants of large matrices computed?** Typically, determinants of large matrices are not calculated using cofactor expansion, but rather through matrix decomposition. For instance, with an  $LU$ -decomposition of a squared matrix  $A$ , the determinant of  $A$  satisfies the relation  $\det(A) = \det(L)\det(U)$ . Since both  $L, U$  are triangular matrices, the previous relation implies that  $\det(A)$  equals the product of the elements on the diagonals of  $L$  and  $U$ .

**3.E.5.** Consider the  $LU$ -decomposition of the matrix  $A$  described in 3.E.1.

- i) Express the lower-triangular matrix  $L$  in terms of elementary matrices and compute its inverse.
- ii) Compute the inverse of the matrix  $U$  using Gauss elimination.
- iii) Calculate both the determinant and the inverse matrix of  $A$ , using its  $LU$ -decomposition as derived above.

○

Let us now focus on the singular value decomposition, which is possibly the most important matrix decomposition, with a wide range of remarkable applications. According to the singular value decomposition (in short SVD), given a matrix  $A \in \text{Mat}_{m,n}(\mathbb{F})$  where  $\mathbb{F} = \mathbb{R}$  or  $\mathbb{F} = \mathbb{C}$ , we can find unitary matrices  $U \in \text{Mat}_m(\mathbb{F})$  and  $V \in \text{Mat}_n(\mathbb{F})$ , and a diagonal matrix  $\Sigma \in \text{Mat}_{m,n}(\mathbb{F})$  with non-negative entries such that  $A = U\Sigma V^*$ , see 3.5.3.

In such a decomposition the diagonal matrix  $\Sigma$  consists of the singular values of  $A$ , which are the non-negative square roots of the eigenvalues of  $A^*A$  (or equivalently of  $AA^*$ ). They are typically denoted by  $\sigma_1, \dots, \sigma_{\min\{m,n\}}$ , and we order them so that  $\sigma_1 \geq \sigma_2 \geq \dots \geq \sigma_{\min\{m,n\}}$ .

In fact, there are exactly  $\text{rank}(A)$  non-zero singular values of  $A$ , as  $\text{rank}(U\Sigma V^*) = \text{rank}(\Sigma)$ , and the rank of a diagonal matrix coincides with the number of non-zero diagonal elements. On the other hand, the columns of  $V$  are (normalized) eigenvectors of  $A^*A$ , while the columns of  $U$  are (normalized) eigenvectors of  $AA^*$ .

and we obtain

$$A^\dagger = A^\dagger A B A A^\dagger = \begin{pmatrix} E & 0 \\ 0 & 0 \end{pmatrix} B \begin{pmatrix} E & 0 \\ 0 & 0 \end{pmatrix} = \begin{pmatrix} D^{-1} & 0 \\ 0 & 0 \end{pmatrix}.$$

Consequently

$$B = \begin{pmatrix} D^{-1} & P \\ Q & R \end{pmatrix}$$

for suitable matrices  $P, Q$  and  $R$ . Next,

$$BA = \begin{pmatrix} D^{-1} & P \\ Q & R \end{pmatrix} \begin{pmatrix} D & 0 \\ 0 & 0 \end{pmatrix} = \begin{pmatrix} E & 0 \\ QD & 0 \end{pmatrix}$$

is Hermitian. Thus  $QD = 0$  which implies  $Q = 0$  (the matrix  $D$  is diagonal and invertible). Analogously, the assumption that  $AB$  is Hermitian implies that  $P$  is zero. Finally, we compute

$$B = BAB = \begin{pmatrix} D^{-1} & 0 \\ 0 & R \end{pmatrix} \begin{pmatrix} D & 0 \\ 0 & 0 \end{pmatrix} \begin{pmatrix} D^{-1} & 0 \\ 0 & R \end{pmatrix}.$$

On the right side in the right-lower corner there is zero, and thus also  $R = 0$  and the claim is proved.

(4): Consider the mapping  $\varphi : \mathbb{K}^n \rightarrow \mathbb{K}^m, x \mapsto Ax$ , and direct sums  $\mathbb{K}^n = (\text{Ker } \varphi)^\perp \oplus \text{Ker } \varphi, \mathbb{K}^m = \text{Im } \varphi \oplus (\text{Im } \varphi)^\perp$  of the orthogonal complements. The restricted mapping  $\tilde{\varphi} := \varphi|_{(\text{Ker } \varphi)^\perp} : (\text{Ker } \varphi)^\perp \rightarrow \text{Im } \varphi$  is a linear isomorphism. If we choose suitable orthonormal bases on  $(\text{Ker } \varphi)^\perp$  and  $\text{Im } \varphi$  and extend them to orthonormal bases on whole spaces, the mapping  $\varphi$  will have matrix  $S$  and  $\tilde{\varphi}$  the matrix  $D$  from the theorem about the singular decomposition. In the next section, we shall discuss in detail that for any given  $b \in \mathbb{K}^m$ , there is the unique vector which minimizes the distance  $\|b - z\|$  among all  $z \in \text{Im } \varphi$  (in analytic geometry we shall say that the point  $z$  realises the distance of  $b$  from the affine subspace  $\text{Im } \varphi$ ), see 4.1.13). The properties of the norm proved in theorem 3.4.3 directly imply that this is exactly the component  $z = b_1$  of the decomposition  $b = b_1 + b_2, b_1 \in \text{Im } \varphi, b_2 \in (\text{Im } \varphi)^\perp$ .

Now, in our choice of bases, the mapping  $\varphi^\dagger$  is given by the matrix  $S^\dagger$  from the singular decomposition theorem. In particular,  $\varphi^\dagger(\text{Im } \varphi) = (\text{Ker } \varphi)^\perp, D^{-1}$  is the matrix of the restriction  $\varphi^\dagger|_{\text{Im } \varphi}$ , and  $\varphi^\dagger|_{(\text{Im } \varphi)^\perp}$  is zero. Indeed,

$$\varphi \circ \varphi^\dagger(b) = \varphi(\varphi^\dagger(z)) = z$$

and the proof is finished.

(5) Evidently, the equality  $Ax = b$ , with  $x \in \mathbb{K}^n$  fixed, implies

$$b = Ax = AA^\dagger Ax = AA^\dagger b.$$

Thus the condition is necessary. On the other hand, if this condition holds, then the choice  $x = A^\dagger b + (E - A^\dagger A)u$  as in (5) implies

$$Ax = A(A^\dagger b + (E - A^\dagger A)u) = b + (A - AA^\dagger A)u = b.$$

The rank of the matrix  $E - A^\dagger A$  gives the correct size of the image of the corresponding mapping according to the Kronecker-Capelli theorem (cf. 2.3.5) about the solution of the system of linear equations, and thus we obtain all solutions in this way.  $\square$

**3.E.6.** How many (non-zero) singular values has the matrix  $A = \begin{pmatrix} 4 & 0 \\ 3 & 5 \end{pmatrix}$ ? Describe them explicitly. ○

**3.E.7.** For the matrix  $A$  given below, derive the matrix  $\Sigma$ , as described above:

$$A = \begin{pmatrix} 0 & 0 & -\frac{1}{2} \\ -1 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix}.$$

There is a simple way to perform the SVD-decomposition, which is described as follows: First compute the matrices  $\Sigma$  and  $V$  as suggested above. To compute the unitary matrix  $U$ , which forms the last piece of the SVD-decomposition, we rely on the relation  $AV = U\Sigma$ . To simplify the description, suppose that  $\text{rank}(A) = r$  and express  $V, U$  in terms of columns, as  $V = (v_1 \mid v_2 \mid \cdots \mid v_n)$  and  $U = (u_1 \mid u_2 \mid \cdots \mid u_m)$  respectively. Then we have

$$\begin{aligned} AV &= (Av_1 \mid Av_2 \mid \cdots \mid Av_n) \\ &= (\sigma_1 u_1 \mid \cdots \mid \sigma_r u_r \mid 0 \mid \cdots \mid 0) = U\Sigma. \end{aligned}$$

Hence we will have  $u_k = \frac{1}{\sigma_k} Av_k$ , for all  $k = 1, \dots, r$ . To determine the remaining  $m - r$  columns of  $U$  it suffices to extend the set  $\{u_1, \dots, u_r\}$  to an orthonormal basis of  $\mathbb{F}^m$ , which usually can be done via the Gram-Schmidt procedure.

**3.E.8.** Describe the singular value decompositions of the matrices given in 3.E.6 and 3.E.7, respectively.

**Solution.** (a) Let us first consider the  $2 \times 2$  matrix  $A$ , where  $\Sigma = \text{diag}(2\sqrt{10}, \sqrt{10})$ . Let us derive the eigenvectors corresponding to the eigenvalues  $\lambda_1 = 40$  and  $\lambda_2 = 10$  of  $A^T A$ , to construct the matrix  $V$ . The solution space of the linear system induced by the matrix equation  $(A^T A - 40E)v$  has the form  $\{(x_1, x_2)^T = (t, t)^T : t \in \mathbb{R}\}$ . Hence, eigenvectors of  $A^T A$  corresponding to  $\lambda_1 = 40$  are scalar multiples of the vector  $(1, 1)^T$ . This vector has norm  $\sqrt{2}$  and we obtain the normalized eigenvector  $v_1 = \left(\frac{\sqrt{2}}{2}, \frac{\sqrt{2}}{2}\right)^T$ . For the second eigenvalue we see that the linear system induced by the matrix equation  $(A^T A - 10E)v$  has solution space  $\{(x_1, x_2)^T = (-s, s)^T : s \in \mathbb{R}\}$ . Consequently, eigenvectors of  $A^T A$  corresponding to  $\lambda_2$  are scalar multiples of  $(-1, 1)^T$ . The norm of this vector is also  $\sqrt{2}$ , and we obtain the normalized eigenvector  $v_2 = \left(-\frac{\sqrt{2}}{2}, \frac{\sqrt{2}}{2}\right)^T$ . Therefore,

$$V = (v_1 \mid v_2) = \begin{pmatrix} \frac{\sqrt{2}}{2} & -\frac{\sqrt{2}}{2} \\ \frac{\sqrt{2}}{2} & \frac{\sqrt{2}}{2} \end{pmatrix},$$

**Remark.** Notice that the last computation in the proof verifies that  $(E - A^\dagger A)$  is the matrix of the projection of  $\mathbb{R}^n$  onto the subspaces of all solutions of the homogenous system  $Ax = 0$ .

It can be also shown that the matrix  $A^\dagger$  minimizes the square of the norm of the expression

$$AA^\dagger - E$$

that is, the sum of squares of all elements of the given matrix.

The claim (4) of the theorem can be also interpreted as follows.  $AA^\dagger$  is the matrix of the orthogonal projection from the vector space  $\mathbb{R}^m$ , onto the subspace generated by the columns of the matrix  $A$  ( $m$  is the number of the rows of the matrix  $A$ ). This interpretation has a strong meaning for matrices having more rows than columns. Moreover, for matrices  $A$  whose columns are independent vectors, the expression  $(A^T A)^{-1} A^T$  makes sense and it is not hard to verify that this matrix satisfies all the properties from (1) and (2) from the previous theorem. Thus it is the pseudoinverse  $A^\dagger$  of the matrix  $A$ .

**3.5.8. Linear regression.** The approximation property (4)

from the previous theorem is very useful in the cases where we are to find as good an approximation as possible for the (non-existent) solution of a given system  $Ax = b$ , where  $A$  is a real matrix of the type  $m/n$  and  $m > n$ .

For instance, an experiment gives many measured real values  $b_j$ ,  $j = 1, \dots, m$ . We want to find a linear combination of only a few fixed functions  $f_i$ ,  $i = 1, \dots, n$  which approximates the values  $b_j$  as good as possible. The actual values of the fixed functions at the relevant points  $y_j \in \mathbb{R}$  define the matrix  $a_{ij} = f_i(y_j)$ . The columns of the matrix are given by values of the individual functions  $f_i$  at the considered points. The goal is to determine the coefficients  $x_i \in \mathbb{R}$  so that the sum of the squares of the deviations from the actual values

$$\sum_{j=1}^m (b_j - \sum_{i=1}^n x_i f_i(y_j))^2 = \sum_{j=1}^m (b_j - \sum_{i=1}^n a_{ij} x_i)^2$$

is minimized. By the previous theorem, the optimal coefficients are  $A^\dagger b$ .

As an example, consider just three functions  $f_0(y) = 1$ ,  $f_1(y) = y$ ,  $f_2(y) = y^2$ . Assume that the “measured values” of their unknown combination  $g(y) = x_0 + x_1 y + x_2 y^2$  in integral values for  $y$  between 1 and 5 are  $b^T = (1, 12, 6, 27, 33)$ . (This vector  $b$  arose by computing the values  $1 + y + y^2$  at the given points adjusted by random integral values in the range  $\pm 10$ .) This leads in our case to the matrix  $A = (b_{ji})$

$$A^T = \begin{pmatrix} 1 & 1 & 1 & 1 & 1 \\ 1 & 2 & 3 & 4 & 5 \\ 1 & 4 & 9 & 16 & 25 \end{pmatrix}.$$

and it is easy to verify that  $V$  is unitary. Next, for the matrix  $U = (u_1 \mid u_2)$  we have

$$u_1 = \frac{1}{\sigma_1} Av_1 = \frac{1}{2\sqrt{10}} \begin{pmatrix} 4 & 0 \\ 3 & 5 \end{pmatrix} \begin{pmatrix} \frac{\sqrt{2}}{2} \\ \frac{\sqrt{2}}{2} \end{pmatrix} = \begin{pmatrix} \frac{\sqrt{5}}{5} \\ \frac{2\sqrt{5}}{5} \end{pmatrix},$$

$$u_2 = \frac{1}{\sigma_2} Av_2 = \frac{1}{\sqrt{10}} \begin{pmatrix} 4 & 0 \\ 3 & 5 \end{pmatrix} \begin{pmatrix} -\frac{\sqrt{2}}{2} \\ \frac{\sqrt{2}}{2} \end{pmatrix} = \begin{pmatrix} -\frac{2\sqrt{5}}{5} \\ \frac{\sqrt{5}}{5} \end{pmatrix}.$$

A direct computations show that  $u_1, u_2$  are orthonormal, and hence the matrix  $U$  is given by

$$U = (u_1 \mid u_2) = \begin{pmatrix} \frac{\sqrt{5}}{5} & -\frac{2\sqrt{5}}{5} \\ \frac{2\sqrt{5}}{5} & \frac{\sqrt{5}}{5} \end{pmatrix},$$

such that  $A = U\Sigma V^T$ . For a quick confirmation, you may use Sage:

```
A=matrix([[4, 0], [3, 5]])
show("\n\nThe matrix A is given by A=", A)
S=diagonal_matrix([2*sqrt(10), sqrt(10)])
show("\n\nThe matrix S is given by S=", S)
V=matrix([[sqrt(2)/2, -sqrt(2)/2],
[sqrt(2)/2, sqrt(2)/2]])
show("\n\nThe matrix V is given by V=", V)
print(V.is_unitary())
U=matrix([[sqrt(5)/5, -2*sqrt(5)/5],
[2*sqrt(5)/5, sqrt(5)/5]])
show("\n\nThe matrix U is given by U=", U)
print(U.is_unitary())
print(A*V==U*S)
```

(b) In this case we have seen that  $\Sigma = \text{diag}(1, 1/2, 0)$ . For the eigenvalues  $\lambda_1 = 1, \lambda_2 = 1/4$  and  $\lambda_3 = 0$  of  $A^T A$  we compute the normalized eigenvectors  $v_1 = (1, 0, 0)^T, v_2 = (0, 0, 1)^T$  and  $v_3 = (0, 1, 0)^T$ . This can be confirmed in Sage by the following cell:

```
A=matrix([[0, 0, -1/2], [-1, 0, 0],
[0, 0, 0]])
AT=A.T; a= AT*A
show(a.eigenvalues())
S=diagonal_matrix([1, 1/2, 0])
show("\n\nThe matrix S is given by S=", S)
aein=a.eigenvectors_right()
show(aein)
```

which also prints the expression of the matrix  $\Sigma$  (denoted inside the cell by  $S$ ). Thus  $V = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 0 & 1 \\ 0 & 1 & 0 \end{pmatrix}$ . Next, for the

matrix  $U = (u_1 \mid u_2 \mid u_3)$  we can compute the first two columns by the rule  $u_k = \frac{1}{\sigma_k} Av_k$ . This gives

$$u_1 = \frac{1}{\sigma_1} Av_1 = \frac{1}{1} \begin{pmatrix} 0 & 0 & -\frac{1}{2} \\ -1 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix} \begin{pmatrix} 1 \\ 0 \\ 0 \end{pmatrix} = \begin{pmatrix} 0 \\ -1 \\ 0 \end{pmatrix},$$

$$u_2 = \frac{1}{\sigma_2} Av_2 = \frac{1}{1/2} \begin{pmatrix} 0 & 0 & -\frac{1}{2} \\ -1 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix} \begin{pmatrix} 0 \\ 0 \\ 1 \end{pmatrix} = \begin{pmatrix} -1 \\ 0 \\ 0 \end{pmatrix}.$$

The requested optimal coefficients for the combination are

$$x = A^\dagger \cdot b$$

$$= \begin{pmatrix} \frac{9}{5} & 0 & -\frac{4}{5} & -\frac{3}{5} & \frac{3}{5} \\ -\frac{37}{35} & \frac{23}{70} & \frac{6}{7} & \frac{37}{70} & -\frac{23}{35} \\ \frac{1}{7} & -\frac{1}{14} & -\frac{1}{7} & -\frac{1}{14} & \frac{1}{7} \end{pmatrix} \cdot \begin{pmatrix} 1 \\ 12 \\ 6 \\ 27 \\ 33 \end{pmatrix}$$

$$\simeq \begin{pmatrix} 0.600 \\ 0.614 \\ 1.214 \end{pmatrix}.$$

The resulting approximation can be seen in the picture, where the given values  $b$  are shown by the diamonds, while the dashed curve stays for the resulting approximation  $g(y) = x_1 + x_2 y + x_3 y^2$ .

The computation was produced in Maple and taking 15 values  $y_i = 1 + i + i^2$ , with a random vector of deviations from the same range added produced the following picture:

It remains to extend  $\{u_1, u_2\}$  to an orthonormal basis of  $\mathbb{R}^3$ . Thus, we need to find a unit vector which is orthogonal to both  $u_1, u_2$ . Such a vector is the vector  $u_3 = (0, 0, -1)^T$  which is in fact the cross product on  $\mathbb{R}^3$  of  $u_1, u_2$ :

$$u_1 \times u_2 = \begin{vmatrix} \vec{i} & \vec{j} & \vec{k} \\ 0 & -1 & 0 \\ -1 & 0 & 0 \end{vmatrix} = 0 \cdot \vec{i} - 0 \cdot \vec{j} + (-1) \cdot \vec{k}.$$

This gives the matrix

$$U = \begin{pmatrix} 0 & -1 & 0 \\ -1 & 0 & 0 \\ 0 & 0 & -1 \end{pmatrix},$$

such that  $A = U\Sigma V^T$ , i.e.,

$$A = \begin{pmatrix} 0 & -1 & 0 \\ -1 & 0 & 0 \\ 0 & 0 & -1 \end{pmatrix} \begin{pmatrix} 1 & 0 & 0 \\ 0 & \frac{1}{2} & 0 \\ 0 & 0 & 0 \end{pmatrix} \begin{pmatrix} 1 & 0 & 0 \\ 0 & 0 & 1 \\ 0 & 1 & 0 \end{pmatrix}.$$

If you would like to verify this computation using Sage, you can continue by typing the following code in the previous block:

```
V=matrix([[1, 0, 0], [0, 0, 1], [0, 1, 0]])
show("\nThe matrix V is given by V=", V)
print(V.is_unitary())
U=matrix([[0, -1, 0], [-1, 0, 0], [0, 0, -1]])
show("\nThe matrix U is given by U=", U)
print(U.is_unitary())
A==U*S*(V.T)
```

In this way Sage confirms that both the matrices  $U$  and  $V$  are unitary, and moreover the relation  $A = U\Sigma V^T$ .

Note that Sage offers a built-in method to compute the singular value decomposition of a matrix, but it is only available for matrices over the numerical systems CDF or RDF. For our matrix  $A$ , for example, one can type

```
A=matrix(RDF, [[0, 0, -1/2], [-1, 0, 0], [0, 0, 0]])
show(A.SVD())
```

Note that Sage's output differs from our result only in terms of signs and column permutations. This variation is expected, as in SVD decomposition, the singular vectors (eigenvectors of  $U$  and  $V$ ) may differ by signs or orderings. Hence, be aware that different software implementations or methods might produce different but equally valid SVD results.  $\square$

*Using the components of the SVD-decomposition of a matrix  $A$  we can construct the polar decomposition, which is another significant matrix factorization, see 3.5.5. This describes a complex matrix  $A$  as a product of a unitary matrix  $U_p$  and a positive semi-definite matrix  $P$ . If  $A$  is real then  $U_p$  is an orthogonal matrix. Recall that saying  $P$  is positive semi-definite we mean that  $P$  has non-negative eigenvalues. If  $A = U\Sigma V^*$  is the SVD decomposition of  $A$ , then the corresponding polar decomposition  $A = PU_p$  occurs easily by setting  $U_p = UV^*$  and  $P = U\Sigma U^*$ , respectively.*

**3.E.9.** For the matrix  $A$  given in 3.E.7 compute its polar decomposition  $A = PU_p$  and use Sage to verify your result. Is

this decomposition unique? Next show that the matrix  $P$  is Hermitian and positive semi-definite.  $\circ$

Let  $A = U\Sigma V^*$  be the SVD-decomposition of a  $m \times n$  matrix  $A$  of rank  $r$ , where  $\Sigma = \text{diag}(\sigma_1, \dots, \sigma_r, 0, \dots, 0)$  is the  $m \times n$  diagonal matrix with the singular values of  $A$ . The pseudo-inverse of  $A$  (also known as the Moore-Penrose-inverse) is defined by

$$A^\dagger = V\Sigma^\dagger U^*,$$

where  $\Sigma^\dagger = \text{diag}\left(\frac{1}{\sigma_1}, \dots, \frac{1}{\sigma_r}, 0, \dots, 0\right)$ .

This matrix functions as a generalized inverse for matrices that are singular or non-square. As such, it extends the concept of an inverse matrix in several ways, see 3.5.7. Notably, while not every matrix has an inverse, every matrix, including non-square ones, has a pseudo-inverse.

**3.E.10.** For the matrices  $A$  given in 3.E.6 and 3.E.7 compute the corresponding pseudo-inverses.

**Solution.** (a) For the matrix  $A$  presented in 3.E.6 we obtain

$$\Sigma^\dagger = \begin{pmatrix} \frac{1}{2\sqrt{10}} & 0 \\ 0 & \frac{1}{\sqrt{10}} \end{pmatrix}.$$

Thus, the explicit form of the pseudo-inverse  $A^\dagger = V\Sigma^\dagger U^T$  of the matrix  $A$  is given by

$$\begin{aligned} A^\dagger &= \begin{pmatrix} \frac{\sqrt{2}}{2} & -\frac{\sqrt{2}}{2} \\ \frac{\sqrt{2}}{2} & \frac{\sqrt{2}}{2} \end{pmatrix} \begin{pmatrix} \frac{1}{2\sqrt{10}} & 0 \\ 0 & \frac{1}{\sqrt{10}} \end{pmatrix} \begin{pmatrix} \frac{\sqrt{5}}{5} & \frac{2\sqrt{5}}{5} \\ -\frac{2\sqrt{5}}{5} & \frac{\sqrt{5}}{5} \end{pmatrix} \\ &= \begin{pmatrix} \frac{1}{4} & 0 \\ -\frac{3}{20} & \frac{1}{5} \end{pmatrix}. \end{aligned}$$

To confirm our result we need to verify the identity  $AA^\dagger A = A$ , which is direct:

$$\begin{aligned} AA^\dagger A &= \begin{pmatrix} 4 & 0 \\ 3 & 5 \end{pmatrix} \begin{pmatrix} \frac{1}{4} & 0 \\ -\frac{3}{20} & \frac{1}{5} \end{pmatrix} \begin{pmatrix} 4 & 0 \\ 3 & 5 \end{pmatrix} \\ &= \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix} \begin{pmatrix} 4 & 0 \\ 3 & 5 \end{pmatrix} = A. \end{aligned}$$

In fact, observe that  $\det(A) = 20 \neq 0$ . Hence  $A$  is non-singular and has a unique inverse that should coincide with  $A^\dagger$ . This provides another confirmation:

$$A^{-1} = \frac{1}{\det(A)} \begin{pmatrix} 5 & 0 \\ -3 & 4 \end{pmatrix} = \begin{pmatrix} \frac{1}{4} & 0 \\ -\frac{3}{20} & \frac{1}{5} \end{pmatrix} = A^\dagger.$$

(b) For the matrix  $A$  presented in 3.E.7 we obtain

$$\Sigma^\dagger = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 2 & 0 \\ 0 & 0 & 0 \end{pmatrix}$$

and hence the corresponding pseudo-inverse has the form

$$\begin{aligned} A^\dagger &= \begin{pmatrix} 1 & 0 & 0 \\ 0 & 0 & 1 \\ 0 & 1 & 0 \end{pmatrix} \begin{pmatrix} 1 & 0 & 0 \\ 0 & 2 & 0 \\ 0 & 0 & 0 \end{pmatrix} \begin{pmatrix} 0 & -1 & 0 \\ -1 & 0 & 0 \\ 0 & 0 & -1 \end{pmatrix} \\ &= \begin{pmatrix} 0 & -1 & 0 \\ 0 & 0 & 0 \\ -2 & 0 & 0 \end{pmatrix}. \end{aligned}$$

Note that  $\det(A) = 0$  hence this matrix does not have an inverse. To confirm the relation  $AA^\dagger A = A$  (or  $A^\dagger AA^\dagger = A^\dagger$ ), you can use Sage as follows;

```
A=matrix([[0, 0, -1/2],
[-1, 0, 0], [0, 0, 0]])
Aps=matrix([[0, -1, 0],
[0, 0, 0], [-2, 0, 0]])
print(A*Aps*A==A)
```

Or you can use the following routine, which relies on Scipy (or Numpy).

```
def pseudo_inverse(mat) :
    from scipy import linalg
    return matrix(linalg.pinv(mat))
Ap=pseudo_inverse(A)
show(Ap)
```

Note that one should add this cell in the previous block.  $\square$

 Let us conclude our description of matrix factorizations with the  $QR$ -decomposition, which expresses a complex matrix as a product of a unitary matrix  $Q$  and an upper-triangular matrix  $R$ , see 3.5.6. If for example  $A \in \text{Mat}_{m,n}(\mathbb{C})$  comes with  $n$  linearly independent columns, then using the Gram-Schmidt orthogonalization we can obtain the factorization  $A = QR$ , where  $Q$  is of type  $m \times n$  with orthonormal columns, and  $R$  is an invertible upper triangular matrix with positive diagonal entries.

Finding the  $QR$ -decomposition only requires simple algebraic operations and it can be useful to summarize the steps, for a matrix  $A \in \text{Mat}_{m,n}(\mathbb{C})$ , as above:

- Step 1 Via the Gram-Schmidt procedure find an orthogonal basis of the column space  $C(A)$  of  $A$ .
- Step 2 Normalize the vectors of this basis to get the columns of  $Q$ .
- Step 3 As the columns of  $Q$  are orthonormal with respect to the dot product, we have  $Q^T Q = E$ , where  $E$  is the  $n \times n$  identity matrix. Hence, the upper triangular matrix  $R$  is given by the formula  $R = Q^T A$ . Alternatively, if  $u_1, \dots, u_n$  are the linearly independent columns of  $A$ , and  $q_1, \dots, q_n$  are the orthonormal vectors obtained by the Gram-Schmidt procedure, then the entries  $r_{ij}$  of  $R$  are given by  $r_{ij} = \langle u_j, q_i \rangle$  for any  $1 \leq i, j \leq n$ , such that  $r_{ij} = 0$  for all  $i > j$ . Note that both  $Q, R$  are unique.

**3.E.11.** Present the  $QR$ -decomposition of the matrix

$$A = \begin{pmatrix} 1 & 1 & 1 \\ 1 & 1 & 1 \\ 1 & 1 & 0 \\ 1 & 0 & 0 \end{pmatrix}.$$

**Solution.** The column of  $A$  are the vectors  $E_1, E_2, E_3$  presented in 2.C.50. Recall that there we constructed the orthonormal basis  $\{\hat{w}_i : i = 1, 2, 3\}$  of the 3-dimensional subspace  $W = \text{span}_{\mathbb{R}}\{E_1, E_2, E_3\}$ . Obviously, this coincides with the column space of  $A$ , i.e.,  $W = C(A)$ . Thus the  $3 \times 4$

matrix  $Q$  is given by  $Q = (\hat{w}_1 \mid \hat{w}_2 \mid \hat{w}_3)$ , or in other words

$$Q = \begin{pmatrix} 1/2 & \sqrt{3}/6 & \sqrt{6}/6 \\ 1/2 & \sqrt{3}/6 & \sqrt{6}/6 \\ 1/2 & \sqrt{3}/6 & -\sqrt{6}/3 \\ 1/2 & -\sqrt{3}/2 & 0 \end{pmatrix}.$$

We can verify that  $Q^T Q = E$  in Sage, but again you should be careful in the following sense. If we use the number system QQbar to define the matrix  $Q$ , then the cell below gives True, which is the correct result.

```
Q=matrix(QQbar,
[[1/2, sqrt(3)/6, sqrt(6)/6],
[1/2, sqrt(3)/6, sqrt(6)/6],
[1/2, sqrt(3)/6, -sqrt(6)/3],
[1/2, -sqrt(3)/2, 0]])
Q.transpose()*Q == matrix.identity(3)
```

However, if we configure the matrix  $Q$ , using one of the number systems RR, CC, or CDF, Sage will return False. Can you explain the possible reasons why this might occur?

Next, the matrix  $R$  occurs by the multiplication  $Q^T A$ , which gives

$$R = \begin{pmatrix} 2 & 3/2 & 1 \\ 0 & \sqrt{3}/2 & \sqrt{3}/3 \\ 0 & 0 & \sqrt{6}/3 \end{pmatrix}.$$

Note that  $\det(R) = \sqrt{2} \neq 0$ , hence  $R$  is invertible, as it should be.

Sage provides a built-in method to obtain the  $QR$ -decomposition of a matrix  $A$ , based on the command `A.QR()`. Hence, you can quickly verify the result, just by typing

```
A=matrix(QQbar, [[1, 1, 1], [1, 1, 1],
[1, 1, 0], [1, 0, 0]])
Q, R = A.QR()
```

In case you like to confirm the expression of  $R$  in a “manual” way, you may use the following cell:

```
Q=matrix(QQbar,
[[1/2, sqrt(3)/6, sqrt(6)/6],
[1/2, sqrt(3)/6, sqrt(6)/6],
[1/2, sqrt(3)/6, -sqrt(6)/3],
[1/2, -sqrt(3)/2, 0]])
A = matrix(RR, [[1, 1, 1], [1, 1, 1],
[1, 1, 0], [1, 0, 0]])
R=(Q.T)*A; R
```

□

*The  $QR$ -decomposition of a matrix  $A$  is very useful when a system of linear equations  $Ax = b$  which has no solution is given, but an approximation as good as possible is needed.*

*In other words, the main point is to minimize  $\|Ax - b\|$ . According to the Pythagorean theorem, one has*

$$\|Ax - b\|^2 = \|Ax - b_{\parallel}\|^2 + \|b_{\perp}\|^2,$$

where  $b$  is decomposed into  $b_{\parallel}$  and into  $b_{\perp}$ . The first component belongs to the range of the linear transformation  $A$ , and the second one is perpendicular to this range. Now, the projection on the range of  $A$  can be written in the form  $QQ^T$  for a suitable matrix  $Q$ , which one obtains by the Gram-Schmidt orthonormalisation of the columns of  $A$ . Then, it follows that

$$Ax - b_{\parallel} = Q(Q^T Ax - Q^T b).$$

The system in the parentheses has a solution, for which  $\|Ax - b_{\parallel}\| = \|b_{\perp}\|$ , and this is the minimal value. Furthermore, the matrix  $R := Q^T A$  is upper triangular, therefore the approximate solution can be easily obtained.

**3.E.12.** Find an approximate solution of the following system of equations:

$$\{x_1 + 2x_2 = 1, 2x_1 + 4x_2 = 4\}.$$

**Solution.** We may express the given system in the matrix form  $Ax = b$ , where

$$A = \begin{pmatrix} 1 & 2 \\ 2 & 4 \end{pmatrix}, \quad b = \begin{pmatrix} 1 \\ 4 \end{pmatrix}.$$

Evidently, this system has no solution. Let us orthonormalize the columns of  $A$ : Take the first of them and divide it by its norm. This yields the first vector of the orthonormal basis  $\frac{1}{\sqrt{5}}(1, 2)^T$ . The second column vector of  $A$  is twice the first and thus we deduce that  $Q = \frac{1}{\sqrt{5}} \begin{pmatrix} 1 \\ 2 \end{pmatrix}$ . The projector on the range of  $A$  is then given by

$$QQ^T = \frac{1}{5} \begin{pmatrix} 1 & 2 \\ 2 & 4 \end{pmatrix}.$$

Next, we see that

$$Q^T b = \frac{1}{\sqrt{5}} (1 \ 2) \begin{pmatrix} 1 \\ 4 \end{pmatrix} = \frac{9}{\sqrt{5}}$$

and

$$R = Q^T A = \frac{1}{\sqrt{5}} (1 \ 2) \begin{pmatrix} 1 & 2 \\ 2 & 4 \end{pmatrix} = \frac{1}{\sqrt{5}} (5 \ 9).$$

Thus, the approximate solution should satisfy the relation

$$Rx = Q^T b,$$

which implies that  $5x_1 + 9x_2 = 9$ . Note that the approximate solution is not unique (instead of the  $QR$ -decomposition). In particular, the  $QR$ -decomposition of our matrix  $A$  has the form

$$\begin{pmatrix} 1 & 2 \\ 2 & 4 \end{pmatrix} = \frac{1}{\sqrt{5}} \begin{pmatrix} 1 \\ 2 \end{pmatrix} \frac{1}{\sqrt{5}} (5 \ 9).$$

□

**3.E.13.** Minimise  $\|Ax - b\|$  for

$$A = \begin{pmatrix} 2 & -1 & -1 \\ -1 & 2 & -1 \\ -1 & -1 & 2 \end{pmatrix}, \quad \text{and} \quad b = \begin{pmatrix} 1 \\ 0 \\ 0 \end{pmatrix}.$$

Write down also the  $QR$ -decomposition of the matrix  $A$ .

**Solution.** The normalised first column of the matrix  $A$  is  $u_1 = \frac{1}{\sqrt{6}}(2, -1, -1)^T$ . From the second column, subtract

its component in the direction  $u_1$  and set  $u = (-1, 2, -1)^T$ . Then we see that  $\langle u, u_1 \rangle = -\frac{3}{\sqrt{6}}$ . Thus it follows that

$$u - \langle u, u_1 \rangle u_1 = \frac{1}{2} \begin{pmatrix} 0 \\ 3 \\ 3 \end{pmatrix}.$$

Hence, we have created an orthogonal vector which we may normalise to obtain the vector

$$u_2 = \frac{1}{\sqrt{2}} \begin{pmatrix} 0 \\ 1 \\ -1 \end{pmatrix}.$$

The third column of the matrix  $A$  is already linearly dependent and thus the orthogonal matrix  $Q$  has the form

$$Q = \frac{1}{\sqrt{6}} \begin{pmatrix} 2 & 0 \\ -1 & \sqrt{3} \\ -1 & -\sqrt{3} \end{pmatrix}.$$

Consequently, we obtain

$$\begin{aligned} R = Q^T A &= \frac{1}{\sqrt{6}} \begin{pmatrix} 2 & -1 & -1 \\ 0 & \sqrt{3} & -\sqrt{3} \end{pmatrix} \begin{pmatrix} 2 & -1 & -1 \\ -1 & 2 & -1 \\ -1 & -1 & 2 \end{pmatrix} \\ &= \frac{1}{\sqrt{6}} \begin{pmatrix} 6 & -3 & -3 \\ 0 & 3\sqrt{3} & -3\sqrt{3} \end{pmatrix} \end{aligned}$$

and

$$Q^T b = \frac{1}{\sqrt{6}} \begin{pmatrix} 2 & -1 & -1 \\ 0 & \sqrt{3} & -\sqrt{3} \end{pmatrix} \begin{pmatrix} 1 \\ 0 \\ 0 \end{pmatrix} = \frac{1}{\sqrt{6}} \begin{pmatrix} 2 \\ 0 \end{pmatrix}.$$

The solution of the equation  $Rx = Q^T b$  is  $x = y = z$ . Thus, multiples of the vector  $(1, 1, 1)^T$  minimize  $\|Ax - b\|$ . Note that the mapping given by the matrix  $A$ , is a projection on the plane with normal vector  $(1, 1, 1)^T$ .  $\square$

*When dealing with an overdetermined system of linear equations (more equations than unknowns), the system may not have an exact solution. In such cases, the pseudo-inverse provides the best approximate solution in the least squares sense. The pseudo-inverse is also used in linear regression for finding the optimal parameters.*

*Next we will analyze how to solve problems with linear regression. Such tasks are about finding the best approximation of some functional dependence, using a linear function.*

*In particular, given a functional dependence for some points, that is,*

$$f(a_1^1, \dots, a_n^1) = y_1, \dots, f(a_1^k, a_2^k, \dots, a_n^k) = y_k,$$

*with  $k > n$ , we wish to find the “best possible” approximation of this dependency using a linear function. Observe that since  $k > n$  one has more equations than unknowns.*

*Hence we want to express the value of the property as a linear function  $f(x_1, \dots, x_n) = b_1 x_1 + b_2 x_2 + \dots + b_n x_n + c$ .*

We choose to define “best possible” by the minimisation of

$$\sum_{i=1}^k \left( y_i - \sum_{j=1}^n (b_j x_j + c) \right)^2$$

with regard to the real constants  $b_1, \dots, b_n, c$ . The goal is to find such a linear combination of the columns of the matrix  $A = (a_j^i)$  (with coefficients  $b_1, \dots, b_n$ ), that is closest to the vector  $(y_1, \dots, y_k)^T$  in  $\mathbb{R}^k$ .

This means that the whole procedure is about specifying an orthogonal projection of the vector  $(y_1, \dots, y_k)^T$  onto the subspace generated by the columns of  $A$ . Using the theorem presented in 3.5.7, it follows that this projection should be described by the vector  $(b_1, \dots, b_n)^T = A^\dagger (y_1, \dots, b_n)$ , where  $A^\dagger$  is the pseudo-inverse of  $A$ .

**3.E.14. Linear regression.** Using the least squares method, solve the linear system given below:

$$\begin{cases} 2x + y + 2z = 1, \\ x + y + 3z = 2, \\ 2x + y + z = 0, \\ x + z = -1. \end{cases}$$

**Solution.** The system has no solution, since its matrix has rank 3, and the extended matrix has rank 4. According to the theorem in 3.5.7, the best approximation of the vector  $b = (1, 2, 0, -1)^T$  can be obtained by the vector  $A^\dagger b$ . In particular,  $AA^\dagger b$  is then the best approximation – the perpendicular projection of the vector  $b$  onto the column space  $C(A)$  of  $A$ . Because the columns of the matrix  $A$  are linearly independent, its pseudo-inverse is given by the relation  $(A^T A)^{-1} A^T$ . We compute

$$\begin{aligned} A^\dagger &= \left( \begin{pmatrix} 2 & 1 & 2 \\ 1 & 1 & 3 \\ 2 & 1 & 1 \\ 1 & 0 & 1 \end{pmatrix} \begin{pmatrix} 2 & 1 & 2 & 1 \\ 1 & 1 & 1 & 0 \\ 2 & 3 & 1 & 1 \end{pmatrix} \right)^{-1} \begin{pmatrix} 2 & 1 & 2 & 1 \\ 1 & 1 & 1 & 0 \\ 2 & 3 & 1 & 1 \end{pmatrix} \\ &= \left( \begin{pmatrix} 10 & 5 & 10 \\ 5 & 3 & 6 \\ 10 & 6 & 15 \end{pmatrix} \right)^{-1} \begin{pmatrix} 2 & 1 & 2 & 1 \\ 1 & 1 & 1 & 0 \\ 2 & 3 & 1 & 1 \end{pmatrix} \\ &= \begin{pmatrix} 3/5 & -1 & 0 \\ -1 & 10/3 & -2/3 \\ 0 & -2/3 & 1/3 \end{pmatrix} \begin{pmatrix} 2 & 1 & 2 & 1 \\ 1 & 1 & 1 & 0 \\ 2 & 3 & 1 & 1 \end{pmatrix} \\ &= \begin{pmatrix} 1/5 & -2/5 & 1/5 & 3/5 \\ 0 & 1/3 & 2/3 & -5/3 \\ 0 & 1/3 & -1/3 & 1/3 \end{pmatrix}, \end{aligned}$$

and now we can compute the desired  $x$ , which is given by

$$x = A^\dagger b = (-6/5, 7/3, 1/3)^T.$$

Consequently, the best possible approximation to the column of the right side, is the vector  $(3/5, 32/15, 4/15, -13/15)^T$ .  $\square$

F. Additional exercises for the whole chapter

As usual, we proceed with supplementary exercises related to the notions that we have discussed so far.

A) MATERIAL ON LINEAR PROGRAMMING

**3.F.1. Manufacturing bolts and nuts.** A company manufactures bolts and nuts. Moulding a box of bolts takes one minute, while a box of nuts is moulded for 2 minutes. Preparing the box itself takes one minute for bolts, 4 minutes for nuts. The company has at its disposal two hours for moulding and three hours for box preparation. Demand says that it is necessary to manufacture at least 90 boxes of bolts more than boxes of nuts. Due to technical reasons it is not possible to manufacture more than 110 boxes of bolts. The profit from one box of bolts is \$4 and the profit from one box of nuts is \$6. The company has no trouble with selling. Write down the corresponding LP problem and present its standard form. Deduce graphically how many boxes of nuts and bolts should be manufactured in order to have maximal profit.

**Solution.** For convenience, let us put the given data into a table:

	Bolts 1 box	Nuts 1 box	Capacity
Mould	1 min./box	2 min./box	160 min.
Box	1 min./box	4 min./box	180 min.
Profit	\$4/box	\$6/box	

Denote by  $x_1$  the number of manufactured boxes of bolts and by  $x_2$  the number of manufactured boxes of nuts. From the restriction on moulding time and from the restriction on the box preparation we obtain the following restrictive conditions:

$$x_1 + 2x_2 \leq 120, \quad x_1 + 4x_2 \leq 180, \quad x_1 \geq x_2 + 90, \quad x_1 \leq 110.$$

The standard form reads as the maximization of the profit function  $h(x_1, x_2) = 4x_1 + 6x_2$  subject to the conditions

$$x_1 + 2x_2 \leq 120, \quad x_1 + 4x_2 \leq 180, \quad x_2 - x_1 \leq -90, \quad x_1 \leq 110,$$

with  $x_1 \geq 0, x_2 \geq 0$ . The feasible region is the grey region in the figure below, where we have also included the objective lines  $4x_1 + 6x_2 = k$ . From this figure we deduce that the point  $P = (110, 5)$  maximizes  $h$ , and the maximum possible income is thus given by  $4 \cdot 110 + 6 \cdot 5 = \$470$ .

□

**3.F.2. Investments and profits.** An insurance company has a capital of 100000€ which aims to invest in two different ways: the investment of type X and the investment of type Y. These types of investments give an annual income of 10% and of 15%, respectively. However, there is a limitation by the government, which requires that at least 25% of the capitals, should be invested in the X-type investment. On the other hand, the policy of the company requires the ratio between the capital used

for the Y-type investment and the capital used for the X-type of investment, not be greater than 1.5. How the company should invest its capital? Articulate the problem as a LP problem, and find the solution via the simplex method. Verify your solution using Sage.

**Solution.** Let  $x_1, x_2$  be the decision variables corresponding to the capitals (in euro) that the company will use for the X-type investment, and Y-type investment, respectively. The objective function is given by

$$h = 0.1x_1 + 0.15x_2 = \frac{1}{10}x_1 + \frac{3}{20}x_2 = \frac{2}{20}x_1 + \frac{3}{20}x_2.$$

The corresponding LP problem is the maximization of  $h$  under the constraints

$$x_1 + x_2 \leq 100000, \quad \frac{x_1}{x_1 + x_2} \geq 0.25, \quad \frac{x_2}{x_1} \leq 1.5, \quad x_1 \geq 0, \quad x_2 \geq 0,$$

which we can equivalently write as

$$x_1 + x_2 \leq 100000, \quad -\frac{3}{4}x_1 + \frac{1}{4}x_2 \leq 0, \quad -\frac{3}{2}x_1 + x_2 \leq 0, \quad x_1 \geq 0, \quad x_2 \geq 0.$$

Let us introduce the slack variables  $y_1, y_2, y_3$ , with  $y_i \geq 0$  for any  $i = 1, 2, 3$ . The application of the simplex method yields four tableaux, which we present as follows:

$-h$	$x_1$	$x_2$	$y_1$	$y_2$	$y_3$	0		$-h$	$x_1$	$x_2$	$y_1$	$y_2$	$y_3$	0	
$y_1$	1	1	1	0	0	100000	$x_2 \xrightarrow{\text{enters}}$ $y_2 \xrightarrow{\text{leaves}}$	$y_1$	4	0	1	-4	0	100000	$x_1 \xrightarrow{\text{enters}}$ $y_3 \xrightarrow{\text{leaves}}$
$y_2$	-3/4	1/4	0	1	0	0		$x_2$	-3	1	0	4	0	0	
$y_3$	-3/2	1	0	0	1	0		$y_3$	3/2	0	0	-4	1	0	
$-h$	$x_1$	$x_2$	$y_1$	$y_2$	$y_3$	0		$-h$	$x_1$	$x_2$	$y_1$	$y_2$	$y_3$	13000	
$y_1$	0	0	1	20/3	-8/3	100000	$y_2 \xrightarrow{\text{enters}}$ $y_1 \xrightarrow{\text{leaves}}$	$y_2$	0	0	3/20	1	-2/5	15000	
$x_2$	0	1	0	-4	2	0		$x_2$	0	1	3/5	0	2/5	60000	
$x_1$	1	0	0	-8/3	2/3	0		$x_1$	1	0	2/5	0	-2/5	40000	

Since in the last tableau the row of  $-h$  has no negative entry, we have arrived to the optimal solution which reads as follows: ( $x_1 = 40000, x_2 = 60000$ ) with  $y_2 = 15000$ . The maximum value of  $h$  is given by 13000, hence the investments will bring to the company a maximum profit of 13000€. To verify the solution in Sage, you can use the block

```
p = MixedIntegerLinearProgram()
v = p.new_variable(real=True, nonnegative=True)
x1, x2 = v["x1"], v["x2"]
p.set_objective((2/20)*x1 + (3/20)*x2)
p.add_constraint(x1 + x2 <= 100000)
p.add_constraint((-3/4)*x1 + (1/4)*x2 <= 0)
p.add_constraint((-3/2)*x1 + x2 <= 0)
k = p.solve()
x1, x2 = p.get_values(x1, x2)
print("Answer =", round(k, 2))
print("(x1, x2) =", (x1, x2))
```

By executing this block we obtain the desired verification:

```
Answer = 13000.0
(x1, x2) = 40000.0 60000.0
```

□

**3.F.3.** If  $x_i \geq 0$  for all  $i = 1, 2, 3$ , minimize the expression  $-3x_1 - x_2 - 2x_3$  subject to the conditions

$$\begin{aligned} x_1 - x_2 + x_3 &\geq -4, \\ 2x_1 + x_3 &\leq 3, \\ x_1 + x_2 + 3x_3 &\leq 8. \end{aligned}$$

**Solution.** We multiply the objective function and the first inequality by  $-1$ , to get the equivalent task of maximizing  $h = 3x_1 + x_2 + 2x_3$  subject to the following conditions

$$\begin{aligned} -x_1 + x_2 - x_3 &\leq 4, \\ 2x_1 + x_3 &\leq 3, \\ x_1 + x_2 + 3x_3 &\leq 8, \end{aligned}$$

with  $x_i \geq 0$  for  $i = 1, 2, 3$ . Introducing the non-negative slacks  $x_4, x_5$  and  $x_6$ , interpret the objective function as  $3x_1 + x_2 + 2x_3 + 0 \cdot x_4 + 0 \cdot x_5 + 0 \cdot x_6$ . We now write down the first simplex tableau (the pivot element always appear circled):

$$\begin{array}{c|cccccc|c} R_0 & -3 & -1 & -2 & 0 & 0 & 0 & 0 \\ \hline R_1 & -1 & 1 & -1 & 1 & 0 & 0 & 4 \\ R_2 & \textcircled{2} & 0 & 1 & 0 & 1 & 0 & 3 \\ R_3 & 1 & 1 & 3 & 0 & 0 & 1 & 8 \end{array}$$

To eliminate the first column which is the driver, we apply the elementary row operations  $R_2 \rightarrow \hat{R}_2 := \frac{1}{2}R_2$ ,  $R_0 \rightarrow R_0 + 3\hat{R}_2$ ,  $R_1 \rightarrow R_1 + \hat{R}_2$ , and  $R_3 \rightarrow R_3 - \hat{R}_2$ . This yields the second tableau:

$$\begin{array}{c|cccccc|c} \hat{R}_0 & 0 & -1 & -1/2 & 0 & 3/2 & 0 & 9/2 \\ \hline \hat{R}_1 & 0 & \textcircled{1} & -1/2 & 1 & 1/2 & 0 & 11/2 \\ \hat{R}_2 & 1 & 0 & 1/2 & 0 & 1/2 & 0 & 3/2 \\ \hat{R}_3 & 0 & 1 & 5/2 & 0 & -1/2 & 1 & 13/23 \end{array}$$

where the new basic variables are  $x_1 = 3/2$ ,  $x_4 = 11/2$ , and  $x_6 = 13/2$ . This reflects the fact that we moved as much from the former slack  $x_5$  to the new basic variable  $x_1$  as possible. This increased the value of the objective function, which we may read in the right top corner of the tableau. We now move to the new work column which is the one containing  $-1$  in  $\hat{R}_0$ . In this column we circled the new pivot, which equals to 1 (since  $11/2 < 13/2$ ). Hence we can directly eliminate the second column by the row operations  $\hat{R}_0 \rightarrow \hat{R}_0 + \hat{R}_1$  and  $\hat{R}_3 \rightarrow \hat{R}_3 - \hat{R}_1$  (observe that  $\hat{R}_2$  already contains 0 in the work column). This gives

$$\begin{array}{c|cccccc|c} \tilde{R}_0 & 0 & 0 & -1 & 1 & 2 & 0 & 10 \\ \hline \tilde{R}_1 & 0 & 1 & -1/2 & 1 & 1/2 & 0 & 11/2 \\ \tilde{R}_2 & 1 & 0 & 1/2 & 0 & 1/2 & 0 & 3/2 \\ \tilde{R}_3 & 0 & 0 & \textcircled{3} & -1 & -1 & 1 & 1 \end{array}$$

and shifts the new basic variable from  $x_4$  to  $x_2$ . In this way we have increased the objective function. However, the first row  $\tilde{R}_0$  still contains a negative number and hence there is one more repetition. The new work column is the third one and the next pivot is the circled number 3. By applying the necessary elementary row operations we result to the final tableau

$$\begin{array}{c|cccccc|c} 0 & 0 & 0 & 2/3 & 5/3 & 1/3 & 31/3 \\ \hline 0 & 1 & 0 & 5/6 & 1/3 & 1/6 & 17/3 \\ 1 & 0 & 0 & 1/6 & 2/3 & -1/6 & 4/3 \\ 0 & 0 & 1 & -1/3 & -1/3 & 1/3 & 1/3 \end{array}$$

where the basic variables are the initial decision variables  $x_1, x_2, x_3$ . This gives the optimal solution  $x_1 = 4/3$ ,  $x_2 = 17/3$  and  $x_3 = 1/3$  with the maximal value of  $h$  being  $31/3$ .  $\square$

**3.F.4. Infinite optimal solutions.** Consider the LP problem of maximizing  $h = 3x_1 + x_2$  subject to the conditions

$$6x_1 + 2x_2 \leq 30, \quad 10x_1 + x_2 \leq 40, \quad x_1 \geq 0, \quad x_2 \geq 0.$$

Use the simplex method to show that an optimal solution of this LP problem is not unique. Verify your answer by a figure.

**Solution.** Let us introduce slack variables  $y_1, y_2$  to bring the problem to its canonical form. This corresponds to the maximization of  $h = 3x_1 + x_2 + 0y_1 + 0y_2$  under the constraints

$$\begin{array}{rclcl} 6x_1 & + & 2x_2 & + & y_1 & & = & 30, \\ 10x_1 & + & x_2 & & & + & y_2 & = & 40, \end{array}$$

with  $x_i \geq 0$  and  $y_j \geq 0$  for  $i, j = 1, 2$ . By applying the simplex method we need two iterations to arrive to an optimal solution. Let us summarize the tableaux together with the pivot elements circled (we also indicate the corresponding elementary row operations).

$$\begin{array}{c|cccc|c} & x_1 & x_2 & y_1 & y_2 & \\ \hline R_0 & -h & -3 & -1 & 0 & 0 & 0 \\ R_1 & y_1 & 6 & 2 & 1 & 0 & 30 \\ R_2 & y_2 & \textcircled{10} & 1 & 0 & 1 & 40 \end{array} \quad \begin{array}{l} R_2 \rightarrow \hat{R}_2 := \frac{1}{10}R_2 \\ R_0 \rightarrow \hat{R}_0 := R_0 + 3\hat{R}_2 \\ R_1 \rightarrow \hat{R}_1 := R_1 - 6\hat{R}_2 \\ \implies \end{array} \quad \begin{array}{c|cccc|c} \hat{R}_0 & -h & 0 & -7/10 & 0 & 3/10 & 12 \\ \hline \hat{R}_1 & y_1 & 0 & \textcircled{7/5} & 1 & -6/10 & 6 \\ \hat{R}_2 & x_1 & 1 & 1/10 & 0 & 1/10 & 4 \end{array}$$

$$\begin{array}{l} \hat{R}_1 \rightarrow \tilde{R}_1 := \frac{5}{7}\hat{R}_1 \\ \hat{R}_0 \rightarrow \tilde{R}_0 := \hat{R}_0 + \frac{7}{10}\tilde{R}_1 \\ \hat{R}_2 \rightarrow \tilde{R}_2 := \hat{R}_2 - \frac{1}{10}\tilde{R}_1 \\ \implies \end{array} \quad \begin{array}{c|cccc|c} & x_1 & x_2 & y_1 & y_2 & \\ \hline \tilde{R}_0 & -h & 0 & 0 & 1/2 & 0 & 15 \\ \hline \tilde{R}_1 & x_2 & 0 & 1 & 5/7 & -3/7 & 30/7 \\ \hline \tilde{R}_2 & x_1 & 1 & 0 & -1/14 & 1/7 & 25/7 \\ \hline \end{array}$$

Hence in the first iteration  $x_1$  enters the column of basic variables and  $y_2$  leaves, while in the second one  $x_2$  enters and  $y_1$  leaves. Since  $\tilde{R}_0$  does not contain a negative entry, we have arrived to an optimal solution given by  $(x_1 = \frac{25}{7}, x_2 = \frac{30}{7})$  (with  $y_1 = 0 = y_2$ ). The maximal value of  $h$  equals to 15. However, observe that in the above table the non-basic variable  $y_2$  appears with zero coefficient in  $\tilde{R}_0$ . Therefore,  $y_2$  can be brought to the basis to generate a new optimal solution with the same value of the objective function  $h$ . For this we use the entry  $1/7$  of  $\tilde{R}_2$  as a pivot and apply the following row operations  $\tilde{R}_2 \rightarrow r_2 := 7\tilde{R}_2$ ,  $\tilde{R}_1 \rightarrow \tilde{R}_1 + \frac{3}{7}r_2$ ,  $\tilde{R}_0 \rightarrow \tilde{R}_0$  (the cost row remains the same). This gives the following tableau

		$x_1$	$x_2$	$y_1$	$y_2$	
$r_0$	$-h$	0	0	1/2	0	15
$r_1$	$x_2$	3	1	1/2	0	15
$r_2$	$y_2$	7	0	-1/2	1	25

which provides the new optimal solution  $(x_1 = 0, x_2 = 15)$  (with  $y_1 = 0$  and  $y_2 = 25$ ), such that  $h(0, 15) = 15$ . Since two optimal solutions have been indicated, their convex combination will be also an optimal solution of the initial LP problem. This means that  $tP_1 + (1-t)P_2$  is also an optimal solution, for any  $t$  with  $0 \leq t \leq 1$ , where  $P_1 := (\frac{25}{7}, \frac{30}{7})$  and  $P_2 := (0, 15)$ . Thus this LP problem admits infinite optimal solutions, as one can also deduce by the help of the following figure:

□

**3.F.5. Cycling in the simplex method.** Consider the following task: maximize the functional  $h = 10x_1 - 57x_2 - 9x_3 - 24x_4$  subject to the conditions

$$\frac{1}{2}x_1 - \frac{11}{2}x_2 - \frac{5}{2}x_3 + 9x_4 \leq 0, \quad \frac{1}{2}x_1 - \frac{3}{2}x_2 - \frac{1}{2}x_3 + x_4 \leq 0, \quad x_1 + x_2 + x_3 + x_4 \leq 1, \quad x_i \geq 0, \quad (i = 1, \dots, 4).$$

Show that the simplex method applied to this LP problem *cycles*, which roughly speaking means that the same tableau occurs more than once. Can you find an optimal solution? <sup>18</sup>

**Solution.** Introduce the slack variables  $y_1, y_2, y_3$ , such that

<sup>18</sup>This example is adapted from the book of V. Chvátal (1983), *Linear Programming*, W. H. Freeman. Vasek Chvátal is a czech mathematician known for his contributions in LP, graph theory and combinatorics.

$$\begin{aligned} \frac{1}{2}x_1 - \frac{11}{2}x_2 - \frac{5}{2}x_3 + 9x_4 + y_1 &= 0, \\ \frac{1}{2}x_1 - \frac{3}{2}x_2 - \frac{1}{2}x_3 + x_4 + y_2 &= 0, \\ x_1 + x_2 + x_3 + x_4 + y_3 &= 1, \end{aligned}$$

with  $x_i \geq 0$  and  $y_j \geq 0$  for any  $i = 1, \dots, 4$  and  $j = 1, 2, 3$ . Thus the initial simplex tableau reads as follows:

		$x_1$	$x_2$	$x_3$	$x_4$	$y_1$	$y_2$	$y_3$	
$R_0$	$-h$	-10	57	9	24	0	0	0	0
$R_1$	$y_1$	$\left(\frac{1}{2}\right)$	-11/2	-5/2	9	1	0	0	0
$R_2$	$y_2$	1/2	-3/2	-1/2	1	0	1	0	0
$R_3$	$y_3$	1	1	1	1	0	0	1	1

In the driver column, which is the column of  $x_1$ , there are two choices of a pivot and we choose the circled  $1/2$  in  $R_1$ . Hence the variable  $x_1$  enters the column of basic variables and the variable  $y_1$  leaves. We replace  $R_1$  by  $\hat{R}_1 := 2R_1$  and next apply the row operations  $R_0 \rightarrow R_0 + 10\hat{R}_1$ ,  $R_2 \rightarrow R_2 - \frac{1}{2}\hat{R}_1$  and  $R_3 \rightarrow R_3 - \hat{R}_1$ . This gives the second tableau which reads as follows:

		$x_1$	$x_2$	$x_3$	$x_4$	$y_1$	$y_2$	$y_3$	
$\hat{R}_0$	$-h$	0	-53	-41	204	20	0	0	0
$\hat{R}_1$	$x_1$	1	-11	-5	18	2	0	0	0
$\hat{R}_2$	$y_2$	0	$\left(4\right)$	2	-8	-1	1	0	0
$\hat{R}_3$	$y_3$	0	12	6	-17	-2	0	1	1

Since  $-53 < -41$ , the column of  $x_2$  is the new work column and the circled 4 in  $\hat{R}_2$  is the new pivot. So  $x_2$  enters and  $y_2$  leaves. To eliminate the second column we replace  $\hat{R}_2$  by  $\tilde{R}_2 := \frac{1}{4}\hat{R}_2$  and apply the row operations  $\hat{R}_0 \rightarrow \hat{R}_0 + 53\tilde{R}_2$ ,  $\hat{R}_1 \rightarrow \hat{R}_1 + 11\tilde{R}_2$  and  $\hat{R}_3 \rightarrow \hat{R}_3 - 12\tilde{R}_2$ . This gives the third tableau:

		$x_1$	$x_2$	$x_3$	$x_4$	$y_1$	$y_2$	$y_3$	
$\tilde{R}_0$	$-h$	0	0	-29/2	98	27/4	53/4	0	0
$\tilde{R}_1$	$x_1$	1	0	$\left(\frac{1}{2}\right)$	-4	-3/4	11/4	0	0
$\tilde{R}_2$	$x_2$	0	1	1/2	-2	-1/4	1/4	0	0
$\tilde{R}_3$	$y_3$	0	0	0	7	1	-3	1	1

The column of  $x_3$  is the new driver and we choose as pivot the circled  $1/2$  in  $\tilde{R}_1$ . So  $x_3$  enters the column of basic variables and  $x_1$  leaves. To do so we replace  $\tilde{R}_1$  by  $\check{R}_1 := 2\tilde{R}_1$  and apply the row operations  $\tilde{R}_0 \rightarrow \tilde{R}_0 + \frac{29}{2}\check{R}_1$  and  $\tilde{R}_2 \rightarrow \tilde{R}_2 - \frac{1}{2}\check{R}_1$ . This gives the fourth tableau:

		$x_1$	$x_2$	$x_3$	$x_4$	$y_1$	$y_2$	$y_3$	
$\check{R}_0$	$-h$	29	0	0	-18	-15	93	0	0
$\check{R}_1$	$x_3$	2	0	1	-8	-3/2	11/2	0	0
$\check{R}_2$	$x_2$	-1	1	0	$\left(2\right)$	1/2	-5/2	0	0
$\check{R}_3$	$y_3$	0	0	0	7	1	-3	1	1

Since  $-18 < -15$ , the next work column is the column of  $x_4$  and the pivot is the circled 2 in  $\check{R}_2$ . Hence  $x_4$  enters and  $x_2$  leaves. For this, replace  $\check{R}_2$  by  $\bar{R}_2 := \frac{1}{2}\check{R}_2$  and apply the row operations  $\check{R}_0 \rightarrow \check{R}_0 + 18\bar{R}_2$ ,  $\check{R}_1 \rightarrow \check{R}_1 + 8\bar{R}_2$  and  $\check{R}_3 \rightarrow \check{R}_3 - 7\bar{R}_2$ . This gives the following table:

		$x_1$	$x_2$	$x_3$	$x_4$	$y_1$	$y_2$	$y_3$	
$\bar{R}_0$	$-h$	20	9	0	0	-21/2	141/2	0	0
$\bar{R}_1$	$x_3$	-2	4	1	0	$\left(\frac{1}{2}\right)$	-9/2	0	0
$\bar{R}_2$	$x_4$	-1/2	1/2	0	1	1/4	-5/4	0	0
$\bar{R}_3$	$y_3$	7/2	-7/2	0	0	-3/4	23/4	1	1

The new column driver is the column of  $y_1$  and we choose as pivot the circled  $1/2$  in  $\bar{R}_1$ . Thus  $y_1$  enters and  $x_3$  leaves. To do so we replace  $\bar{R}_1$  by  $r_1 := 2\bar{R}_1$  and apply the row operations  $\bar{R}_0 \rightarrow \bar{R}_0 + \frac{21}{2}r_1$ ,  $\bar{R}_2 \rightarrow \bar{R}_2 - \frac{1}{4}r_1$  and  $\bar{R}_3 \rightarrow \bar{R}_3 + \frac{3}{4}r_1$ . This yields the following table:

		$x_1$	$x_2$	$x_3$	$x_4$	$y_1$	$y_2$	$y_3$	
$r_0$	$-h$	-22	93	21	0	0	-24	0	0
$r_1$	$y_1$	-4	8	2	0	1	-9	0	0
$r_2$	$x_4$	1/2	-3/2	-1/2	1	0	1	0	0
$r_3$	$y_3$	1/2	5/2	3/2	0	0	-1	1	1

Since  $-24 < -22$  the new work column is that of  $y_2$  and the pivot is the circled 1 in  $r_2$ . Hence  $y_2$  enters the column of basic variables and  $x_4$  leaves. To eliminate the driver column we leave  $r_2$  identical and apply the row operations  $r_0 \rightarrow r_0 + 24r_2$ ,  $r_1 \rightarrow r_1 + 9r_2$  and  $r_3 \rightarrow r_3 + r_2$ . This gives us the initial simplex tableau, and hence this LP problem exhibits cycling.

A simple remedy against cycling is the so called *Bland's rule*. This says that for the entering variable we should take the first one in the present ordering of variables, which has a negative entry in the objective row. For choosing the leaving variable, if there is a tie for least ratio, take the candidate that is first in the ordering. For our problem, the ordering of the variables is  $x_1, \dots, x_4, y_1, \dots, y_3$  and an application of Bland's rule will leave everything the same up to the last pivot. This means that  $x_1$  should enter, instead of  $y_2$  and the pivot for this is the number 1/2 in  $r_2$  in the above table. Thus we replace the row  $r_2$  by  $\hat{r}_2 := 2r_2$  and apply the row operations  $r_0 \rightarrow r_0 + 22\hat{r}_2$ ,  $r_1 \rightarrow r_1 + 4\hat{r}_2$  and  $r_3 \rightarrow r_3 - \frac{1}{2}\hat{r}_2$ . This yields the following table:

		$x_1$	$x_2$	$x_3$	$x_4$	$y_1$	$y_2$	$y_3$	
$\hat{r}_0$	$-h$	0	27	-1	44	0	20	0	0
$\hat{r}_1$	$y_1$	0	-4	-2	8	1	-1	0	0
$\hat{r}_2$	$x_1$	1	-3	-1	2	0	2	0	0
$\hat{r}_3$	$y_3$	0	4	2	-1	0	-2	1	1

The next iteration will increase the value of the objective function and in particular will provide an optimal solution. Indeed,  $x_3$  enters and the new pivot is circled in the row  $\hat{r}_3$ , so  $y_3$  leaves. The final row operations are  $\hat{r}_3 \rightarrow \tilde{r}_3 := \frac{1}{2}\hat{r}_3$ ,  $\hat{r}_0 \rightarrow \hat{r}_0 + \tilde{r}_3$ ,  $\hat{r}_1 \rightarrow \hat{r}_1 + 2\tilde{r}_3$  and  $\hat{r}_2 \rightarrow \hat{r}_2 + \tilde{r}_3$  and we arrive to the following optimal table:

		$x_1$	$x_2$	$x_3$	$x_4$	$y_1$	$y_2$	$y_3$	
$\tilde{r}_0$	$-h$	0	29	0	87/2	0	19	1/2	1/2
$\tilde{r}_1$	$y_1$	0	0	0	7	1	-3	1	1
$\tilde{r}_2$	$x_1$	1	-1	0	3/2	0	1	1/2	1/2
$\tilde{r}_3$	$x_3$	0	2	1	-1/2	0	-1	1/2	1/2

Hence we have the optimal solution given by  $x_1 = 1/2 = x_3$  and  $x_2 = 0 = x_4$ , with the maximal value being  $h = 1/2$ .  $\square$

**3.F.6. Matrix games.** Imagine a game played by two players – a billionaire and fate. The billionaire would like to invest into gold, silver, diamonds or stocks of an important IT software company. Suppose that the wins and losses of such investments are well known for a period of four-five years (for simplicity, we consider only a period of four years and write them into the matrix  $A = (a_{ij})$ ):

	gold	silver	diamonds	software
2018	2%	1%	4%	3%
2019	3%	-1%	-2%	6%
2020	1%	2%	3%	-4%
2021	-2%	1%	2%	3%

The billionaire would like to invest for one year only. How should he split his investment in order to ensure the maximal win independently of development on the stock market? We assume that next year will be some (unknown) probabilistic mix of the previous four ones. In terms of our game, fate will play some stochastic vector  $(x_1, x_2, x_3, x_4)^T$  fixing the behaviour of the market (as a probabilistic mixture of the previous ones), while the billionaire will play another stochastic vector  $(y_1, y_2, y_3, y_4)^T$  describing the split of his investment. The win of the billionaire is  $\sum_{i,j=1}^4 x_i y_j a_{ij}$ .

**Solution.** The task is to find the stochastic vector  $(y_1, y_2, y_3, y_4)^T$ , which will maximize the minimum of all values

$$\sum_{i,j=1}^4 x_i y_j a_{ij}$$

for the fixed matrix  $A$  and any stochastic vector  $(x_1, x_2, x_3, x_4)^T$ . This is equivalent to the problem of maximizing  $z_1 + z_2 + z_3 + z_4$  under the condition  $A^T z \leq (1, \dots, 1)^T$ ,  $z \geq 0$  (and the requested stochastic vector  $y$  is then obtained by

normalizing the vector  $z$ , the requested optimal value is the inverse of the optimal value obtained).<sup>19</sup> Thus, one has to solve a LP problem and the first step is to introduce the slack variables  $w_1, w_2, w_3, w_4$ , and transform the problem to the standard form:

$$\max \{z_1 + z_2 + z_3 + z_4 \mid (A^T \mid E_4)(z, w) = (1, 1, 1, 1)^T\}.$$

The initial tableau of the simplex method is the following one

-1	-1	-1	-1	0	0	0	0	0	0
2	3	1	-2	1	0	0	0	0	1
1	-1	2	1	0	1	0	0	0	1
4	-2	3	2	0	0	1	0	0	1
3	6	-4	3	0	0	0	1	0	1

and after four iterations we arrive to the final table, given by

$\frac{188}{89}$	0	0	0	$\frac{25}{89}$	0	$\frac{44}{89}$	$\frac{17}{89}$	$\frac{86}{89}$
$\frac{114}{89}$	0	1	0	$\frac{18}{89}$	0	$\frac{21}{89}$	$-\frac{2}{89}$	$\frac{37}{89}$
$-\frac{146}{89}$	0	0	0	$-\frac{9}{89}$	1	$-\frac{55}{89}$	$\frac{1}{89}$	$\frac{26}{89}$
$-\frac{85}{89}$	0	0	1	$-\frac{10}{89}$	0	$\frac{18}{89}$	$\frac{11}{89}$	$\frac{19}{89}$
$\frac{78}{89}$	1	0	0	$\frac{17}{89}$	0	$\frac{5}{89}$	$\frac{8}{89}$	$\frac{30}{89}$

We can read off the optimal solution:  $z_2 = \frac{30}{89}, z_3 = \frac{37}{89}, z_4 = \frac{19}{89}, z_1 = 0$ . The optimal value (upper right corner) is  $z_1 + z_2 + z_3 + z_4 = \frac{86}{89}$ . After rescaling to a stochastic vector (multiplying with  $\frac{89}{86}$ ) we get the solution of the original problem:  $y_1 = 0, y_2 = \frac{30}{86}, y_3 = \frac{37}{86}, y_4 = \frac{19}{86}$ . with the optimal value  $\frac{89}{86}$ . □

### B) MATERIAL ON DIFFERENCE EQUATIONS

**3.F.7.** Find a real basis of solutions for the difference equation  $x_{n+4} = x_{n+3} - x_{n+2} + x_{n+1} - x_n$ .

**Solution.** The space of the solutions is a four-dimensional vector space whose generators can be obtained from the roots of the characteristic polynomial of the given equation. The characteristic equation has the form  $r^4 - r^3 + r^2 - r + 1 = 0$ . This is a so-called *reciprocal equation*, which means that the coefficients at the  $(n - k)$ -th and  $k$ -th power of  $r$  for  $k = 1, \dots, n$ , are equal. After dividing the characteristic equation by  $r^2$  (zero cannot be a root) and setting  $u := r + \frac{1}{r}$  (note that  $r^2 + \frac{1}{r^2} = u^2 - 2$ ) we obtain

$$r^2 - r + 1 - \frac{1}{r} + \frac{1}{r^2} = u^2 - u - 1 = 0.$$

This gives the indeterminates  $u_{1,2} = \frac{1 \pm \sqrt{5}}{2}$  and by the equation  $r^2 - ur + 1 = 0$  we determine the roots

$$r_{1,2,3,4} = \frac{1 \pm \sqrt{5} \pm \sqrt{-10 \pm 2\sqrt{5}}}{4}.$$

In fact, since  $r^5 + 1 = (r + 1)(r^4 - r^3 + r^2 - r + 1)$ , the roots of the characteristic equation could have been “guessed” right away. Thus, the roots of the characteristic polynomial are also the roots of the polynomial  $r^5 + 1$ , which are exactly the fifth roots of the  $-1$ . By this we obtain that the solutions of the characteristic polynomial are the numbers

$$r_{1,2} = \cos\left(\frac{\pi}{5}\right) \pm i \sin\left(\frac{\pi}{5}\right) \quad \text{and} \quad r_{3,4} = \cos\left(\frac{3\pi}{5}\right) \pm i \sin\left(\frac{3\pi}{5}\right).$$

Now, by the description in 3.2.5 it follows that a real basis of the space of the solutions of the given difference equation, is given by the sequences

$$\cos\left(\frac{n\pi}{5}\right), \sin\left(\frac{n\pi}{5}\right), \cos\left(\frac{3n\pi}{5}\right), \sin\left(\frac{3n\pi}{5}\right).$$

Note that these are sines and cosines of the arguments of the corresponding powers of the roots of the characteristic polynomial. □

<sup>19</sup>The observation comes from the proof of the von Neumann Minimax theorem, 1928. The theorem claims that any probabilistic extension of a matrix game enjoys an equilibrium state.

**3.F.8. A simplified model for the behaviour of gross domestic product.** Non homogeneous difference equations of second order are known in the science of *macroeconomics*. Consider for example the difference equation

$$x_{n+2} - A(1 + B)x_{n+1} + ABx_n = 1,$$

where  $x_k$  is the gross domestic product at the year  $k$ . The constant  $A$  is the *consumption tendency*, which is a macro economical factor that gives the fraction of money that the people spend (from what they have at their disposal). The constant  $B$  describes the dependence of the measure of investment of the private sector on the consumption tendency. Moreover, we assume that the size of the domestic product is normalised such that the right-hand side of the equation is 1. Compute the values  $x_n$  for  $A = 3/4$ ,  $B = 1/3$ ,  $x_0 = 1 = x_1$ .

**Solution.** For  $A = 3/4$  and  $B = 1/3$ , it is easy to check that the constant function  $x_n = 4$  is a particular solution of the initial (non-homogeneous) equation. We now look for solutions of the corresponding homogeneous equation. The general characteristic equation has the form

$$r^2 - A(1 + B)r + AB = 0,$$

which reduces to  $r^2 - r + 1/4 = 0$  for the particular values of  $A$  and  $B$ . Hence  $1/2$  is a double root. In this case, as we have seen before (cf. 3.B.3), the solutions of the homogeneous equation are given by  $a(1/2)^n + bn(1/2)^n$ , for some  $a, b \in \mathbb{R}$ . Hence, according to the theoretical description in 3.2.6, the solutions of the given difference equation (for  $A = 3/4$  and  $B = 1/3$ ), are expressed by

$$4 + a(1/2)^n + bn(1/2)^n.$$

Using the initial conditions  $x_0 = x_1 = 1$  we also obtain  $a = b = -3$ , and we are able to present the solution explicitly:

$$x_n = 4 - 3 \left(\frac{1}{2}\right)^n - 3n \left(\frac{1}{2}\right)^n.$$

Let us verify this result in Sage, by the method that we learned in the main part (cf. 3.B.11)

```
from sympy import Function, rsolve
from sympy.abc import n
a = Function("a")
f = a(n+2) - a(n+1) + (1/4)*a(n) - 1
initial = {a(0):1, a(1):1}
rsolve(f, a(n), initial)
```

Sage's output is the expression  $4 + (-3 * n - 3)/2 * n$ . □

**3.F.9.** Find the solution of the recurrence relation  $x_{n+2} - 6x_{n+1} + 5x_n = ne^n$ .

**Solution.** Solving first the homogeneous part we obtain:

$$x_n^{(h)} = c_1 \cdot (1)^n + c_2 \cdot 5^n.$$

To find the particular solution we can use the method of variation of the constant, described in ?? For this, we should compute the Wronski determinant:

$$W_{j+1} = \det \begin{pmatrix} 1^{j+1} & 5^{j+1} \\ 1^{j+2} & 5^{j+2} \end{pmatrix} = 4 \cdot 5^{j+1}.$$

Thus,

$$x_n = c_1 + c_2 \cdot 5^n - \frac{1}{4} \sum_{j=0}^{n-1} j e^j + \left( \sum_{j=0}^{n-1} \frac{j e^j}{4 \cdot 5^{j+1}} \right) 5^n,$$

with  $c_1, c_2 \in \mathbb{R}$ . □

**3.F.10.** Find the solution of the recurrence relation  $-x_{n+3} = 3x_{n+2} + 3x_{n+1} + x_n$ , with initial conditions  $x_1 = x_2 = x_3 = 1$ . ○

C) MATERIAL ON MODELS OF GROWTH AND ITERATED PROCESSES

*In this paragraph, the initial set of exercises addresses population growth and the Leslie model. However, it is crucial to first recognize the role that "primitive matrices" have in the theory of linear iterative models. Recall that a matrix  $A$  is called primitive if there exists a positive integer  $k$  such that  $A^k$  has only positive entries. These matrices are discussed in detail in Section 3.3.3, where further information can be found.*

**3.F.11.** Which of the matrices given below are primitive?

$$A = \begin{pmatrix} 0 & 1/7 \\ 1 & 6/7 \end{pmatrix}, \quad B = \begin{pmatrix} 1/2 & 0 & 1/3 \\ 0 & 1 & 1/2 \\ 1/2 & 0 & 1/6 \end{pmatrix}, \quad C = \begin{pmatrix} 0 & 1 & 0 \\ 1/4 & 0 & 1/2 \\ 3/4 & 0 & 1/2 \end{pmatrix}, \quad D = \begin{pmatrix} 1/3 & 1/2 & 0 & 0 \\ 1/2 & 1/3 & 0 & 0 \\ 0 & 1/6 & 1/6 & 1/3 \\ 1/6 & 0 & 5/6 & 2/3 \end{pmatrix}.$$

**Solution.** We see that

$$A^2 = \begin{pmatrix} 1/7 & 6/49 \\ 6/7 & 43/49 \end{pmatrix}, \quad C^3 = \begin{pmatrix} 3/8 & 1/4 & 1/4 \\ 1/4 & 3/8 & 1/4 \\ 3/8 & 3/8 & 1/2 \end{pmatrix}.$$

So the matrices  $A$  and  $C$  are primitive, since  $A^2$  and  $C^3$  are positive matrices. For  $n \in \mathbb{N}$ , the middle column of the matrix  $B^n$  is always the vector  $(0, 1, 0)^T$ , which contains the entry 0. Hence the matrix  $B$  cannot be primitive. Finally, the product

$$\begin{pmatrix} 1/3 & 1/2 & 0 & 0 \\ 1/2 & 1/3 & 0 & 0 \\ 0 & 1/6 & 1/6 & 1/3 \\ 1/6 & 0 & 5/6 & 2/3 \end{pmatrix} \cdot \begin{pmatrix} 0 \\ 0 \\ a \\ b \end{pmatrix} = \begin{pmatrix} 0 \\ 0 \\ a/6 + b/3 \\ 5a/6 + 2b/3 \end{pmatrix},$$

with  $a, b \in \mathbb{R}$ , implies that the matrix  $D^2$  has in the right upper corner a zero two-dimensional (square) sub-matrix. By induction, the same property is shared by the matrices  $D^3 = D \cdot D^2$ ,  $D^4 = D \cdot D^3$ ,  $\dots$ ,  $D^n = D \cdot D^{n-1}$ , and so on. Consequently, the matrix  $D$  is not primitive.  $\square$

**3.F.12. Rabbits and their population growth.** We are again interested in the population of rabbits on a meadow, as in the problem 3.B.1. However, we now assume that the rabbits are dying after reaching the ninth year of age.<sup>20</sup> Show that according to this model the population grows approximately with the geometric sequence  $1.608^t$ .

**Solution.** Denote by  $x_1(t), x_2(t), \dots, x_9(t)$  the number of rabbits according to their age (in years), at time  $t$ . Then, the number of rabbits in individual categories are described after one year by the formula

$$x_1(t+1) = x_2(t) + x_3(t) + \dots + x_9(t), \quad x_i(t+1) = x_{i-1}(t)$$

for  $i = 2, 3, \dots, 10$ . Equivalently, we may write

$$\begin{pmatrix} x_1(t+1) \\ x_2(t+1) \\ x_3(t+1) \\ x_4(t+1) \\ x_5(t+1) \\ x_6(t+1) \\ x_7(t+1) \\ x_8(t+1) \\ x_9(t+1) \end{pmatrix} = \begin{pmatrix} 0 & 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 \\ 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 & 0 \end{pmatrix} \begin{pmatrix} x_1(t) \\ x_2(t) \\ x_3(t) \\ x_4(t) \\ x_5(t) \\ x_6(t) \\ x_7(t) \\ x_8(t) \\ x_9(t) \end{pmatrix}.$$

The characteristic polynomial of the given matrix is  $\lambda^9 - \lambda^7 - \lambda^6 - \lambda^5 - \lambda^4 - \lambda^3 - \lambda^2 - \lambda - 1$ . To obtain a verification in Sage we can apply the command `A.eigenvalues()`, as usual:

```
A = matrix(QQ, [[0, 1, 1, 1, 1, 1, 1, 1, 1],
                [1, 0, 0, 0, 0, 0, 0, 0, 0],
                [0, 1, 0, 0, 0, 0, 0, 0, 0],
                [0, 0, 1, 0, 0, 0, 0, 0, 0],
                [0, 0, 0, 1, 0, 0, 0, 0, 0],
                [0, 0, 0, 0, 1, 0, 0, 0, 0],
                [0, 0, 0, 0, 0, 1, 0, 0, 0],
                [0, 0, 0, 0, 0, 0, 1, 0, 0],
                [0, 0, 0, 0, 0, 0, 0, 1, 0]])
A.eigenvalues()
```

The answer shows that  $\lambda_1 \approx 1.608$  is indeed the only positive real eigenvalue, a property that every Leslie matrix satisfies (there are also eight complex eigenvalues). In fact we can estimate this root of the characteristic polynomial very well (think why this must be smaller than  $(\sqrt{5} + 1)/2$ ).

Now, the normalized eigenvector corresponding to  $\lambda_1$  has the form (the coordinates of  $X_1$  sum to 100)

<sup>20</sup>In the original model the rabbits were immortal. Note that domesticated rabbits can live between eight to twelve years.

$$X_1 \approx (38.36, 23.85, 14.83, 9.22, 5.73, 3.56, 2.21, 1.37, 0.85)^T.$$

Consequently, according to this model the population grows approximately with the geometric sequence  $1.608^t$ .  $\square$

**3.F.13.** Consider the following Leslie model in which a farmer breeds sheep. The birth-rate of sheep depends only on their age and on average is 2 lambs per sheep between one and two years of age, 5 lambs per sheep between two and three years of age and 2 lambs per sheep between three and four years of age. Younger sheep do not deliver any lambs. Every year, half of the sheep die, uniformly distributed among all age groups. Every sheep older than four years is sent to the butchery. The farmer would like to sell (living) lambs younger than one year for their skin. What proportion of the lambs can be sold every year to ensure that the size of the herd remains the same? In what ratio will the sheep then be distributed among individual age categories?

**Solution.** The matrix of the model, without an action of the farmer, can be expressed as

$$L = \begin{pmatrix} 0 & 2 & 5 & 2 \\ \frac{1}{2} & 0 & 0 & 0 \\ 0 & \frac{1}{2} & 0 & 0 \\ 0 & 0 & \frac{1}{2} & 0 \end{pmatrix}.$$

The farmer can influence how many sheep younger than one year stay in his herd to the next year, that is, he can influence the element  $l_{12}$  of the matrix  $L$ . Thus finally we are dealing with the model encoded by the matrix

$$L = \begin{pmatrix} 0 & 2 & 5 & 2 \\ a & 0 & 0 & 0 \\ 0 & \frac{1}{2} & 0 & 0 \\ 0 & 0 & \frac{1}{2} & 0 \end{pmatrix}.$$

We are looking for this  $a$  such that the matrix has the eigenvalue 1 (we know that it has only one real positive eigenvalue). The characteristic polynomial of this matrix is  $\lambda^4 - 2a\lambda^2 - \frac{5}{2}\lambda - \frac{1}{2}$ . If we require 1 as a root of this polynomial, then we get the solution  $a = \frac{1}{5}$ . Thus, the farmer can sell  $\frac{1}{2} - \frac{1}{5} = \frac{3}{10}$  of lambs that are born that year. The corresponding eigenvector for the eigenvalue 1 of the given matrix is  $(20, 4, 2, 1)^T$ , and in these ratios the population stabilises.  $\square$

**3.F.14.** Consider the Leslie population growth model for the population of rats, divided into three groups according to age: younger than one year, between one year and two years, and between two years and three years. Assume that there exist no rats older than three years. The average birth-rate of one rat in individual age categories is the following: in the first group it is zero, in the second and in the third it is 2 rats. The mortality in the second group is zero, that is, the rats that survive their first year die after three years of life. Determine the mortality in the first group, if you know that the population stagnates (the total number of rats does not change).  $\circ$

**3.F.15. Model of evolution of a whale population.** For the evolution of a population (of whales), females are important. The important factor is not age but fertility. From this point of view, one can divide the females into newborns (juvenile), that is, females who are yet fertile; young fertile females; adult females with the highest fertility, and postclimacterial females who are no longer fertile, but are still important with respect to taking care of newborns and food gathering.

We model the evolution of such a population by time. For a time unit, we choose the time it takes to reach adulthood. A newborn female who survives this interval becomes fertile. The evolution of a young female to full fertility and to post-climacterial state depends mainly on the environment. That is, the transition to the next category is a random event. Analogously, the death of an individual is also a random event. Note that a young fertile female has less children per unit interval, than an adult female. Let us not try to formalise these statements.

Denote by  $x_1(t)$ ,  $x_2(t)$ ,  $x_3(t)$ ,  $x_4(t)$  the number of juvenile, young, adult and postclimacterial females in time  $t$  respectively. The amount can be expressed as a number of individuals, but also as a number of individuals relative per unit area (population density), or as a total biomass. Denote further by  $p_1$  the probability that a juvenile female survives the unit time interval and becomes fertile. Let also  $p_2$  and  $p_3$  be the respective probabilities that a young female becomes adult and that an adult female becomes old. Another random event is the death (positively formulated: survival) of females who do not move to the next category – we denote these probabilities respectively as  $q_2$ ,  $q_3$  and  $q_4$  for young, adult and old females. Of course, Each of the numbers  $p_1, p_2, p_3, q_2, q_3, q_4$  is a probability from the interval  $[0,1]$ .

Now, a young female can survive, reach adulthood or die. These events are mutually exclusive, together they form a sure certain event and cannot be excluded. Thus,  $p_2 + q_2 < 1$ . For similar reasons  $p_3 + q_3 < 1$ . Finally, we denote by  $f_2$  and  $f_3$  the average number of daughters of a young and adult female, respectively. These parameters satisfy  $0 < f_2 < f_3$ . The expected number of newborn females in the next time interval is the sum of the daughters of young and of the adult females, that is

$$x_1(t+1) = f_2x_2(t) + f_3x_3(t).$$

Let us temporarily denote by:

- $x_{2,1}(t+1)$  the number of young females in time  $t+1$ , who were juvenile in the previous time interval.
- $x_{2,2}(t+1)$  the number of young females, who were already fertile in time  $t$ , survived that time interval, but did not move into the adulthood.

The probability  $p_1$  that a juvenile female survives the interval can be expressed by classical probability, that is, by the ratio  $x_{2,1}(t+1)/x_1(t)$ . Similarly, the probability  $q_2$  can be expressed as the ratio  $x_{2,2}(t+1)/x_2(t)$  and we finally have the relation

$$x_2(t+1) = x_{2,1}(t+1) + x_{2,2}(t+1) = p_1x_1(t) + q_2x_2(t).$$

In the same way we deduce the expected number of fully fertile females:

$$x_3(t+1) = p_2x_2(t) + q_3x_3(t),$$

and finally the expected number of postclimacterical females is

$$x_4(t+1) = p_3x_3(t) + q_4x_4(t).$$

Set now

$$A := \begin{pmatrix} 0 & f_2 & f_3 & 0 \\ p_1 & q_2 & 0 & 0 \\ 0 & p_2 & q_3 & 0 \\ 0 & 0 & p_3 & q_4 \end{pmatrix} \quad \text{and} \quad x(t) := \begin{pmatrix} x_1(t) \\ x_2(t) \\ x_3(t) \\ x_4(t) \end{pmatrix}.$$

Then, we may rewrite the previous recurrent formulas in matrix form as  $x(t+1) = Ax(t)$ . Using this matrix difference equation it is possible to compute the expected number of females in individual categories, assuming that the distribution of the population at some initial time is known. Let us focus for example on the population of orca whales, where we may assume the following parameters:

$$\begin{aligned} p_1 &= 0.9775, & q_2 &= 0.9111, & f_2 &= 0.0043, \\ p_2 &= 0.0736, & q_3 &= 0.9534, & f_3 &= 0.1132. \\ p_3 &= 0.0452, & q_4 &= 0.9804, \end{aligned}$$

In this case the time interval is one year. If we start at the time  $t=0$  with a unit measure of young females in some unoccupied area, that is, with the vector  $x(0) = (0, 1, 0, 0)^T$ , then with the help of Sage one easily computes

$$x(1) = \begin{pmatrix} 0 & 0.0043 & 0.1132 & 0 \\ 0.9775 & 0.9111 & 0 & 0 \\ 0 & 0.0736 & 0.9534 & 0 \\ 0 & 0 & 0.0452 & 0.9804 \end{pmatrix} \begin{pmatrix} 0 \\ 1 \\ 0 \\ 0 \end{pmatrix} = \begin{pmatrix} 0.0043 \\ 0.9111 \\ 0.0736 \\ 0 \end{pmatrix},$$

and

$$x(2) = \begin{pmatrix} 0 & 0.0043 & 0.1132 & 0 \\ 0.9775 & 0.9111 & 0 & 0 \\ 0 & 0.0736 & 0.9534 & 0 \\ 0 & 0 & 0.0452 & 0.9804 \end{pmatrix} \begin{pmatrix} 0.0043 \\ 0.9111 \\ 0.0736 \\ 0 \end{pmatrix} = \begin{pmatrix} 0.01224925 \\ 0.83430646 \\ 0.13722720 \\ 0.00332672 \end{pmatrix}.$$

The reader may try a computation and graphical depiction of the results for a different initial distribution of the population. The result should be an observation that the total population grows exponentially, but the ratios of the sizes of individual groups stabilise on constant values. In fact, the matrix  $A$  has the following eigenvalues

$$\lambda_1 = 1.025441326, \lambda_2 = 0.980400000, \lambda_3 = 0.834222976, \lambda_4 = 0.004835698.$$

The eigenvector associated with  $\lambda_1$  is given by  $w = (0.03697187, 0.31607121, 0.32290968, 0.32404724)^T$ , and this vector is normalized such that the sum of its components equals to the unit.

 We will now explore a variety of further exercises related to discrete Markov chains. For the reader's convenience, we have included some classic problems that lend themselves to a Markov process interpretation, such as the "ruin of a player" (see 3.F.21), the "algorithm for determining the importance of web pages" (see 3.F.20), and other. We begin with an enjoyable problem.

**3.F.16. Students into three groups.** Suppose that we can divide students into three groups, as follows: Those that are present at a lecture and pay attention, those that are present but pay no attention, and those who are in a pub instead. Now observe, lecture after lecture, how the numbers in the individual groups change.

The first step is to observe what are the probabilities that a student changes his state. Suppose that this goes as follows. For a student who pays attention: with probability 50% stays in the same state, with 40% stops paying attention and with 10% moves to the pub. For a student who pays no attention: starts paying attention with 10%, with 50% stays in the same state and with 40% moves to the pub. Finally, for a student who is in the pub we assume that there is zero probability of

returning to the lectures. How does the model evolve in time? How does the situation change if we assume at least ten percent probability that a student returns from the pub to the lecture (but is not going to pay any attention)?

**Solution.** This is obviously a (homogeneous) discrete Markov process. Its transition matrix  $T$  has the form

$$T = \begin{pmatrix} 0.5 & 0.1 & 0 \\ 0.4 & 0.5 & 0 \\ 0.1 & 0.4 & 1 \end{pmatrix},$$

where the first column is about the students paying attention, the second one about those no paying attention and the third one for those in the pub. We will prove that all the students end up in the pub. Indeed, by Sage we see that  $T$  has the following three eigenvalues:  $\lambda_1 = 1$  and the rest two are given by 0.3 and 0.4. We also see that the eigenvector associated to  $\lambda_1$  is a multiple of  $(0, 0, 1)^T$ . This vector describes the distribution of students into the three groups with the passing of time and this proves our claim (of course, such a result is clear even without any computation, as the probability of returning from the pub is zero, all students end up in the pub).

For the second task, we will show that adding 10 percent possibility for leaving the pub, will only slightly change the situation. The corresponding transition matrix is given by

$$T = \begin{pmatrix} 0.5 & 0.1 & 0 \\ 0.4 & 0.5 & 0.1 \\ 0.1 & 0.4 & 0.9 \end{pmatrix}.$$

We see by Sage (or by Mathematica), that  $\lambda_1 = 1$  is an eigenvalue of  $T$ , with corresponding eigenvector given by  $(1, 5, 21)^T$ . This means that the distribution of the students in the individual groups is encoded by the multiple of this vector such that the coordinates sum to one, that is, the vector  $(\frac{1}{27}, \frac{5}{27}, \frac{21}{27})$ . Therefore again most of the students end up in the pub.  $\square$

**3.F.17. Daily running.** Jonas goes running every evening. He has three tracks – short, middle and long. Whenever he chooses a short track, the next day he feels bad about it and chooses with equal probabilities between long and medium. Whenever he chooses a long track, the next day he chooses arbitrarily among all three. Whenever he chooses the medium track, the next he feels good about it, and again chooses with equal probabilities between medium and long. Joans claims that he has been running in this mode for a very long period. How often does he choose the short track and how often the long track? What is the probability that Jonas follows a long track, under the assumption that he did the same a week ago?

**Solution.** Clearly this task forms a (homogeneous) discrete Markov process with a three-dimensional state space:  $S = \{\text{short track, medium track, long track}\}$  (that silently one can encode as  $\{1, 2, 3\}$ ). This order of the states gives the following transition matrix

$$T = \begin{pmatrix} 0 & 0 & 1/3 \\ 1/2 & 1/2 & 1/3 \\ 1/2 & 1/2 & 1/3 \end{pmatrix}.$$

Let explain the computation for the second column, which corresponds to the choice of the medium track during the previous day. This means that with the probability  $1/2$ , a medium track will be chosen (the second row), and with probability  $1/2$  a long track will be chosen (the third row). Hence  $T$  follows. Now, we see that

$$T^2 = \begin{pmatrix} 1/6 & 1/6 & 1/9 \\ 5/12 & 5/12 & 4/9 \\ 5/12 & 5/12 & 4/9 \end{pmatrix}.$$

Therefore, we can use the corollary of the Perron-Frobenius theorem for Markov chains, see 3.3.4. The eigenvector corresponding to the eigenvalue 1 is the stochastic vector  $(\frac{1}{7}, \frac{3}{7}, \frac{3}{7})^T$ , where recall that the numbers  $1/7, 3/7, 3/7$  are respectively the probabilities that in a randomly chosen day, Joans choose a short, medium or long track. Suppose now that on a certain day (that is, in time  $n \in \mathbb{N}$ ), Jonas follows a long track. This corresponds to the probabilistic vector  $x^{(n)} = (0, 0, 1)^T$ . As we know, for the following day we will have

$$x^{(n+1)} = \begin{pmatrix} 0 & 0 & 1/3 \\ 1/2 & 1/2 & 1/3 \\ 1/2 & 1/2 & 1/3 \end{pmatrix} \cdot \begin{pmatrix} 0 \\ 0 \\ 1 \end{pmatrix} = \begin{pmatrix} 1/3 \\ 1/3 \\ 1/3 \end{pmatrix}.$$

In particular, after seven days

$$x^{(n+7)} = T^7 \cdot \begin{pmatrix} 0 \\ 0 \\ 1 \end{pmatrix} = T^6 \cdot \begin{pmatrix} 1/3 \\ 1/3 \\ 1/3 \end{pmatrix}.$$

Let us present this computation in Sage:

```
T=matrix(QQbar, [[0, 0, 1/3], [1/2, 1/2, 1/3], [1/2, 1/2, 1/3]])
x=vector(QQbar, [1/3, 1/3, 1/3]); T^6*x
```

Sage prints out  $(4999/34992, 29993/69984, 29993/69984)$  and hence we deduce that

$$x^{(n+7)} \approx (4999/34992 \approx 0.142861, 29993/69984 \approx 0.428569, 29993/69984 \approx 0.428569)^T.$$

Consequently, the probability that Jonas follows a long track under the assumption that he did the same a week ago, is  $0.428569 \approx 3/7$ .  $\square$

**3.F.18. Car rental.** A car rental company has two branches – one in Prague and one in Brno. A car rented in Brno can be returned in Prague and vice versa. After operating for some time, the company has observed that roughly 80% of the cars rented in Prague and 90% of the cars rented in Brno, are finally returned in Prague. However, the strategy of the company says that in both branches, in the start of every week should exist the same number of the cars, as in the week before. How the cars should be then distributed?

**Solution.** Let us denote by  $x_B$  and  $x_P$ , the initial number of cars in Brno and in Prague, respectively. Then  $x = (x_B, x_P)^T$  is the vector describing car's distribution between the two branches. Now, according to the statement the matrix describing the (linear) system of car rental is given by

$$A = \begin{pmatrix} 0.1 & 0.2 \\ 0.9 & 0.8 \end{pmatrix}.$$

The state at the end of the week is given by  $Ax$ . However, at the end of the week in the branches the same number of cars should exist as at the beginning. This means that  $x$  must satisfy  $Ax = x$ , and so it must be an eigenvector of the matrix  $A$  associated with the eigenvalue  $\lambda_1 = 1$ . We can save time on computations by using Sage as follows:

```
A = matrix(QQ, [[0.1, 0.2], [0.9, 0.8]])
print(A.eigenvalues())
show(A.eigenvectors_right())
```

Sage's output for the eigenvector has the form

$$\left[ \left( 1, \left[ \left( 1, \frac{9}{2} \right) \right], 1 \right), \left( -\frac{1}{10}, [(1, -1)], 1 \right) \right],$$

and we deduce that the eigenvector corresponding to  $\lambda_1$  is given by  $(1, 9/2)^T$ . This implies that  $x = (1, 9/2)^T$ .

Now, the percentage distribution of the cars is given by the normalized vector associated to  $x$  and this is the vector whose entries sum to 1. This vector is given by

$$\frac{2}{11} \begin{pmatrix} 1 \\ 9/2 \end{pmatrix} = \begin{pmatrix} 0.181818 \\ 0.818182 \end{pmatrix}.$$

Therefore, the optimal distribution of cars would have approximately 18% stationed in Brno and 82% in Prague.  $\square$

**3.F.19.** Suppose that two students A and B spend every Monday morning playing a certain computer game. The person who wins pays for both of them in the evening in the restaurant. The game can also be a draw – then each pays for half the meal. The result of the previous game partially determines the next game. If a week ago student A has won, then with the probability  $3/4$  wins again and with probability  $1/4$  it is a draw. A draw is repeated with probability  $2/3$ . With probability  $1/3$  the next game is won by B. Moreover, if student B won a game, then with probability  $1/2$  he/she wins again and with probability  $1/4$ , student A wins the next game. Determine the probability that today each of them pays half of the costs, if the first game played long time ago and was won by A.

**Solution.** This is a Markov process with the following three states: "student A wins", "the game ends with a draw", "student B wins". Labelling these states in this order as  $\{1, 2, 3\}$  we arrive to the following transition matrix of the process:

$$T = \begin{pmatrix} 3/4 & 0 & 1/4 \\ 1/4 & 2/3 & 1/4 \\ 0 & 1/3 & 1/2 \end{pmatrix}.$$

We want to find the probability of the transition from the first state to the second after a large number  $n \in \mathbb{N}$  of steps (weeks). Observe that the matrix  $T$  is primitive, because

$$T^2 = \begin{pmatrix} 9/16 & 1/12 & 5/16 \\ 17/48 & 19/36 & 17/48 \\ 1/12 & 7/18 & 1/3 \end{pmatrix}.$$

Thus, it suffices to find the probabilistic eigenvector  $x_\infty$  of the matrix  $T$  associated with the eigenvalue  $\lambda_1 = 1$ . As before, giving the following block in Sage we compute the eigenvalues and eigenvectors corresponding to  $T$ :

```
T = matrix(QQbar, [[3/4, 0, 1/4], [1/4, 2/3, 1/4], [0, 1/3, 1/2]])
T.eigenvalues()
T.eigenvectors_right()
```

We deduce that the eigenvector associated to the eigenvalue  $\lambda_1 = 1$  is the vector  $(1, 3/2, 1)^T$  which we may normalize as  $x_\infty = (\frac{2}{7}, \frac{3}{7}, \frac{2}{7})^T$ . Recall now that  $x_\infty$  differs only very slightly from the probabilistic vector for large  $n$  and in particular it does not depend on the initial state. Indeed, for large  $n \in \mathbb{N}$  we compute

$$T^n \approx \begin{pmatrix} 2/7 & 2/7 & 2/7 \\ 3/7 & 3/7 & 3/7 \\ 2/7 & 2/7 & 2/7 \end{pmatrix}.$$

The desired probability is the element of this matrix on the second position in the first column (the second component of the vector  $x_\infty$ ). Hence the answer is  $3/7$ .  $\square$

**3.F.20. Algorithm for determining the importance of pages.** Internet browsers can find (almost) all pages containing a given word or phrase on the Internet. But how can a user sort the pages such that a list is sorted according to the relevance of the given pages? One of the possibilities is the following algorithm: the collection of all found pages is considered to be a system, and each of the found pages is one of its states. We describe a random walk on these pages as a Markov process.

The transition probabilities between web pages are determined by hyperlinks: each link from page A to page B establishes the probability of moving from A to B as

$$\frac{1}{\text{total number of links from page A}}.$$

If a page has no outgoing links, it is treated as a page that links to every other page. This creates a probability matrix  $M = (m_{ij})$ , where each entry  $m_{ij}$  represents the probability of moving from the  $i$ th page to the  $j$ th page.

Assume that a user randomly clicks on links, and chooses a random page when encountering a linkless page. In this case, the probability of being on the  $i$ th page at a sufficiently large time from the beginning, is given by the  $i$ th component of the unit eigenvector of the matrix  $M$ , corresponding to the unit eigenvalue. The importance of individual pages is then determined by the magnitudes of these probabilities.

This algorithm can be modified by assuming that the user eventually stops clicking on links after some time and starts again from a random page. Suppose that the user chooses a new page randomly with probability  $d$ , and with probability  $1 - d$ , continues clicking on links. In this scenario, the probability  $m_{ij}$  of transitioning from the page  $S_i$  to page  $S_j$  is given by

$$m_{ij} = \begin{cases} \frac{d}{n} + \frac{(1-d)}{\text{total number of links at the page } S_i}, & \text{if from } S_i \text{ there is a link to } S_j, \\ \frac{d}{n}, & \text{otherwise.} \end{cases}$$

Note that  $m_{ij} \neq 0$ . Now, According to the Perron-Frobenius theorem, the eigenvalue 1 is with multiplicity one and dominant, and thus the corresponding eigenvector is unique. For an illustration, consider pages A, B, C and D. The links lead from A to B and to C, from B to C and from C to A, and finally from D nowhere. Suppose that the probability that the user chooses a random new page is  $1/5$ . Then the matrix  $M$  looks as follows:

$$M = \begin{pmatrix} 1/20 & 1/20 & 17/20 & 1/4 \\ 9/20 & 1/20 & 1/20 & 1/4 \\ 9/20 & 17/20 & 1/20 & 1/4 \\ 1/20 & 1/20 & 1/20 & 1/4 \end{pmatrix}.$$

We find that the eigenvector corresponding to the eigenvalue 1 is the vector  $u = (305/53, 175/53, 315/53, 1)^T \in \mathbb{R}^4$ . Hence, the importance of the pages is given according to the order of the sizes of the corresponding components, that is,  $C > A > B > D$ .

**3.F.21. Ruining of a player.** Two players, A and B, gamble for money repeatedly in a certain game, which can result only in a victory for one of the players. The winning probability for player A in each individual game is  $p \in [0, 1/2)$ . Both players bet always the amount of 1€. Consequently, after each game player B gives 1€ to player A with probability  $p$ , and player A gives 1€ to player B with probability  $1 - p$ . Suppose that in the start of the game that A has € $x$ , B has € $y$  and that they play, as long as they both have some money. Determine the probability that the player A will lose all of his/her money.

**Solution.** This is the so-called *ruining of a player*. It is a special Markov chain (see also the exercise Sweet-toothed gambler) with many important applications. The probability in question is given by

$$\frac{1 - \left(\frac{p}{1-p}\right)^y}{1 - \left(\frac{p}{1-p}\right)^{x+y}}.$$

We can now investigate what this value is for specific choices of  $p, x, y$ . We give an example. Suppose that the player B wants the probability that the player A will lose the amount of 1 000 000€ to be at least 0.999. Assume for instance that  $p$  is given by  $p = 0.495$ . Then, for the player B we see that is sufficient to have the amount of 346€. If  $p = 0.499$ , this amount increases to 1727€. Therefore, it is possible in big casinos that “passionate” players play almost fair games.  $\square$

**3.F.22.** In a certain game you can choose one of two opponents. The probability that you beat the better one is  $1/4$ , while the probability that you beat the worse one is  $1/2$ . But the opponents cannot be distinguished, thus you do not know which one is the better one. You await a large number of games. For each of them you can choose a different opponent. Consider the following two strategies:

1. For the first game choose the opponent randomly. If you win a game, carry on with the same opponent; if you lose a game, change the opponent.
2. For the first two games, choose an opponent randomly. Then for the next two games, if you lost both the previous games, change the opponent, otherwise stay with the same opponent.

Which of the two strategies is better?

**Solution.** Both strategies define a Markov chain. For simplicity denote the worse opponent by A and the better opponent by B. In the first case the state space has two states: “game with A” and “game with B”. In this order, we obtain the probabilistic transition matrix

$$\begin{pmatrix} 1/2 & 3/4 \\ 1/2 & 1/4 \end{pmatrix}.$$

This matrix has all of its elements positive. Thus it suffices to find the probabilistic vector  $x_\infty$ , which is associated with the eigenvalue 1. We compute  $x_\infty = \left(\frac{3}{5}, \frac{2}{5}\right)^T$ . Its components correspond to the probabilities that after a long sequence of games the opponent is A, or B. Therefore, we can expect that 60 % of the games will be played against the worse of the two opponents. Because  $0.4 = \frac{2}{5} = \frac{3}{5} \cdot \frac{1}{2} + \frac{2}{5} \cdot \frac{1}{4}$ , there will be roughly 40 % against the better of the two opponents.

For the second strategy, use the states “two games in a row with A”, and “two games in a row with B”, which lead to the probabilistic transition matrix

$$\begin{pmatrix} 3/4 & 9/16 \\ 1/4 & 7/16 \end{pmatrix}.$$

In this case we compute  $x_\infty = \left(\frac{9}{13}, \frac{4}{13}\right)^T$ . Against the worse opponent one would then play (9/4)-times more frequently than against the better one. Recall that for the first strategy it is (3/2)-times more frequently, which means that second strategy is better. Note also that for the second strategy, roughly 42, 3 % of the games are winning ones, as we can see from the relation

$$0.423 \approx \frac{11}{26} = \frac{9}{13} \cdot \frac{1}{2} + \frac{4}{13} \cdot \frac{1}{4}. \quad \square$$

**3.F.23.** In a certain country there are two television channels. From a public survey it follows that in one year  $1/6$  of the viewers of the first channel move to the second one, while  $1/5$  viewers of the second channel move to the first one. Determine the time evolution of the number of viewers watching the channels, using Markov processes. Write down a matrix of the process, and find its eigenvalues and eigenvectors.  $\circ$

**3.F.24. Daily casino routine.** A female roulette player has the following strategy: she comes at a casino to play with €10. She always bets everything she has, and she always bets on black (there are 37 numbers in the roulette, 18 black, 18 red and zero). The player ends whenever she has either nothing, or when she wins €80. Consider this problem as a Markov process and write down its transition matrix.

**Solution.** In the course of the game and at its end, the player can have only one of the following amounts of money (in €): 0, 10, 20, 40, 80. If we view the situation as a Markov process, then these amounts corresponds to the states of the process, and we construct the following transition matrix

$$A = \begin{pmatrix} 1 & a & a & a & 0 \\ 0 & 0 & 0 & 0 & 0 \\ 0 & b & 0 & 0 & 0 \\ 0 & 0 & b & 0 & 0 \\ 0 & 0 & 0 & b & 1 \end{pmatrix},$$

with  $a = \frac{19}{37}$  and  $b = \frac{18}{37}$ , respectively.

Note that the matrix is probabilistic and singular, while the eigenvalue  $\lambda_1 = 1$  has multiplicity two (and this is the unique non-zero eigenvalue of  $A$ ), as we see from the following block in Sage:

```
a = var('a'); b = var('b')
assume(a, 'real'); assume(b, 'real')
A = matrix(SR, 5, 5, [[1, a, a, a, 0], [0, 0, 0, 0, 0], [0, b, 0, 0, 0],
[0, 0, b, 0, 0], [0, 0, 0, b, 1]])
A.eigenvalues()
```

Executing this block we obtain the list  $[0, 0, 0, 1, 1]$ . Observe that the game does *not* converge to a single vector  $x_\infty$ , but ends in one of the eigenvectors associated with the eigenvalue  $\lambda_1$ , that is, either  $(1, 0, 0, 0, 0)^T$  (the player loses it all), or  $(0, 0, 0, 0, 1)^T$  (the player wins €80). We verify this as follows (after introducing the matrix  $A$  as above)

```
A.eigenvectors_right()
```

In this case Sage output has the form

```
[(0, [(1, 0, 0, -1/a, b/a)], 3), (1, [(1, 0, 0, 0, 0), (0, 0, 0, 0, 1)], 2)]
```

Furthermore, using Sage we can easily check that the game ends after three bets, that is, the sequence  $\{A^n\}_{n=1}^\infty$ , is constant for  $n \geq 3$ . For instance, you may type

```
A^3 == A^4
A^3 == A^5
```

and for both cases Sage prints out True (and similarly for any other power  $A^n$  with  $n \geq 3$ ). Moreover, we see that  $A^3$  is given by

```
[ 1 (a*b + a)*b + a      a*b + a      a      0]
[ 0      0      0      0      0]
[ 0      0      0      0      0]
[ 0      0      0      0      0]
[ 0      0      b^3      b^2      b      1]
```

which means that

$$A^\infty := A^3 = A^n = \begin{pmatrix} 1 & a + ab + ab^2 & a + ab & a & 0 \\ 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 \\ 0 & b^3 & b^2 & b & 1 \end{pmatrix}.$$

We deduce that the game ends with the probability  $a + ab + ab^2 \doteq 0.885$  as a loss, and with the probability roughly 0.115 as a win of €80. This conclusion occurs by multiplying the matrix  $A^\infty$  with the initial vector  $(0, 1, 0, 0, 0)^T$ . This gives the vector  $(a + ab + ab^2, 0, 0, 0, b^3)^T$ . Notice that whether the player was female or male, makes no difference to the result.  $\square$

**3.F.25.** Consider the situation from the previous case and assume that the probability of both win and loss is  $1/2$ . Denote by  $A$  the matrix of the process. Without using any computational software determine  $A^{100}$ .  $\circ$

**3.F.26. Reliable products.** A production line is not reliable: individual products differ in quality in a significant way. A certain worker tries to improve the quality of the products and intervenes to the process. The products are distributed into classes I, II, and III, according to their quality, and a report found out the following:

- After a product of class I, the next product has the same quality in 80% of the cases and is of quality II in 10% of the cases.
  - After a product of class II, the next product is of class II in 60% of the cases and is of quality I in 20% of the cases.
  - After a product of class III, the next product is of quality III in 50% of the cases. while in 25% of the cases it is of class II.
- Compute the probability that the 18th product has quality of class I, given that the 16th product is of quality III.

**Solution.** There are at least two ways to provide an answer. First we solve the problem without using a Markov chain. Since the 16th product has quality of class III, the event in question is satisfied by the cases

- The 17th product has quality of class I and the 18th product has quality of class I,
- The 17th product has quality of class II and the 18th product has quality of class I,
- The 17th product has quality of class III and the 18th product has quality of class I,

with probabilities respectively

$$0.25 \cdot 0.8 = 0.2, \quad 0.25 \cdot 0.2 = 0.05, \quad 0.5 \cdot 0.25 = 0.125.$$

Thus the solution is  $0.375 = 0.2 + 0.05 + 0.125$ .

Let us now view the problem as a discrete Markov process. From the statement it follows that the transition matrix has the form

$$T = \begin{pmatrix} 0.8 & 0.2 & 0.25 \\ 0.1 & 0.6 & 0.25 \\ 0.1 & 0.2 & 0.5 \end{pmatrix}.$$

The situation that the product is in class III is given by the probabilistic vector  $(0.0.1)^T$ . For the next product we obtain the probabilistic vector

$$\begin{pmatrix} 0.25 \\ 0.25 \\ 0.5 \end{pmatrix} = \begin{pmatrix} 0.8 & 0.2 & 0.25 \\ 0.1 & 0.6 & 0.25 \\ 0.1 & 0.2 & 0.5 \end{pmatrix} \begin{pmatrix} 0 \\ 0 \\ 1 \end{pmatrix}.$$

Finally, for the next product in order, we compute the vector

$$\begin{pmatrix} 0.375 \\ 0.3 \\ 0.325 \end{pmatrix} = \begin{pmatrix} 0.8 & 0.2 & 0.25 \\ 0.1 & 0.6 & 0.25 \\ 0.1 & 0.2 & 0.5 \end{pmatrix} \begin{pmatrix} 0.25 \\ 0.25 \\ 0.5 \end{pmatrix},$$

and the first component is the desired probability.

Observe that the first method (without using the Markov process) led to the result faster and easier. But notice also how unclear it would become if we wanted to compute, say, the 22nd or 30th product. For the second method one can in a sense restrict the computations to the relevant parts of the matrices only, instead of mindlessly multiplying the whole matrix. When using the Markov process, we have also directly obtained the probabilities that the 18th product belongs to the class II and III.  $\square$

**3.F.27.** Suppose that there are two boxes, which together contain  $n$  white and  $n$  black balls. Each box can contain up to  $n$  balls. At regular time intervals, a ball is taken from each box and moved to the other box. For this Markov process, find its probabilistic transition matrix  $T$ .

**Solution.** This problem is often used in physics as a model for blending two incompressible liquids (already introduced by D. Bernoulli during 1769), or analogously, as a model of diffusion of gases.

Let the states  $0, 1, \dots, n$  correspond to the number of white balls in the first box. This information already says how many black balls are in the first box (the remaining balls are then in the second box). If, for a certain step, the state changes from  $j \in \{1, \dots, n\}$  to  $j - 1$ , then from the first box a white ball was drawn and from the second a black ball was drawn. This happens with probability

$$\frac{j}{n} \cdot \frac{j}{n} = \frac{j^2}{n^2}.$$

The transition from state  $j \in \{0, \dots, n - 1\}$  to the state  $j + 1$  corresponds to drawing the black ball from the first box, and a white ball from the second box, with probability

$$\frac{n - j}{n} \cdot \frac{n - j}{n} = \frac{(n - j)^2}{n^2}.$$

The system stays in state  $j \in \{1, \dots, n - 1\}$ , if from both boxes balls of the same colour are drawn, which has the same probability, namely

$$\frac{j}{n} \cdot \frac{n - j}{n} + \frac{n - j}{n} \cdot \frac{j}{n} = \frac{2j(n - j)}{n^2}.$$

Notice that from the state 0 it is necessary (with probability 1) to go to the state 1 and similarly from the state  $n$  with probability one to the state  $n - 1$ . In summary, for the order of the states  $0, 1, \dots, n$ , we obtain the following  $n \times n$  transition matrix:

$$T = \begin{pmatrix} 0 & 1 & 0 & \cdots & 0 & 0 & 0 \\ n^2 & 2 \cdot 1(n - 1) & 2^2 & \ddots & 0 & 0 & 0 \\ 0 & (n - 1)^2 & 2 \cdot 2(n - 2) & \ddots & 0 & 0 & 0 \\ \vdots & \ddots & \ddots & \ddots & \ddots & \ddots & \vdots \\ 0 & 0 & 0 & \ddots & 2 \cdot (n - 2) & (n - 1)^2 & 0 \\ 0 & 0 & 0 & \ddots & 2^2 & 2 \cdot (n - 1) & n^2 \\ 0 & 0 & 0 & \cdots & 0 & 1 & 0 \end{pmatrix}.$$

In physics we are of course interested in the distribution of balls in boxes, after a certain time (the number of drawings). If the initial state is for instance 0, we can use this model and the powers of the matrix  $T$  to observe with what probability the number of white balls in the first box is increasing. We can confirm the expected result that the initial distribution of the balls influences their distribution, after a certain time in a very negligible way.  $\square$

D) MATERIAL ON LINEAR ALGEBRA – UNITARY SPACES, ORTHOGONALITY, JORDAN FORMS

**3.F.28. The Cauchy–Schwarz inequality.** Let  $(V, \langle \cdot, \cdot \rangle)$  be a unitary space over  $\mathbb{R}$ . Describe an alternative proof of the Cauchy inequality, in comparison with the one presented in 3.4.3.

**Solution.** We should prove the inequality  $|\langle x, y \rangle| \leq \|x\| \|y\|$ , for any two vectors  $x, y \in V$ . We may assume that  $y \neq 0$  since otherwise the statement is trivial. For some scalar  $t \in \mathbb{R}$  define the function  $\zeta(t) = \|ty - x\|^2 = \langle ty - x, ty - x \rangle$ . Then we get

$$\zeta(t) = t^2 \|y\|^2 - 2t \langle y, x \rangle + \|x\|^2.$$

Since  $(V, \langle \cdot, \cdot \rangle)$  is a real unitary space we have  $\langle y, x \rangle = \langle x, y \rangle$ , and hence  $\zeta(t) = t^2 \|y\|^2 - 2t \langle x, y \rangle + \|x\|^2$ . When  $y \neq 0$ , by setting  $a = \|y\|^2$ ,  $b = 2\langle y, x \rangle$  and  $c = \|x\|^2$  we result to a second order polynomial given by  $\zeta(t) = at^2 - bt + c$ . However,  $\|\cdot\|$  is a norm and thus  $\|ty - x\|^2 \geq 0$ , that is,  $\zeta(t) \geq 0$ . Therefore the discriminant of  $\zeta(t)$  must be non-positive:  $\Delta = b^2 - 4ac \leq 0$ , which is equivalent to  $4ac \geq b^2$ . This means  $4\|y\|^2 \|x\|^2 \geq 4\langle y, x \rangle^2$  or equivalently  $\|y\| \|x\| \geq |\langle x, y \rangle|$  and the proof is complete.  $\square$

*The next problem is about the so-called polarization identities on a unitary space. According to these formulas one can recover the inner product from the norm. The polarization identities can be used in many situations, see for example 3.F.32. (and see also Chapter 4 for a description in terms of quadratic forms).*

**3.F.29. Polarization identities.** Let  $(V, \langle \cdot, \cdot \rangle)$  be a unitary space.

(i) If  $V$  is defined over  $\mathbb{R}$  and so  $(V, \langle \cdot, \cdot \rangle)$  is a real unitary space, prove that

$$4\langle u, v \rangle = \|u + v\|^2 - \|u - v\|^2, \quad u, v \in V.$$

(ii) If  $V$  is defined over  $\mathbb{C}$  and so  $(V, \langle \cdot, \cdot \rangle)$  is a complex unitary space, prove that

$$4\langle u, v \rangle = \|u + v\|^2 - \|u - v\|^2 + i\|u + iv\|^2 - i\|u - iv\|^2, \quad u, v \in V.$$

**Solution.** (i) By assumption,  $(V, \langle \cdot, \cdot \rangle)$  is a real inner product space, hence  $\langle u, v \rangle = \langle v, u \rangle$  and by bilinearity we get

$$\|u + v\|^2 - \|u - v\|^2 = \langle u + v, u + v \rangle - \langle u - v, u - v \rangle = \|u\|^2 + 2\langle u, v \rangle + \|v\|^2 - (\|u\|^2 - 2\langle u, v \rangle + \|v\|^2) = 4\langle u, v \rangle.$$

(ii) In this case  $(V, \langle \cdot, \cdot \rangle)$  is a complex inner product space and thus  $\langle u, v \rangle \neq \langle v, u \rangle$ . We compute

$$\begin{aligned} \|u + v\|^2 &= \langle u + v, u + v \rangle = \|u\|^2 + \langle u, v \rangle + \langle v, u \rangle + \|v\|^2, \\ -\|u - v\|^2 &= -\langle u - v, u - v \rangle = -\|u\|^2 + \langle u, v \rangle + \langle v, u \rangle - \|v\|^2, \\ i\|u + iv\|^2 &= i\langle u + iv, u + iv \rangle = i\|u\|^2 + i\langle u, iv \rangle + i\langle iv, u \rangle + i\langle iv, iv \rangle = i\|u\|^2 + i\bar{i}\langle u, v \rangle + i^2\langle v, u \rangle + i^2\bar{i}\|v\|^2 \\ &= i\|u\|^2 + \langle u, v \rangle - \langle v, u \rangle + i\|v\|^2, \\ -i\|u - iv\|^2 &= -i\langle u - iv, u - iv \rangle = -i\|u\|^2 + \langle u, v \rangle - \langle v, u \rangle - i\|v\|^2. \end{aligned}$$

Hence adding these relations we arrive to the desired identity:  $4\langle u, v \rangle = \|u + v\|^2 - \|u - v\|^2 + i\|u + iv\|^2 - i\|u - iv\|^2$ .  $\square$

*Beyond the theory of unitary spaces the notion of norm appears in many other areas of mathematics. For instance, we couldn't imagine the so-called theory of normed vector spaces without a norm. This is a topic that we will analyze in Chapter 7, but since we are already familiar with scalar products we can present a few exercises on norms induced by scalar products. In this point an important remark is that not all the norms are of this type, see the Problem 3.F.30 which establishes a very first link with the material that we are going to treat in Chapter 7.*

**3.F.30. Parallelogram law.** Prove that the following relation makes sense on any unitary vector space  $(V, \langle \cdot, \cdot \rangle)$ :

$$\|u + v\|^2 + \|u - v\|^2 = 2(\|u\|^2 + \|v\|^2), \quad (\dagger)$$

for any  $u, v \in V$ , where  $\|\cdot\|$  denotes the induced norm by  $\langle \cdot, \cdot \rangle$ . Then, show with an example that there are norms which are not induced by an inner product.

**Solution.** Many students in a high-school can solve the first task, at least for the real vector space  $\mathbb{R}^n$ . It occurs by the properties of a scalar product and the details of the proof are left to the reader. The second task is a bit more demanding. Consider for example  $\mathbb{R}^2$  and set

$$\|(x_1, x_2)\|_\infty := \max\{|x_1|, |x_2|\}$$

for any  $x = (x_1, x_2)^T \in \mathbb{R}^2$ . We can easily show that this is a norm since it satisfies the characteristic properties of a norm. For example the triangle inequality occurs as follows:

$$\|x + y\|_\infty = \max\{|x_1| + |y_1|, |x_2| + |y_2|\} \leq \max\{|x_1|, |x_2|\} + \max\{|y_1|, |y_2|\} = \|x\|_\infty + \|y\|_\infty.$$

However, this norm is not induced by an inner product on  $\mathbb{R}^2$ , since it does not satisfy the relation  $(\dagger)$  posed above. To understand this, consider for example the vectors  $x = (1, 0)^T$  and  $y = (0, 1/2)^T$ . Then we compute  $\|x + y\|_\infty^2 + \|x - y\|_\infty^2 = 2$  but  $2(\|x\|_\infty^2 + \|y\|_\infty^2) = 5/2$ .  $\square$

**3.F.31.** Let  $F : \text{Mat}_2(\mathbb{R}) \rightarrow \mathbb{R}_2[x]$  the mapping defined by

$$F \left( \begin{pmatrix} a & b \\ c & d \end{pmatrix} \right) = (a + d) + (a + b)x + 2(c + d)x^2, \quad a, b, c, d \in \mathbb{R}.$$

After verifying that  $F$  is linear, find the dimension of the null space  $\ker(F) \subset \text{Mat}_2(\mathbb{R})$  of  $F$ . Next provide an orthonormal basis of  $\ker(F)$ , with respect to the Frobenius scalar product  $\mathcal{B}(A, B) = \text{tr}(B^T A)$  on  $\text{Mat}_2(\mathbb{R})$ .  $\circ$

**3.F.32. Linear isometries.** Let  $(V, \langle \cdot, \cdot \rangle_V)$  and  $(W, \langle \cdot, \cdot \rangle_W)$  be two (finite-dimensional) unitary spaces. For a linear mapping  $\psi : V \rightarrow W$  prove the following:

(a)  $\psi$  is a linear isometry if and only if  $\|u\|_V = \|\psi(u)\|_W$  for any  $u \in V$ , i.e.,  $\psi$  is distance preserving.

(b)  $\psi$  is a linear isometry if and only if  $\psi^* \psi = I_V$ , where  $I_V$  is the identity map on  $V$ .

**Solution.** (a) Let  $u \in V$  and assume that  $\psi$  is an isometry. This means that  $\langle u, v \rangle_V = \langle \psi(u), \psi(v) \rangle_W$  for any  $u, v \in V$  and we see that  $\|\psi(u)\|_W^2 = \langle \psi(u), \psi(u) \rangle_W = \langle u, u \rangle_V = \|u\|_V^2$ , and hence  $\|\psi(u)\|_W = \|u\|_V$  for any  $u \in V$ . Conversely, assume that  $\|u\|_V = \|\psi(u)\|_W$  for any  $u \in V$ . Then, recall by 3.F.29 that the scalar product is defined by the norm via the formula

$$4\langle u, v \rangle_V = \|u + v\|_V^2 - \|u - v\|_V^2 + i\|u + iv\|_V^2 - i\|u - iv\|_V^2,$$

for any  $u, v \in V$ , and similarly for  $\langle \cdot, \cdot \rangle_W$ . Because  $\psi$  preserves norms, a direct calculation via the above formula certifies that it will preserve also the inner products, and so  $\psi$  is an isometry.

(b) Suppose that  $\psi$  satisfies  $\psi^* \psi = I_V$ . Then, for any  $u, v \in V$  we have

$$\|u - v\|_V^2 = \langle u - v, u - v \rangle_V = \langle u - v, (\psi^* \psi)(u - v) \rangle_V = \langle \psi(u - v), \psi(u - v) \rangle_W = \|\psi(u) - \psi(v)\|_W^2.$$

Thus  $\|u - v\|_V = \|\psi(u) - \psi(v)\|_W$  which shows that  $\psi$  is an isometry. Conversely, if  $\psi : V \rightarrow W$  is an isometry, then  $\langle (\psi^* \psi)(u), v \rangle_V = \langle \psi(u), \psi(v) \rangle_W = \langle u, v \rangle_V$  for any  $u, v \in V$ . Since  $\langle \cdot, \cdot \rangle_V$  is an inner product this implies  $(\psi^* \psi)(u) = u$  for any  $u \in V$ . Thus  $\psi^* \psi = I_V$ .  $\square$

**3.F.33.** Consider the vector  $v = \left(0, \frac{\sqrt{2}}{2}, -\frac{\sqrt{2}}{2}\right)^T \in \mathbb{R}^3$ . Find an orthogonal operator  $F : \mathbb{R}^3 \rightarrow \mathbb{R}^3$  such that  $F(v) = e_1$ , where  $e_1 = (1, 0, 0)^T$  is the first vector of the standard basis on  $\mathbb{R}^3$ . Next confirm your result using Sage.

**Solution.** Let  $A$  be the  $3 \times 3$  matrix corresponding to  $F$ , such that  $F(u) = Au$  for all  $u \in \mathbb{R}^3$ . Since  $F$  should be orthogonal,  $A$  satisfies  $AA^T = E$ , where  $E$  is the  $3 \times 3$  identity matrix. Recall that the columns of an orthogonal matrix  $n \times n$  matrix form an orthonormal basis of  $\mathbb{R}^n$ . For the given vector  $v$  we know that  $F(v) = Av = e_1$ , from where we get  $v = A^T e_1$ . Thus  $v$  sits in the first column of  $A^T$ , and we may assume that  $A^T = (v \mid v_1 \mid v_2)$  for some vectors  $v_1, v_2$  on  $\mathbb{R}^3$  that we should specify. These vectors should be orthogonal to  $v$ , i.e.,  $v_1, v_2 \in v^\perp$  and it is easy to see that any vector  $(x_1, x_2, x_3)^T$  on the orthogonal complement  $v^\perp$  should satisfy the equation

$$\frac{\sqrt{2}}{2}x_2 - \frac{\sqrt{2}}{2}x_3 = 0$$

or equivalently,  $x_2 - x_3 = 0$ . Thus, the solution space has the form

$$\left\{ \begin{pmatrix} x_1 \\ x_2 \\ x_3 \end{pmatrix} = \begin{pmatrix} t \\ s \\ s \end{pmatrix} = t \begin{pmatrix} 1 \\ 0 \\ 0 \end{pmatrix} + s \begin{pmatrix} 0 \\ 1 \\ 1 \end{pmatrix} : t, s \in \mathbb{R} \right\}$$

and we deduce that  $v^\perp$  is generated by the vectors  $(1, 0, 0)^T$  and  $(0, 1, 1)^T$ . Obviously, these vectors are orthogonal each other. Setting  $v_1 = (1, 0, 0)^T$  and  $v_2 = \left(0, \frac{\sqrt{2}}{2}, \frac{\sqrt{2}}{2}\right)^T$  such that  $\|v_1\| = 1 = \|v_2\|$  and  $v_1 \perp v_2$ , we finally obtain

$$A^T = \begin{pmatrix} 0 & 1 & 0 \\ \frac{\sqrt{2}}{2} & 0 & \frac{\sqrt{2}}{2} \\ -\frac{\sqrt{2}}{2} & 0 & \frac{\sqrt{2}}{2} \end{pmatrix} \implies A = \begin{pmatrix} 0 & \frac{\sqrt{2}}{2} & -\frac{\sqrt{2}}{2} \\ 1 & 0 & 0 \\ 0 & \frac{\sqrt{2}}{2} & \frac{\sqrt{2}}{2} \end{pmatrix}.$$

Using this expression we can verify that  $Av = e_1$ . Consequently, if  $u = (x, y, z)^T$  is an arbitrary vector of  $\mathbb{R}^3$  we have

$$F(u) = Au = \begin{pmatrix} 0 & \frac{\sqrt{2}}{2} & -\frac{\sqrt{2}}{2} \\ 1 & 0 & 0 \\ 0 & \frac{\sqrt{2}}{2} & \frac{\sqrt{2}}{2} \end{pmatrix} \begin{pmatrix} x \\ y \\ z \end{pmatrix} = \begin{pmatrix} \frac{\sqrt{2}}{2}(y - z) \\ x \\ \frac{\sqrt{2}}{2}(y + z) \end{pmatrix}.$$

As for a confirmation in Sage, use the cell given here:

```
A=matrix([[0, sqrt(2)/2, -sqrt(2)/2], [1, 0, 0], [0, sqrt(2)/2, sqrt(2)/2]])
v=vector([0, sqrt(2)/2, -sqrt(2)/2]); e1=vector([1, 0, 0])
print(A.is_unitary()); print(A*v==e1)
```

□

Let us now analyze an example related to the notion of matrix groups  $G \subset \text{GL}_n(\mathbb{F})$ , where  $\mathbb{F} \in \{\mathbb{R}, \mathbb{C}\}$  and  $\text{GL}_n(\mathbb{F})$  is the general linear group. In this part, to prove the crucial property of “closedness” that characterizes such a group  $G$ , we require a basic understanding of continuous functions, as well as some familiarity with closed subsets of Euclidean space. These concepts are explored in Chapter 5, and our tasks below establish a first link between analysis and group theory. Notably, we have already encountered the concept of “closedness” in the proof of the lemma presented in 3.3.3, and the reader may find it helpful to refer to a similar explanation below.<sup>21</sup>

**3.F.34.** Prove that the orthogonal group  $O(n)$  is a matrix group, that is, a closed subgroup of  $\text{GL}_n(\mathbb{R})$ .

**Solution.** Hints: The fact that  $O(n)$  is a subgroup was discussed in 3.D.18. Consider the map

$$\rho : \text{Mat}_n(\mathbb{R}) \rightarrow \text{Sym}(n, \mathbb{R}), \quad A \mapsto AA^T.$$

Here,  $\text{Sym}(n, \mathbb{R})$  is the set of  $n \times n$  symmetric matrices with real entries. First, establish a linear isomorphism between  $\text{Sym}(n, \mathbb{R})$  and the Euclidean space  $\mathbb{R}^{\frac{1}{2}n(n+1)}$ . Then, deduce that the function  $\rho$  is continuous and moreover that  $O(n) = \rho^{-1}(\{E\})$ , where  $E$  is the  $n \times n$  identity matrix. Since the preimage of a closed set under a continuous map is closed, this shows that  $O(n)$  is closed in  $\text{GL}_n(\mathbb{R})$ , thereby confirming that  $O(n)$  is indeed a matrix group. □

**3.F.35. Matrix of general rotation in  $\mathbb{R}^3$ .** Derive the matrix of a general rotation in  $\mathbb{R}^3$ ,

**Solution.** Consider an arbitrary unit vector  $(x, y, z)^T \in \mathbb{R}^3$ . Rotation in the positive sense by an angle  $\varphi$  about this vector can be written down as a composition of the following rotations (whose matrices we already know):

- rotation  $\mathcal{R}_1$  in the negative sense about the  $z$  axis through the angle with cosine equal to  $x/\sqrt{x^2 + y^2} = x/\sqrt{1 - z^2}$ , that is, with sine  $y/\sqrt{1 - z^2}$ , under which the line with the directional vector  $(x, y, z)^T$  goes over on the line with the directional vector  $(0, y, z)^T$ . The matrix of this rotation has the form

$$R_1 = \begin{pmatrix} x/\sqrt{1 - z^2} & y/\sqrt{1 - z^2} & 0 \\ -y/\sqrt{1 - z^2} & x/\sqrt{1 - z^2} & 0 \\ 0 & 0 & 1 \end{pmatrix}.$$

- Rotation  $\mathcal{R}_2$  in the positive sense about the  $y$  axis through the angle with cosine  $\sqrt{1 - z^2}$ , that is, with sine  $z$ , under which the line with the directional vector  $(0, y, z)^T$  goes over on the line with the directional vector  $(1, 0, 0)^T$ . The matrix of this rotation is given by

$$R_2 = \begin{pmatrix} \sqrt{1 - z^2} & 0 & z \\ 0 & 1 & 0 \\ -z & 0 & \sqrt{1 - z^2} \end{pmatrix}.$$

- Rotation  $\mathcal{R}_3$  in the positive sense about the  $x$  axis through the angle  $\varphi$ , with the following matrix

$$R_3 = \begin{pmatrix} 1 & 0 & 0 \\ 0 & \cos(\varphi) & -\sin(\varphi) \\ 0 & \sin(\varphi) & \cos(\varphi) \end{pmatrix}.$$

- Rotation  $\mathcal{R}_2^{-1}$  with the matrix  $R_2^{-1}$ ,
- Rotation  $\mathcal{R}_1^{-1}$  with the matrix  $R_1^{-1}$ .

<sup>21</sup>Recall that we have an inclusion  $\text{GL}_n(\mathbb{R}) \subset \mathbb{R}^{n^2} \cong \text{Mat}_n(\mathbb{R})$ .

The matrix of the composition of these mappings, that is, the matrix we are looking for, is given by the product of the rotations in the reverse order:

$$R_1^{-1} \cdot R_2^{-1} \cdot R_3 \cdot R_2 \cdot R_1 = \begin{pmatrix} 1 - t + tx^2 & txy - zs & txz + ys \\ yxt + zs & 1 - t + ty^2 & tyz - xs \\ zxt - ys & tzy + xs & 1 - t + tz^2 \end{pmatrix}$$

where  $t = 1 - \cos \varphi$  and  $s = \sin \varphi$ . □

**3.F.36.** Find the matrix of the rotation in the positive sense by the angle  $\pi/3$  about the line passing through the origin with the oriented directional vector  $(1, 1, 0)^T$  under the standard basis  $\mathbb{R}^3$ . ○

**3.F.37.** Using basic plotting functions in Sage, visualize the 2-dimensional square on  $\mathbb{R}^3$ , having vertices the points  $[1, 1, 0]$ ,  $[1, -1, 0]$ ,  $[-1, -1, 0]$  and  $[-1, 1, 0]$ , as it rotates around the  $x$ ,  $y$  and  $z$  axes. Hint: Use the matrices  $R_x$ ,  $R_y$  and  $R_z$  presented in the solution of 3.D.19.

**Solution.** We should define the given square, next, apply the rotation matrices described in ?? and finally, plot the rotated squares. It will be easier to fix the rotation angle, say  $\theta = \pi/4$ , in order to visualize our goal by a figure, as follows:

In this figure, the initial square is shown in black. The square rotated about the  $x$ -axis is shown in red, the square rotated around the  $y$ -axis is in green, and the square rotated around the  $z$ -axis is in blue. Let us present the code and include the necessary explanations within the code block.

```
# Define the vertices of the square in the xy-plane
square_vertices = [(1, 1, 0), (1, -1, 0), (-1, -1, 0), (-1, 1, 0)]
# Define the edges of the square
square_edges = [(square_vertices[0], square_vertices[1]),
                (square_vertices[1], square_vertices[2]),
                (square_vertices[2], square_vertices[3]),
                (square_vertices[3], square_vertices[0])]
# Define the rotation angle in radians theta=pi/4 #45degrees
theta = pi / 4 # 45 degrees
# Rotation matrices
Rx = Matrix([[1, 0, 0], [0, cos(theta), -sin(theta)], [0, sin(theta), cos(theta)]])
Ry = Matrix([[cos(theta), 0, sin(theta)], [0, 1, 0], [-sin(theta), 0, cos(theta)]])
Rz = Matrix([[cos(theta), -sin(theta), 0], [sin(theta), cos(theta), 0], [0, 0, 1]])
# Function to rotate vertices and create plot for each axis
def plot_rotation(rotation_matrix, color, label):
    rotated_edges = []
    for start, end in square_edges:
        start_rotated = rotation_matrix * vector(start)
        end_rotated = rotation_matrix * vector(end)
        rotated_edges.append((start_rotated, end_rotated))
    return sum([line([edge[0], edge[1]], color=color,
                    thickness=2, legend_label=label) for edge in rotated_edges])
```

```

# Plot the original and rotated squares
original_plot = plot_rotation(Matrix.identity(3), "black", "Original")
rotated_x_plot = plot_rotation(Rx, "red", "Rotation around x-axis")
rotated_y_plot = plot_rotation(Ry, "green", "Rotation around y-axis")
rotated_z_plot = plot_rotation(Rz, "blue", "Rotation around z-axis")
# Combine the plots and show them
final_plot = original_plot + rotated_x_plot + rotated_y_plot + rotated_z_plot
final_plot.show(aspect_ratio=1, frame=True, legend=True)
    
```

The most advanced part of our program is the definition of the `plot_rotation` function. This is designed to take a rotation matrix, a colour, and a label as inputs. It then applies the rotation matrix to each edge of the given square, creates lines for these rotated edges, and returns a plot object that can be displayed, making it easier to visualize the effect of the rotation in  $\mathbb{R}^3$ . The command `rotated_edges = []` initializes a list for rotated edges. In particular, this is an empty list that will store the pairs of points (edges) after they have been transformed by the rotation matrix. Next, the syntax

```
for start, end in square_edges:
```

forms a loop over each edge of the square. In particular, the option `square_edges` is a list of tuples, where each tuple represents an edge of the square as a pair of vertex coordinates. The loop iterates over each edge, extracting the start and end points (`start, end`) of the edge. On the other hand, the syntax

```
start_rotated = rotation_matrix * vector(start)
end_rotated = rotation_matrix * vector(end)
```

plays the following role: The first operation multiplies the rotation matrix by a vector created from the start point of the edge. The `vector()` function then converts the coordinate tuple into a vector object, allowing for matrix multiplication. Thus, the syntax `start_rotated` encodes the new vector representing the rotated position of the start point, while, the syntax `end_rotated` encodes the new vector representing the rotated position of the end point. Next, the syntax

```
rotated_edges.append((start_rotated, end_rotated))
```

adds the newly rotated edge, represented as a tuple of the rotated start and end points, to the `rotated_edges` list. Finally, to create line plots for each rotated edge we typed the last line within the `def` environment. This creates a list of line objects, each representing a line plot for an edge. To summarize, the `plot_rotation` function efficiently rotates the square's vertices using a specified rotation matrix, then plots each rotated edge with a given color and label. You can experiment further by changing the rotation angle  $\theta$  from the value we used, i.e.,  $\theta = \pi/4$ .  $\square$

**3.F.38.** Let  $(V, \langle \cdot, \cdot \rangle)$  be a unitary vector space and suppose that  $\varphi : V \rightarrow V$  is a linear mapping having the property  $\varphi^2 = \varphi$ . Prove that there exists a linear subspace of  $W$  such that  $\varphi$  is the orthogonal projection on  $W$ , i.e.,  $\varphi = \text{proj}_W$ , if and only if  $\varphi$  is self-adjoint.

**Solution.** Assume that  $\varphi$  is self adjoint. Then, by linearity and the condition that satisfies  $\varphi$  we see that  $\varphi(u - \varphi(u)) = \varphi(u) - \varphi^2(u) = 0$  for any  $u \in V$ . Thus  $u - \varphi(u) \in \ker(\varphi)$ . Recall now by 3.F.41 that any endomorphism  $\varphi$  on  $V$  satisfies  $\ker(\varphi^*) = (\text{Im}(\varphi))^\perp$  and  $\text{Im}(\varphi^*) = (\ker(\varphi))^\perp$ . By the second relation we get  $\ker(\varphi) = (\text{Im}(\varphi^*))^\perp$  and since  $\varphi$  is self-adjoint this gives  $\ker(\varphi) = (\text{Im}(\varphi))^\perp$ . Thus writing

$$u = \varphi(u) + (u - \varphi(u)),$$

we have  $\varphi(u) \in \text{Im}(\varphi)$  and  $(u - \varphi(u)) \in (\text{Im}(\varphi))^\perp$ . Since  $V = \text{Im}(\varphi) \oplus (\text{Im}(\varphi))^\perp$ , we deduce that  $\varphi(u) = \text{proj}_W u$ , for any  $u \in V$ , where  $W = \text{Im}(\varphi) \subset V$ . This proves the one direction. For the converse, assume that there exists a subspace  $W \subset V$ , such that  $\varphi = \text{proj}_W$ . Let  $W^\perp$  the orthogonal complement of  $W$  with respect to  $\langle \cdot, \cdot \rangle$ . Given arbitrary  $u, v \in V$ , write  $u = u_1 + u_2, v = v_1 + v_2$  with  $u_1, v_1 \in W$  and  $u_2, v_2 \in W^\perp$ , respectively. Then, since  $\varphi = \text{proj}_W$  we have  $\varphi(u) = u_1, \varphi(v) = v_1$ , and thus

$$\langle \varphi(u), v \rangle = \langle u_1, v_1 + v_2 \rangle = \langle u_1, v_1 \rangle = \langle u_1 + u_2, v_1 \rangle = \langle u, v_1 \rangle = \langle u, \varphi(v) \rangle.$$

Thus  $\varphi = \varphi^*$  and  $\varphi$  is self-adjoint. □

**3.F.39.** Show that for any symmetric matrix  $A \in \text{Mat}_n(\mathbb{R})$  the operator  $L_A : \mathbb{R}^n \rightarrow \mathbb{R}^n$  defined by  $L_A x = Ax$  ( $x \in \mathbb{R}^n$ ) is self-adjoint. ○

**3.F.40.** For  $A \in \text{Mat}_m(\mathbb{C})$  Hermitian, prove that the linear operator  $L_A : \text{Mat}_{m,n}(\mathbb{C}) \rightarrow \text{Mat}_{m,n}(\mathbb{C})$  defined by  $L_A(B) = AB$  is self-adjoint. ○

**3.F.41.** Let  $f : V \rightarrow V$  be an endomorphism on a (finite-dimensional) inner product space  $(V, \langle \cdot, \cdot \rangle)$ . Prove that  $\ker(f^*) = (\text{Im}(f))^\perp$  and  $\text{Im}(f^*) = (\ker(f))^\perp$ . ○

**3.F.42.** Let  $\varphi_u : \mathbb{R}^n \rightarrow \mathbb{R}^n$  be the linear mapping that reflects  $\mathbb{R}^n$  through the line in the direction of the unit vector  $u \in \mathbb{R}^n$ . Show that its matrix  $[\varphi_u] = 2uu^T - E$  is unitary. ○

**3.F.43.** Let  $A \in \text{Mat}_n(\mathbb{C})$  be a complex matrix. Prove that the product  $A^*A$  has only real eigenvalues. Next suppose that there exists a unitary matrix  $U$  such that  $A = U^*DU$  for some diagonal matrix  $D$ . Show that  $A$  is normal. ○

**3.F.44.** Find the values of the complex parameters  $a, b, c$  such that the matrix  $A$  is a Hermitian matrix, where

$$A = \begin{pmatrix} 1 & a & -i \\ 2 - 2i & 0 & b \\ c & 1 + i & 0 \end{pmatrix}.$$
○

**3.F.45.** Given a Hermitian matrix  $A$  show that its determinant  $\det(A)$  is a real number.

**Solution.** The matrix  $A$  is supposed to be Hermitian, and hence unitary diagonalizable. Thus  $U^*AU = D$  for some unitary matrix  $U$  and diagonal (real) matrix  $D$  (since  $A$  has only real eigenvalues). Then, since  $U^{-1} = U^*$  a direct computation shows that  $A = U^*DU$ . Therefore,

$$\det(A) = \det(U^*) \det(D) \det(U) = \det(U^{-1}) \det(D) \det(U) = \det(D),$$

and our claim follows. □

*So far, we have explored various methods in Sage for applying the Gram-Schmidt orthogonalization process. However, we have not yet discussed the `gram_schmidt()` function, which is only used to orthogonalize the columns of a matrix. When the `gram_schmidt()` method is applied to a matrix, it returns two matrices: a matrix whose columns are mutually orthogonal (but not necessarily of unit length) and an upper triangular matrix that contains the coefficients used in the Gram-Schmidt process to express the original columns as linear combinations of the orthogonalized columns. In 3.F.46 below, we will apply this method and use only the first of the two resulting matrices.*

**3.F.46.** Present an orthogonal diagonalization of the following symmetric matrix  $A = \begin{pmatrix} -\frac{1}{3} & 1 & 0 \\ 1 & -\frac{1}{3} & 0 \\ 0 & 0 & -\frac{1}{3} \end{pmatrix}$ . Next implement

the task in Sage using the `gram_schmidt()` function mentioned above.

**Solution.** The characteristic polynomial of  $A$  is given by

$$\chi_A(\lambda) = \begin{vmatrix} -\frac{1}{3} - \lambda & 1 & 0 \\ 1 & -\frac{1}{3} - \lambda & 0 \\ 0 & 0 & -\frac{1}{3} - \lambda \end{vmatrix} = -(\lambda + \frac{1}{3})(\lambda^2 + \frac{2}{3}\lambda - \frac{8}{9}) = -(\lambda + \frac{1}{3})(\lambda + \frac{4}{3})(\lambda - \frac{2}{3}).$$

Thus, the eigenvalues of  $A$  are given by  $\lambda_1 = \frac{2}{3}$ ,  $\lambda_2 = -\frac{2}{3}$  and  $\lambda_3 = -\frac{4}{3}$ , all with algebraic multiplicity one. The geometric multiplicity of each  $\lambda_i$  is also one, for all  $i = 1, 2, 3$ , and hence the matrix  $A$  is diagonalizable. Let us find the corresponding eigenvectors.

- For  $\lambda_1 = \frac{2}{3}$  we need to solve the matrix equation  $(A - \frac{2}{3}E)u = 0$  for some vector  $u = (x_1, x_2, x_3)^T \in \mathbb{R}^3$ . We see that  $A - \frac{2}{3}E = \begin{pmatrix} -1 & 1 & 0 \\ 1 & -1 & 0 \\ 0 & 0 & -1 \end{pmatrix}$  and the corresponding linear system has solution space  $\left\{ \begin{pmatrix} x_1 \\ x_2 \\ x_3 \end{pmatrix} = \begin{pmatrix} t \\ t \\ 0 \end{pmatrix} : t \in \mathbb{R} \right\}$ . Hence,

the eigenvectors corresponding to  $\lambda_1$  are multiples of the vector  $u_1 = (1, 1, 0)^T$ .

- For  $\lambda_2 = -\frac{1}{3}$  we have the matrix equation  $(A + \frac{1}{3}E)u = 0$  for some vector  $u = (x_1, x_2, x_3)^T \in \mathbb{R}^3$ , where  $A + \frac{1}{3}E = \begin{pmatrix} 0 & 1 & 0 \\ 1 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix}$ . The solution space of the corresponding linear system has the form  $\left\{ \begin{pmatrix} x_1 \\ x_2 \\ x_3 \end{pmatrix} = \begin{pmatrix} 0 \\ 0 \\ s \end{pmatrix} : s \in \mathbb{R} \right\}$ . Hence, the

eigenvectors corresponding to  $\lambda_2$  are multiples of the vector  $u_2 = (0, 0, 1)^T$ .

- For  $\lambda_3 = -\frac{4}{3}$  we have the matrix equation  $(A + \frac{4}{3}E)u = 0$  for some vector  $u = (x_1, x_2, x_3)^T \in \mathbb{R}^3$ , where  $A + \frac{4}{3}E =$

$\begin{pmatrix} 1 & 1 & 0 \\ 1 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix}$ . The solution space of the corresponding linear system has the form  $\left\{ \begin{pmatrix} x_1 \\ x_2 \\ x_3 \end{pmatrix} = \begin{pmatrix} r \\ -r \\ 0 \end{pmatrix} : r \in \mathbb{R} \right\}$ . Hence, the eigenvectors corresponding to  $\lambda_3$  are multiples of the vector  $u_3 = (1, -1, 0)^T$ .

In Sage we can confirm these results as follows:

```

A=matrix(QQ, [[-1/3, 1, 0], [1, -1/3, 0], [0, 0, -1/3]])
chi_A=A.characteristic_polynomial()
print(chi_A.factor())
print(A.eigenvalues())
show(A.eigenmatrix_right())
D, Pein=A.eigenmatrix_right()
show(D, Pein)
    
```

Executing this cell Sage prints out the characteristic polynomial of  $A$ , its eigenvalues, the diagonal matrix  $D = \text{diag}(\lambda_1, \lambda_2, \lambda_3)$  and the matrix whose columns are the eigenvectors  $u_1, u_2, u_3$  (the latter is denoted by `Pein` inside the program).

Next, we see that  $u_1 \perp u_2$ ,  $u_1 \perp u_3$  and  $u_2 \perp u_3$ :

$$\langle u_1, u_2 \rangle = u_2^T u_1 = 0, \quad \langle u_1, u_3 \rangle = u_3^T u_1 = 0, \quad \langle u_2, u_3 \rangle = u_3^T u_2 = 0.$$

Moreover, we compute  $\|u_1\| = \sqrt{2} = \|u_3\|$ , while  $\|u_2\| = 1$ . Thus, the eigenvectors given below are orthonormal:

$$\hat{u}_1 = \frac{u_1}{\|u_1\|} = \left( \frac{\sqrt{2}}{2}, \frac{\sqrt{2}}{2}, 0 \right)^T, \quad \hat{u}_2 = u_2 = (0, 0, 1)^T, \quad \hat{u}_3 = \frac{u_3}{\|u_3\|} = \left( \frac{\sqrt{2}}{2}, -\frac{\sqrt{2}}{2}, 0 \right)^T.$$

We are now ready to present the matrix  $P$ :

$$P = (\hat{u}_1 \mid \hat{u}_2 \mid \hat{u}_3) = \begin{pmatrix} \frac{\sqrt{2}}{2} & 0 & \frac{\sqrt{2}}{2} \\ \frac{\sqrt{2}}{2} & 0 & -\frac{\sqrt{2}}{2} \\ 0 & 1 & 0 \end{pmatrix}.$$

By adding the following cell to the previous block, we can quickly verify that  $P$  is orthogonal, and furthermore that

$$P^{-1}AP = P^TAP = D = \begin{pmatrix} \frac{1}{3} & 0 & 0 \\ 0 & -\frac{2}{3} & 0 \\ 0 & 0 & -\frac{4}{3} \end{pmatrix}.$$

```

P=matrix([[sqrt(2)/2, 0, sqrt(2)/2], [sqrt(2)/2, 0, -sqrt(2)/2], [0, 1, 0]])
print(P.is_unitary())
print(D==P.inverse()*A*P)
    
```

Let us now implement the solution of the task using the `gram_schmidt` method, as suggested in the statement. As mentioned earlier, we will only utilize the first matrix returned by this method. To normalize the column vectors of a given matrix, we will define another function, which we may call `normalize_col`. This takes a matrix  $M$  as input and returns another matrix, with each column normalized. It works as follows:

- It iterates through each column vector  $u$  of the matrix  $M$ .
- Then, each vector  $u$  is divided by its norm to normalize it.
- Finally the normalized columns are recombined into a new matrix, using the `column_matrix()` command.

For our task we also need the matrices `D` and `Pein`, as introduced in the initial block via the `eigenmatrix_right` command. Our program has the following form:

```
A=matrix(QQ, [[-1/3, 1, 0], [1, -1/3, 0], [0, 0, -1/3]])
D, Pein=A.eigenmatrix_right()
# store the transpose of the matrix whose columns are the unnormalized eigenvectors of A as Q
Q=Pein.T
# orthogonalize the columns of Q
Q.gram_schmidt()[0]
# take the transpose of the matrix obtained by Gram-Schmidt
R=Q.gram_schmidt()[0].T
show(R)
#construct the function that normalizes the column vectors of a matrix M
def normalize_col(M):
    return column_matrix([v/norm(v) for v in M.columns()])
```

```
#normalize the columns of the matrix R and store the resulting matrix as P
P=normalize_col(R)
show(P)
print(P.is_unitary())
print(P.inverse()*A*P==D)
```

Running this program, Sage displays the matrix  $P$  as shown below, along with the message “True” printed twice, verifying that  $P$  is an orthogonal matrix that satisfies the relation  $P^TAP = D$ :

$$\begin{pmatrix} \frac{1}{2}\sqrt{2} & 0 & \frac{1}{2}\sqrt{2} \\ \frac{1}{2}\sqrt{2} & 0 & -\frac{1}{2}\sqrt{2} \\ 0 & 1 & 0 \end{pmatrix}.$$

□

**3.F.47.** Using the program in Sage constructed in 3.F.46, present the orthogonal diagonalization of the following matrices:

$$A = \begin{pmatrix} 2 & 2 & 2 \\ 2 & 0 & 4 \\ 2 & 4 & 0 \end{pmatrix}, \quad B = \begin{pmatrix} -4 & 4 & 4 \\ 4 & -4 & 4 \\ 4 & 4 & -4 \end{pmatrix}.$$

**Solution.** For the matrix  $A$  the program has the form

```
A=matrix(QQ, [[2, 2, 2], [2, 0, 4], [2, 4, 0]])
show(A.eigenmatrix_right())
D, Pein=A.eigenmatrix_right()
show(D,Pein)
Q=Pein.T
R=Q.gram_schmidt()[0].T
def normalize_columns(M):
    return column_matrix([v/norm(v) for v in M.columns()])
P=normalize_columns(R);show(P)
print(P*D*P.T==A); print(P.is_unitary())
```

In this case we get the orthogonal matrix  $P = \begin{pmatrix} \frac{\sqrt{3}}{3} & \frac{2}{3}\sqrt{\frac{3}{2}} & 0 \\ \frac{\sqrt{3}}{3} & -\frac{1}{3}\sqrt{\frac{3}{2}} & \frac{\sqrt{2}}{2} \\ \frac{\sqrt{3}}{3} & -\frac{1}{3}\sqrt{\frac{3}{2}} & -\frac{\sqrt{2}}{2} \end{pmatrix}$ , such that

$$P^TAP = \begin{pmatrix} \frac{\sqrt{3}}{3} & \frac{\sqrt{3}}{3} & \frac{\sqrt{3}}{3} \\ \frac{2}{3}\sqrt{\frac{3}{2}} & -\frac{1}{3}\sqrt{\frac{3}{2}} & -\frac{1}{3}\sqrt{\frac{3}{2}} \\ 0 & \frac{\sqrt{2}}{2} & -\frac{\sqrt{2}}{2} \end{pmatrix} \begin{pmatrix} 2 & 2 & 2 \\ 2 & 0 & 4 \\ 2 & 4 & 0 \end{pmatrix} \begin{pmatrix} \frac{\sqrt{3}}{3} & \frac{2}{3}\sqrt{\frac{3}{2}} & 0 \\ \frac{\sqrt{3}}{3} & -\frac{1}{3}\sqrt{\frac{3}{2}} & \frac{\sqrt{2}}{2} \\ \frac{\sqrt{3}}{3} & -\frac{1}{3}\sqrt{\frac{3}{2}} & -\frac{\sqrt{2}}{2} \end{pmatrix} = \begin{pmatrix} 6 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & -4 \end{pmatrix} = D,$$

where  $\lambda_1 = 6$ ,  $\lambda_2 = 0$  and  $\lambda_3 = -4$  are the eigenvalues of  $A$ .

Similarly for the matrix  $B$ :

```
B=matrix(QQ, [[-4, 4, 4], [4, -4, 4], [4, 4, -4]])
show(B.eigenmatrix_right())
D, Pein=B.eigenmatrix_right()
show(D,Pein)
Q=Pein.T
show(Q.gram_schmidt()[0])
R=Q.gram_schmidt()[0].T
show(R)
def normalize_columns(M):
    return column_matrix([v/norm(v) for v in M.columns()])
P=normalize_columns(R)
show(P)
print(P*D*P.T==B)
print(P.is_unitary())
```

Running this block Sage prints out the orthogonal matrix  $P = \begin{pmatrix} \frac{\sqrt{3}}{3} & \frac{\sqrt{2}}{2} & -\frac{1}{3}\sqrt{\frac{3}{2}} \\ \frac{\sqrt{3}}{3} & 0 & \frac{2}{3}\sqrt{\frac{3}{2}} \\ \frac{\sqrt{3}}{3} & -\frac{\sqrt{2}}{2} & -\frac{1}{3}\sqrt{\frac{3}{2}} \end{pmatrix}$ , such that

$$P^T B P = \begin{pmatrix} \frac{\sqrt{3}}{3} & \frac{\sqrt{3}}{3} & \frac{\sqrt{3}}{3} \\ \frac{\sqrt{2}}{2} & 0 & -\frac{\sqrt{2}}{2} \\ -\frac{1}{3}\sqrt{\frac{3}{2}} & \frac{2}{3}\sqrt{\frac{3}{2}} & -\frac{1}{3}\sqrt{\frac{3}{2}} \end{pmatrix} \begin{pmatrix} -4 & 4 & 4 \\ 4 & -4 & 4 \\ 4 & 4 & -4 \end{pmatrix} \begin{pmatrix} \frac{\sqrt{3}}{3} & \frac{\sqrt{2}}{2} & -\frac{1}{3}\sqrt{\frac{3}{2}} \\ \frac{\sqrt{3}}{3} & 0 & \frac{2}{3}\sqrt{\frac{3}{2}} \\ \frac{\sqrt{3}}{3} & -\frac{\sqrt{2}}{2} & -\frac{1}{3}\sqrt{\frac{3}{2}} \end{pmatrix} = \begin{pmatrix} 4 & 0 & 0 \\ 0 & -8 & 0 \\ 0 & 0 & -8 \end{pmatrix} = D,$$

where  $\lambda_1 = 4$  and  $\lambda_2 = -8$  are the eigenvalues of  $B$ , the second with an algebraic multiplicity of two.  $\square$

**3.F.48.** Present a unitary diagonalization of the matrix  $B = \begin{pmatrix} 0 & i & 1 \\ -i & 0 & 0 \\ 1 & 0 & 0 \end{pmatrix}$ .

**Solution.** The matrix  $B$  is Hermitian, so it has real eigenvalues given by  $\lambda_1 = 0$  and  $\lambda_{2,3} = \pm\sqrt{2}$ . The corresponding eigenvectors have the form

$$u_1 = (0, i, 1)^T, \quad u_2 = (\sqrt{2}, -i, 1)^T, \quad u_3 = (-\sqrt{2}, -i, 1)^T.$$

By running in a sequence the following commands in Sage, one can verify that  $\langle u_i, u_j \rangle = 0$  for any  $1 \leq i \neq j \leq 3$ , and  $\|u_1\| = \sqrt{2}$ ,  $\|u_2\| = \|u_3\| = 2$ .

```
u1=vector(QQbar, [0, I, 1])
u2=vector(QQbar, [sqrt(2), -I, 1])
u3=vector(QQbar, [-sqrt(2), -I, 1])
u2.hermitian_inner_product(u1)
u1.hermitian_inner_product(u3)
u3.hermitian_inner_product(u2)
u1.norm(); u2.norm(); u3.norm()
```

The normalized eigenvectors  $\hat{u}_i = u_i/\|u_i\|$  for  $i = 1, 2, 3$  form the columns of the matrix  $U$ ,

$$U = \begin{pmatrix} 0 & \frac{\sqrt{2}}{2} & -\frac{\sqrt{2}}{2} \\ \frac{i\sqrt{2}}{2} & -\frac{i}{2} & -\frac{i}{2} \\ \frac{\sqrt{2}}{2} & \frac{1}{2} & \frac{1}{2} \end{pmatrix}.$$

We can verify that  $U$  is unitary; for example in Sage you can type

```
U=matrix(QQbar, [[0, sqrt(2)/2, -sqrt(2)/2],
[(sqrt(2)/2)*I, (-1/2)*I, (-1/2)*I],
[sqrt(2)/2, 1/2, 1/2]])
U.is_unitary()
```

which returns: True. This diagonalizes the given matrix  $B$  with  $D = \text{diag}(0, \sqrt{2}, -\sqrt{2})$ . Recall by 3.D.38 that a verification in Sage of this final claim relies on the block

```
U=matrix(QQbar, [[0, sqrt(2)/2, -sqrt(2)/2],
[(sqrt(2)/2)*I, (-1/2)*I, (-1/2)*I],
[sqrt(2)/2, 1/2, 1/2]])
A = matrix(QQbar, [[0, I, 1], [-I, 0, 0], [1, 0, 0]])
D = matrix(QQbar, [[0, 0, 0], [0, sqrt(2), 0], [0, 0, -sqrt(2)]])
U.conjugate_transpose()*A*U == D
```

Run this block yourself to see the output generated by Sage.  $\square$

**3.F.49.** Adapt the method of orthogonal diagonalization presented in 3.F.46, to implement the unitary diagonalization of the matrix  $B$  given in 3.F.48 using Sage.

**Solution.** We only need to make a few adjustments to the program presented in 3.F.46 for it to work with unitary diagonalization. In particular, since unitary diagonalization deals with complex matrices we need to replace carefully the transposes by conjugate transposes. Also, to achieve a more readable display of the printed matrices by Sage, it is useful to pass the matrix to a low-precision ring before printing it. This adjustment will not effect the original matrices and the final results, only their display. Below is the our program:

```
CC20 = ComplexField(prec=20)
MatPrint = MatrixSpace(CC20, 3, 3)
B=matrix(QQbar, [[0, i, 1], [-i, 0, 0], [1, 0, 0]])
show(MatPrint(B))
print(B==B.H)
chi_B=B.characteristic_polynomial()
```

```

print(chi_B.factor())
print(B.eigenvalues())
D, Pein=B.eigenmatrix_right()
show(MatPrint(D))
show(MatPrint(Pein))
Q=Pein.H #show(MatPrint(Q))
q=Q.gram_schmidt()[0]
R=Q.gram_schmidt()[0].H
def normalize_columns(M):
    return column_matrix([v/norm(v) for v in M.columns()])

P=normalize_columns(R)
show(MatPrint(P))
print(P*D*P.H==B); print(P.is_unitary())
    
```

Sage's prints the solution matrix  $P$  as follows

$$P = \begin{pmatrix} 0.70711 & 9.5829 \times 10^{-21}i & 0.70711 \\ -0.50000i & 0.70711 & 0.50000i \\ 0.50000 & -0.70711i & -0.50000 \end{pmatrix} = \begin{pmatrix} 0.70711 & 0 & 0.70711 \\ -0.50000i & 0.70711 & 0.50000i \\ 0.50000 & -0.70711i & -0.50000 \end{pmatrix}.$$

This matrix slightly differs from our solution matrix  $P$  in 3.F.48, since for example Sage enumerates the eigenvalues differently and uses different eigenvectors (recall that  $P$  is not uniquely determined). However, Sage verifies that  $P$  is unitary and satisfies the unitary diagonalization condition. To understand the importance of using the low-precision ring before printing our matrices, try running the program in Sage without including the initial lines related to matrix display. Then, compare the corresponding output with the one presented above.  $\square$

Next we will explore several tasks involving the bracket of square matrices of the same size, also known as the commutator  $[\cdot, \cdot]$ , defined as  $[A, B] := AB - BA$ . The commutator is a fundamental operation in linear algebra and plays a crucial role in various branches of mathematics and physics, particularly in the study of the so called “Lie algebras”. When  $[A, B] = 0$ , the matrices commute in the sense that  $AB = BA$ . Hence, the commutator  $[A, B]$  measures the extend to which two matrices  $A, B$  fail to commute.

The commutator is a central concept in the theory of Lie algebras, which are algebraic structures used to study symmetry, particularly in the context of continuous transformations. A “Lie algebra” is a vector space  $V$  over a field  $\mathbb{F}$ , equipped with a bilinear operation  $[\cdot, \cdot] : V \times V \rightarrow V$ , known as the “Lie bracket”. This is skew-symmetric and satisfies the so called Jacobi identity

$$\mathfrak{S}_{X,Y,Z}[X, [Y, Z]] = 0,$$

where  $\mathfrak{S}_{X,Y,Z}$  is the cyclic sum over the elements  $X, Y, Z \in V$ .

We should mention that while the commutator of matrices is a primary example, the concept of a Lie algebra extends far beyond matrices, encompassing a broad range of algebraic structures.

**3.F.50.** For  $\mathbb{F} = \mathbb{R}$  or  $\mathbb{F} = \mathbb{C}$ , prove that the vector space of square matrices  $\text{Mat}_n(\mathbb{F})$  endowed with the commutator  $[A, B] := AB - BA$  has the structure of a (finite-dimensional) Lie algebra.

**Solution.** It suffices to prove that the commutator is a bilinear mapping  $[\cdot, \cdot] : \text{Mat}_n(\mathbb{F}) \times \text{Mat}_n(\mathbb{F}) \rightarrow \text{Mat}_n(\mathbb{F})$ , which is skew-symmetric and satisfies the Jacobi identity. Consider arbitrary matrices  $A_1, A_2 \in \text{Mat}_n(\mathbb{F})$  and scalars  $\lambda, \mu \in \mathbb{F}$ . Then, for any  $B \in \text{Mat}_n(\mathbb{F})$  we see that

$$\begin{aligned} [\lambda A_1 + \mu A_2, B] &= (\lambda A_1 + \mu A_2)B - B(\lambda A_1 + \mu A_2) = \lambda A_1 B + \mu A_2 B - \lambda B A_1 - \mu B A_2 \\ &= \lambda(A_1 B - B A_1) + \mu(A_2 B - B A_2) = \lambda[A_1, B] + \mu[A_2, B]. \end{aligned}$$

This prove linearity in the first argument and in a similar way we obtain  $[A, \lambda B_1 + \mu B_2] = \lambda[A, B_1] + \mu[A, B_2]$ , for all  $A, B_1, B_2 \in \text{Mat}_n(\mathbb{F})$  and  $\lambda, \mu \in \mathbb{F}$ . Since the bracket  $[\cdot, \cdot]$  is linear also in the second argument, is a bilinear mapping. Skew-symmetry is obvious:  $[B, A] = BA - AB = -(AB - BA) = -[A, B]$ , for any  $A, B \in \text{Mat}_n(\mathbb{F})$ . Finally, for the Jacobi identity, let  $A, B, C$  be some arbitrary  $n \times n$  matrices over  $\mathbb{F}$ . Then, we see that

$$\begin{aligned} [A, [B, C]] &= A(BC - CB) - (BC - CB)A = ABC - ACB - BCA + CBA, \\ [B, [C, A]] &= B(CA - AC) - (CA - AC)B = BCA - BAC - CAB + ACB, \\ [C, [A, B]] &= C(AB - BA) - (AB - BA)C = CAB - CBA - ABC + BAC, \end{aligned}$$

and the Jacobi identity  $[A, [B, C]] + [B, [C, A]] + [C, [A, B]] = 0$  is now direct.

The Lie algebra  $(\text{Mat}_n(\mathbb{R}), [ , ])$ , also denoted by  $\mathfrak{gl}(n, \mathbb{R})$  or  $\mathfrak{gl}_n(\mathbb{R})$ , underpins a wide range of applications in science, engineering, and technology. Its significance stems from its ability to model and solve real-world problems that involve linear transformations and systems. Note that in a similar way one can prove that  $(\text{Mat}_n(\mathbb{C}), [ , ])$  is a Lie algebra over  $\mathbb{C}$ .  $\square$

**3.F.51.** The dimension of a Lie algebra  $(V, [ , ]_V)$  over a field  $\mathbb{F}$ , is the dimension of the vector space  $V$  over  $\mathbb{F}$ . What is the dimension of the Lie algebra  $(\text{Mat}_n(\mathbb{R}), [ , ])$  described above?  $\circ$

**3.F.52.** Show that the set of matrices  $M = \left\{ \begin{pmatrix} a & b \\ 0 & -a \end{pmatrix} : a, b \in \mathbb{R} \right\}$  forms a Lie algebra under matrix commutation.

**Solution.** The given set of matrices is a linear subspace of the vector space  $\text{Mat}_2(\mathbb{R})$ , the latter consisting of  $2 \times 2$  real matrices. This is because  $M$  contains the zero matrix (it occurs for  $a = b = 0$ ), and is closed under addition and scalar multiplication:

$$A + B = \begin{pmatrix} a_1 & b_1 \\ 0 & -a_1 \end{pmatrix} + \begin{pmatrix} a_2 & b_2 \\ 0 & -a_2 \end{pmatrix} = \begin{pmatrix} a_1 + a_2 & b_1 + b_2 \\ 0 & -(a_1 + a_2) \end{pmatrix} \in M, \quad \lambda A = \begin{pmatrix} \lambda a & \lambda b \\ 0 & -\lambda a \end{pmatrix} \in M,$$

for all  $A, B \in M$  and  $\lambda \in \mathbb{R}$ . Next we should prove that the commutator  $[A, B]$  for  $A, B \in M$  satisfies the properties of a Lie bracket, as defined above and hence  $M$  is a 2-dimensional Lie algebra. An easier way relies on proving that  $M$  is a ‘‘Lie subalgebra’’ of the Lie algebra  $(\text{Mat}_2(\mathbb{R}), [ , ])$ . A *Lie subalgebra* of a Lie algebra  $(V, [ , ]_V)$  is a subspace  $W \subset V$  which is closed under the corresponding Lie bracket operation, i.e.,  $[W, W]_V \subset W$ . It is easy to see that a Lie subalgebra is a Lie algebra itself. For two elements  $A, B \in M$  we see that

$$\begin{aligned} [A, B] &= AB - BA = \begin{pmatrix} a_1 & b_1 \\ 0 & -a_1 \end{pmatrix} \begin{pmatrix} a_2 & b_2 \\ 0 & -a_2 \end{pmatrix} - \begin{pmatrix} a_2 & b_2 \\ 0 & -a_2 \end{pmatrix} \begin{pmatrix} a_1 & b_1 \\ 0 & -a_1 \end{pmatrix} \\ &= \begin{pmatrix} a_1 a_2 & a_1 b_2 - b_1 a_2 \\ 0 & a_1 a_2 \end{pmatrix} - \begin{pmatrix} a_2 a_1 & a_2 b_1 - b_2 a_1 \\ 0 & a_2 a_1 \end{pmatrix} = \begin{pmatrix} 0 & 0 \\ 0 & 0 \end{pmatrix} \in M. \end{aligned}$$

Thus  $M$  is closed under the commutator, making it a Lie subalgebra of  $\text{Mat}_2(\mathbb{R})$  and hence a Lie algebra in its own right. Since  $[A, B] = 0$  for any  $A, B \in M$ , this Lie algebra is an example of an *Abelian Lie algebra*, a special type of Lie algebras where all Lie brackets are zero.  $\square$

**3.F.53.** Let us denote by  $\mathfrak{so}(3)$  the set of skew-symmetric  $3 \times 3$  matrices.

- Prove that  $\mathfrak{so}(3)$  is a vector subspace of  $\text{Mat}_3(\mathbb{R})$  and compute its dimension.
- Prove that  $\mathfrak{so}(3)$  endowed with the matrix commutator  $[ , ]$  is a Lie subalgebra of  $(\text{Mat}_3(\mathbb{R}), [ , ])$ . Next compute the brackets of the basis elements and use Sage to verify the result.
- Show that  $\mathbb{R}^3$  endowed with the cross product  $\times$  as a Lie bracket, forms another 3-dimensional Lie algebra.
- Establish an linear isomorphism  $\varphi$  between  $\mathbb{R}^3$  and  $\mathfrak{so}(3)$  that preserves the Lie algebra structures, i.e.,  $\varphi(u \times v) = [\varphi(u), \varphi(v)]$ .<sup>22</sup>

**Solution.** (i) An element in  $\mathfrak{so}(3)$  has the form  $\begin{pmatrix} 0 & -x_3 & x_2 \\ x_3 & 0 & -x_1 \\ -x_2 & x_1 & 0 \end{pmatrix}$  for some  $x_1, x_2, x_3 \in \mathbb{R}$ . Thus it is easy to see that

$A + B \in \mathfrak{so}(3)$  and  $\lambda A \in \mathfrak{so}(3)$  for any two matrices  $A, B \in \mathfrak{so}(3)$  and scalar  $\lambda \in \mathbb{R}$ . Hence  $\mathfrak{so}(3)$  is a vector subspace of  $\text{Mat}_3(\mathbb{R})$  with  $\dim \mathfrak{so}(3) = 3$ , as a basis is given by the matrices

$$E_{12} = \begin{pmatrix} 0 & -1 & 0 \\ 1 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix}, \quad E_{23} = \begin{pmatrix} 0 & 0 & 0 \\ 0 & 0 & -1 \\ 0 & 1 & 0 \end{pmatrix}, \quad E_{31} = \begin{pmatrix} 0 & 0 & 1 \\ 0 & 0 & 0 \\ -1 & 0 & 0 \end{pmatrix}.$$

(ii) Let us prove that  $\mathfrak{so}(3)$  is closed under the matrix commutator. Let  $A, B \in \mathfrak{so}(3)$  be skew-symmetric matrices, i.e.,  $A^T = -A$  and  $B^T = -B$ . Then we see that

$$([A, B])^T = (AB - BA)^T = B^T A^T - A^T B^T = (-B)(-A) - (-A)(-B) = BA - AB = -[A, B],$$

which implies that  $[A, B] \in \mathfrak{so}(3)$ . Thus  $[\mathfrak{so}(3), \mathfrak{so}(3)] \subset \mathfrak{so}(3)$  and  $\mathfrak{so}(3)$  is Lie subalgebra of  $\text{Mat}_3(\mathbb{R})$ , and hence a Lie algebra itself. Alternatively, one may compute the Lie brackets of the basis elements, and prove that they belong to  $\mathfrak{so}(3)$ ,

$$[E_{12}, E_{23}] = E_{31} \in \mathfrak{so}(3), \quad [E_{12}, E_{31}] = -E_{23} \in \mathfrak{so}(3), \quad [E_{23}, E_{31}] = E_{12} \in \mathfrak{so}(3).$$

To verify the brackets in Sage you may use the following block (see also 2.E.66).

<sup>22</sup>Such isomorphisms are called *Lie algebra isomorphisms*.

```
E12=matrix([[0, -1, 0], [1, 0, 0], [0, 0, 0]])  
E23=matrix([[0, 0, 0], [0, 0, -1], [0, 1, 0]])  
E31=matrix([[0, 0, 1], [0, 0, 0], [-1, 0, 0]])
```

```

show("\n\nThe matrix E12 has the form:", E12)
show("\n\nThe matrix E23 has the form:", E23)
show("\n\nThe matrix E31 has the form:", E31)
def Lie_bracket(A, B):
    return A*B-B*A
show("\n\nThe commutator [E12, E23] equals to:", Lie_bracket(E12, E23))
show("\n\nThe commutator [E12, E31] equals to:", Lie_bracket(E12, E31))
show("\n\nThe commutator [E23, E31] equals to:", Lie_bracket(E23, E31))
print(Lie_bracket(E12, E23)==E31)
print(Lie_bracket(E12, E31)==-E23)
print(Lie_bracket(E23, E31)==E12)
    
```

(iii) Recall that the cross product  $v \times w$  of two vectors  $v = (v_1, v_2, v_3)^T$  and  $w = (w_1, w_2, w_3)^T$  on  $\mathbb{R}^3$  is the vector

$$v \times w = \begin{vmatrix} \vec{i} & \vec{j} & \vec{k} \\ v_1 & v_2 & v_3 \\ w_1 & w_2 & w_3 \end{vmatrix} = \begin{pmatrix} v_2 w_3 - w_2 v_3 \\ v_3 w_1 - w_3 v_1 \\ v_1 w_2 - w_1 v_2 \end{pmatrix} \in \mathbb{R}^3.$$

Hence  $\mathbb{R}^3$  is closed with respect to the operation  $[v, w]_{\mathbb{R}^3} := v \times w$ . This is by definition bilinear and skew-symmetric,  $v \times w = -w \times v$  for all  $v, w \in \mathbb{R}^3$ . For the Jacobi identity recall that  $u \times (v \times w) = (u \cdot w)v - (u \cdot v)w$ . Thus

$$\begin{aligned} [u, [v, w]_{\mathbb{R}^3}]_{\mathbb{R}^3} + [v, [w, u]_{\mathbb{R}^3}]_{\mathbb{R}^3} + [w, [u, v]_{\mathbb{R}^3}]_{\mathbb{R}^3} &= u \times (v \times w) + v \times (w \times u) + w \times (u \times v) \\ &= (u \cdot w)v - (u \cdot v)w + (v \cdot u)w - (v \cdot w)u + (w \cdot v)u - (w \cdot u)v \\ &= ((u \cdot w) - (w \cdot u))v - ((u \cdot v) - (v \cdot u))w + ((w \cdot v) - (v \cdot w))u \\ &= 0. \end{aligned}$$

Thus  $(\mathbb{R}^3, [\cdot, \cdot]_{\mathbb{R}^3})$  is also Lie algebra.

(iv) The map  $\varphi: \mathbb{R}^3 \rightarrow \mathfrak{so}(3)$  with

$$u = (x_1, x_2, x_3)^T \mapsto A_u := \begin{pmatrix} 0 & -x_3 & x_2 \\ x_3 & 0 & -x_1 \\ -x_2 & x_1 & 0 \end{pmatrix}$$

is clearly a vector space isomorphism. To show that is a Lie algebra isomorphism it remains to prove that  $\varphi([u, v]_{\mathbb{R}^3}) = [\varphi(u), \varphi(v)]$  or equivalently,  $A_{u \times v} = [A_u, A_v]$ , which we leave as an exercise.  $\square$

**3.F.54.** Consider Hermitian matrices  $A, B, C$  satisfying  $[A, C] = [B, C] = 0$  and  $[A, B] \neq 0$ . Prove that at least one eigenspace of the matrix  $C$  has dimension  $> 1$ .

**Solution.** We prove it by contradiction. Assume that all eigenspaces of the matrix  $C$  are 1-dimensional. Then, any vector  $u$  can be written as  $u = \sum_k \langle u, u_k \rangle u_k = \sum_k c_k u_k$ , where  $u_k$  are the linearly independent eigenvectors of  $C$ , associated with the eigenvalue  $\lambda_k$ . Now a computation shows that

$$0 = [A, C]u_k = ACu_k - CAu_k = \lambda_k Au_k - C(Au_k).$$

Therefore  $Au_k$  is also an eigenvector of the matrix  $C$  corresponding to eigenvalue  $\lambda_k$ . Then we get  $Au_k = \lambda_k^A u_k$  for some number  $\lambda_k^A$ . Similarly,  $Bu_k = \lambda_k^B u_k$  for some number  $\lambda_k^B$ . Then for the commutator of matrices  $A$  and  $B$  one computes:

$$[A, B]u_k = ABu_k - BAu_k = \lambda_k^A \lambda_k^B u_k - \lambda_k^B \lambda_k^A u_k = 0$$

and hence

$$[A, B]u = [A, B] \sum_k c_k u_k - \sum_k c_k [A, B]u_k = 0.$$

This final relation implies  $[A, B] = 0$ , a contradiction.  $\square$

**3.F.55.** Given the matrix  $A = \begin{pmatrix} 0 & -2 & 2 \\ -2 & 0 & 2 \\ 2 & 2 & 0 \end{pmatrix}$ , compute the trace of the matrix

$$\exp(A) := \sum_{k=0}^{\infty} \frac{1}{k!} A^k = I_2 + A + \frac{A^2}{2} + \dots$$

Hint: Use the eigenvalues of  $A$ .

**Solution.** Recall that trace of a matrix  $A \in \text{Mat}_n(\mathbb{F})$ , for  $\mathbb{F} = \mathbb{R}$  or  $\mathbb{F} = \mathbb{C}$  equals to the sum of the eigenvalues of  $A$ . The given matrix is symmetric and hence its eigenvalues are real. An application of the following block in Sage gives  $\lambda_1 = -4$ , with multiplicity 1 and  $\lambda_2 = 2$  with multiplicity 2:

```
A=matrix(QQ, 3, 3, [[0, -2, 2], [-2, 0, 2], [2, 2, 0]])
A.eigenvalues ()
```

Thus, the eigenvalues of  $\exp(A)$  are  $e^{-4}$  and  $e^2$ , the second with multiplicity 2 again. It follows that  $\text{tr}(\exp(A)) =$  sum of eigenvalues of  $\exp(A) = e^{-4} + 2e$ .  $\square$

**3.F.56.** Show that if  $H$  is a Hermitian matrix, then  $U = \exp(iH) = \sum_{n=0}^{\infty} \frac{1}{n!} (iH)^n$  is a unitary matrix. Next compute its determinant.

**Solution.** From the definition of  $\exp$  we can show that  $\exp(A + B) = \exp(A)\exp(B)$  just as with the exponential mapping in the domain of real numbers. Because  $(u + v)^* = u^* + v^*$  and  $(cv)^* = \bar{c}v^*$ , we obtain

$$U^* = \left( \sum_{n=0}^{\infty} \frac{1}{n!} (iH)^n \right)^* = \sum_{n=0}^{\infty} \frac{1}{n!} (-iH^*)^n.$$

Since  $H^* = H$ , we finally see that

$$U^* = \sum_{n=0}^{\infty} (-1)^n \frac{1}{n!} (iH)^n = \exp(-iH).$$

Thus  $U^*U = \exp(iH)\exp(-iH) = \exp(0) = 1$ , and  $\det(U) = \exp(\text{tr}(iH))$ .  $\square$

*We will now continue with additional tasks related to generalized eigenspaces and the Jordan canonical form.*

**3.F.57.** Determine the algebraic and geometric multiplicities of the eigenvalues for the matrices below, and use Sage to validate your results:

$$A = \begin{pmatrix} 1 & 1 & 2 \\ 0 & 1 & 2 \\ 0 & 0 & 3 \end{pmatrix}, \quad B = \begin{pmatrix} 1 & 0 & 2 \\ 0 & 1 & 2 \\ 0 & 0 & 3 \end{pmatrix}, \quad C = \begin{pmatrix} 4 & 0 & 1 \\ 2 & 3 & 2 \\ 1 & 0 & 4 \end{pmatrix}.$$

**Solution.** The matrices  $A$  and  $B$  are upper triangular having the same diagonal entries. Thus  $A, B$  have the same eigenvalues,  $|A - \lambda E| = |B - \lambda E| = \lambda^3 - 5\lambda^2 + 7\lambda - 3 = (\lambda - 1)^2(\lambda - 3)$  and we get  $\lambda_1 = 1$  with multiplicity 2,  $\alpha_A(\lambda_1) = 2 = \alpha_B(\lambda_1)$  and  $\lambda_2 = 3$  with multiplicity 1,  $\alpha_A(\lambda_2) = 1 = \alpha_B(\lambda_2)$ . Using Sage we can obtain the same conclusion as follows:

```
A=matrix(QQbar, [[1, 1, 2], [0, 1, 2], [0, 0, 3]])
A.characteristic_polynomial ()
B=matrix(QQbar, [[1, 0, 2], [0, 1, 2], [0, 0, 3]])
B.characteristic_polynomial ()
A.characteristic_polynomial () == B.characteristic_polynomial ()
```

Recall also that in Sage the command `A.fcp('t')` factors the characteristic polynomial corresponding to a matrix. For the matrix  $C$ , the following cell

```
C=matrix(QQbar, [[4, 0, 1], [2, 3, 2], [1, 0, 4]])
C.fcp('x')
C.eigenvalues ()
```

gives the characteristic polynomial of  $C$  as well as its eigenvalues:  $\lambda_1 = 5$  with  $\alpha_C(\lambda_1) = 1$  and  $\lambda_2 = 1$  with  $\alpha_C(\lambda_2) = 2$ . Let us now compute the geometric multiplicities,

$$\gamma_A(\lambda) = \dim_{\mathbb{C}}(\ker(A - \lambda E)) = n - \text{rank}(A - \lambda E).$$

Here  $A$  is a  $n \times n$  matrix and  $\lambda$  is an eigenvalue of  $A$ .

Thus, for the given matrix  $A$  we get  $A - E = \begin{pmatrix} 0 & 1 & 2 \\ 0 & 0 & 2 \\ 0 & 0 & 2 \end{pmatrix}$ . In particular,  $A - E$  consists of 2 independent column

vectors. Thus  $\text{rank}(A - E) = 2$  and  $\gamma_A(1) = 3 - 2 = 1$ . Here is a confirmation using Sage:

```
A=matrix(QQbar, [[1, 1, 2], [0, 1, 2], [0, 0, 3]])
E =matrix(QQbar, [[1, 0, 0], [0, 1, 0], [0, 0, 1]])
(A-E).rank ()
```

Or we can type

```
A=matrix(QQbar, [[1, 1, 2], [0, 1, 2], [0, 0, 3]])
A.eigenspaces_right ()
```

The second block returns the eigenvalues of  $A$  and their eigenspaces:

```
(3, Vector space of degree 3 and dimension 1 over Algebraic Field
User basis matrix:
[ 1.0000000000000000? 0.6666666666666667? 0.6666666666666667?]),
(1, Vector space of degree 3 and dimension 1 over Algebraic Field
User basis matrix:
[1 0 0])
```

In a similar way you can verify that  $\gamma_B(1) = 2$ ,  $\gamma_A(3) = 1 = \gamma_B(3)$ ,  $\gamma_C(5) = 1$  and  $\gamma_C(3) = 2$ . □

**3.F.58.** Find the Jordan canonical form of the matrices  $A = \begin{pmatrix} -1 & 1 \\ -6 & 4 \end{pmatrix}$  and  $B = \begin{pmatrix} -1 & 1 \\ -4 & 3 \end{pmatrix}$ . Additionally, provide the geometric interpretation of the Jordan canonical form decomposition corresponding to these matrices.

**Solution.** The eigenvalues of  $A$  are real, given by  $\lambda_1 = 1$  and  $\lambda_2 = 2$ . Since the size of  $A$  is  $2 \times 2$  and it has two distinct eigenvalues, the Jordan form of  $A$  is diagonal, i.e.,  $J = \begin{pmatrix} 1 & 0 \\ 0 & 2 \end{pmatrix}$ . It is easy to see that the eigenvector  $u_1 = (x, y)^T$  associated with the eigenvalue  $\lambda_1 = 1$  satisfies the matrix equation

$$0 = (A - E)u_1 = \begin{pmatrix} -2 & 1 \\ -6 & 3 \end{pmatrix} \begin{pmatrix} x \\ y \end{pmatrix}.$$

This given the equation  $-2x + y = 0$ , thus the eigenvectors are multiples of the vector  $u_1 = (1, 2)^T$ . Similarly, the eigenvector associated with the eigenvalue  $\lambda_2$  is given by  $u_2 = (1, 3)^T$ . The matrix  $P$  is then obtained by writing these eigenvectors into the columns,  $P = \begin{pmatrix} 1 & 1 \\ 2 & 3 \end{pmatrix}$ . Then, for the matrix  $A$  we have  $A = PJP^{-1}$ . The inverse of  $P$  is  $P^{-1} = \begin{pmatrix} 3 & -1 \\ -2 & 1 \end{pmatrix}$ , and we can confirm the relation  $A = PJP^{-1}$ :

$$\begin{pmatrix} -1 & 1 \\ -6 & 4 \end{pmatrix} = \begin{pmatrix} 1 & 1 \\ 2 & 3 \end{pmatrix} \begin{pmatrix} 1 & 0 \\ 0 & 2 \end{pmatrix} \begin{pmatrix} 3 & -1 \\ -2 & 1 \end{pmatrix}.$$

This decomposition says that the matrix  $A$  determines a linear mapping which has the aforementioned diagonal form with respect to the basis  $\{u_1, u_2\}$ . Geometrically, this means that in the direction of  $u_1$  nothing is changing and in the direction of  $u_2$  every vector is being stretched twice.

Let us now focus on  $B$ . This has a unique eigenvalue given by  $\lambda = 1$  with multiplicity 2. The corresponding eigenvector  $v = (x, y)^T$  satisfies the matrix equation

$$0 = (B - E)v = \begin{pmatrix} -2 & 1 \\ -4 & 2 \end{pmatrix} \begin{pmatrix} x \\ y \end{pmatrix}.$$

We find that the solutions are multiples of the vector  $v = (1, 2)^T$ . The fact that the system does not have two linearly independent vectors as a solution, implies the following expression for the Jordan canonical form:  $J = \begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix}$ . The basis for which  $A$  has this form consists of the eigenvector  $v_1$  and the vector that is assigned to  $v_1$  via the linear transformation  $B - E$ . This provides a solution of the following system of equations:

$$\left( \begin{array}{cc|c} -2 & 1 & 1 \\ -4 & 2 & 2 \end{array} \right) \sim \left( \begin{array}{cc|c} -2 & 1 & 1 \\ 0 & 0 & 0 \end{array} \right).$$

You can easily check that the solutions are multiples of the vector  $v_2 = (1, 3)^T$ . Moreover, one obtains the same basis as in the previous case, and we can verify the relation  $B = PJP^{-1}$ :

$$\begin{pmatrix} -1 & 1 \\ -4 & 3 \end{pmatrix} = \begin{pmatrix} 1 & 1 \\ 2 & 3 \end{pmatrix} \begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix} \begin{pmatrix} 3 & -1 \\ -2 & 1 \end{pmatrix}.$$

In this case, the mapping acts on the vectors as follows: the component in the direction of  $v_2$  stays the same. On the other hand, the component in the direction of  $v_1$  is multiplied by the sum of the coefficients that determine the components in the directions of  $v_2$  and  $v_1$ . □

**3.F.59.** Consider the matrix  $A = \begin{pmatrix} -1 & -1 & -1 & 0 \\ 3 & 2 & 3 & -1 \\ 2 & 1 & 3 & -1 \\ 2 & 1 & 4 & -2 \end{pmatrix}$ . Solve the following tasks:

- i) Show that the eigenvalues of  $A$  are given by  $\pm 1$ . Compute their algebraic and geometric multiplicities and find the corresponding eigenvectors of  $A$ .
- ii) Use Sage to verify that the dimensions of the null spaces  $\ker((A - E)^j)$  do not increase for  $j > 3$ . Next verify that  $\dim \mathcal{R}_{\lambda_1} = 3$  by computing the rank of the matrix  $(A - E)^3$  in Sage and applying the rank-nullity theorem.

- iii) Derive the generalized eigenvectors of  $A$ .  
 iv) Describe the Jordan canonical form  $J$  of  $A$  and find a matrix  $P$  satisfying  $P^{-1}AP = J$ . Next verify your answer by Sage.  
 v) Prove the direct sum decomposition  $\mathbb{R}^4 = \mathcal{R}_{\lambda_1} \oplus \mathcal{R}_{\lambda_2}$ , where  $\lambda_1 = 1$  and  $\lambda_2 = -1$  are the eigenvalues of  $A$ .

**Solution.** (i) The characteristic polynomial of  $A$  is given by

$$\chi_A(\lambda) = \begin{vmatrix} -1 - \lambda & -1 & -1 & 0 \\ 3 & 2 - \lambda & 3 & -1 \\ 2 & 1 & 3 - \lambda & -1 \\ 2 & 1 & 4 & -2 - \lambda \end{vmatrix} = (\lambda - 1)^3(\lambda + 1).$$

To confirm this expression we may use Sage via the block

```
A=matrix([[ -1, -1, -1, 0], [3, 2, 3, -1], [2, 1, 3, -1], [2, 1, 4, -2]])
p=A.characteristic_polynomial(); show(factor(p))
```

Thus the eigenvalues of  $A$  are  $\lambda_1 = 1$  with multiplicity 3 and  $\lambda_2 = -1$  with multiplicity 1.

• Let us first focus on  $\lambda_1$  and describe the eigenspace  $V_{\lambda_1} = V_1 = \ker(A - E)$ . We will perform elementary row operations to obtain the reduced row echelon form of the matrix  $A - E$ :

$$\begin{aligned} A - E &= \begin{pmatrix} -2 & -1 & -1 & 0 \\ 3 & 1 & 3 & -1 \\ 2 & 1 & 2 & -1 \\ 2 & 1 & 4 & -3 \end{pmatrix} \xrightarrow{R_4 \rightarrow R_4 + R_1} \begin{pmatrix} -2 & -1 & -1 & 0 \\ 3 & 1 & 3 & -1 \\ 2 & 1 & 2 & -1 \\ 0 & 0 & 3 & -3 \end{pmatrix} \xrightarrow{R_3 \rightarrow R_3 + R_1} \begin{pmatrix} -2 & -1 & -1 & 0 \\ 3 & 1 & 3 & -1 \\ 0 & 0 & 1 & -1 \\ 0 & 0 & 3 & -3 \end{pmatrix} \\ &\xrightarrow{R_4 \rightarrow R_4 - 3R_3} \begin{pmatrix} -2 & -1 & -1 & 0 \\ 3 & 1 & 3 & -1 \\ 0 & 0 & 1 & -1 \\ 0 & 0 & 0 & 0 \end{pmatrix} \xrightarrow{R_1 \rightarrow -\frac{1}{2}R_1} \begin{pmatrix} 1 & 1/2 & 1/2 & 0 \\ 3 & 1 & 3 & -1 \\ 0 & 0 & 1 & -1 \\ 0 & 0 & 0 & 0 \end{pmatrix} \xrightarrow{R_2 \rightarrow R_2 - 3R_1} \\ &\begin{pmatrix} 1 & 1/2 & 1/2 & 0 \\ 0 & -1/2 & 3/2 & -1 \\ 0 & 0 & 1 & -1 \\ 0 & 0 & 0 & 0 \end{pmatrix} \xrightarrow{R_1 \rightarrow R_1 + R_2} \begin{pmatrix} 1 & 0 & 2 & -1 \\ 0 & -1/2 & 3/2 & -1 \\ 0 & 0 & 1 & -1 \\ 0 & 0 & 0 & 0 \end{pmatrix} \xrightarrow{R_2 \rightarrow -2R_2} \begin{pmatrix} 1 & 0 & 2 & -1 \\ 0 & 1 & -3 & 2 \\ 0 & 0 & 1 & -1 \\ 0 & 0 & 0 & 0 \end{pmatrix} \\ &\xrightarrow{R_2 \rightarrow R_2 + 3R_3} \begin{pmatrix} 1 & 0 & 2 & -1 \\ 0 & 1 & 0 & -1 \\ 0 & 0 & 1 & -1 \\ 0 & 0 & 0 & 0 \end{pmatrix} \xrightarrow{R_1 \rightarrow R_1 - 2R_3} \begin{pmatrix} 1 & 0 & 0 & 1 \\ 0 & 1 & 0 & -1 \\ 0 & 0 & 1 & -1 \\ 0 & 0 & 0 & 0 \end{pmatrix}. \end{aligned}$$

You can verify this expression in Sage by adding the following cel to the initial block:

```
E=identity_matrix(4); AEprref=(A-E).rref(); show(AEprref)
```

Thus, the solutions of the matrix equation  $(A - E)u_1 = 0$  for some vector  $u_1 = (x_1, x_2, x_3, x_4)^T$  correspond to solutions of the linear system  $\{x_1 + x_4 = 0, x_2 - x_3 = 0, x_3 - x_4 = 0\}$ , where  $x_4$  is a free parameter. This gives

$$V_1 = \ker(A - E) = \{t(-1, 1, 1, 1)^T : t \in \mathbb{R}\}$$

and hence the geometric multiplicity of  $\lambda_1 = 1$  equals 1, i.e.,  $\gamma(\lambda_1) = 1 = \dim V_1$ . Moreover, the vector  $u_1 = (-1, 1, 1, 1)^T$  is an eigenvector of  $A$  corresponding to  $\lambda_1 = 1$ .

• For the second eigenvalue  $\lambda_2 = -1$  we have algebraic multiplicity 1 and thus also the geometric multiplicity should be 1, i.e.,  $\gamma(\lambda_2) = \dim V_{-1} = \dim \ker(A + E) = 1$ . This also implies that  $\dim \mathcal{R}_{\lambda_2} = 1$ , in particular  $\mathcal{R}_{\lambda_2} \cong V_{-1}$  (the dimension of the null spaces  $\ker((A + E)^\ell)$  stabilizes for  $\ell > 1$ ). We will apply elementary row operations to derive the reduced row echelon form of the matrix  $A + E$ .

$$\begin{aligned} A + E &= \begin{pmatrix} 0 & -1 & -1 & 0 \\ 3 & 3 & 3 & -1 \\ 2 & 1 & 4 & -1 \\ 2 & 1 & 4 & -1 \end{pmatrix} \xrightarrow{R_4 \rightarrow R_4 - R_3} \begin{pmatrix} 0 & -1 & -1 & 0 \\ 3 & 3 & 3 & -1 \\ 2 & 1 & 4 & -1 \\ 0 & 0 & 0 & 0 \end{pmatrix} \xrightarrow{R_1 \leftrightarrow R_2} \begin{pmatrix} 3 & 3 & 3 & -1 \\ 0 & -1 & -1 & 0 \\ 2 & 1 & 4 & -1 \\ 0 & 0 & 0 & 0 \end{pmatrix} \xrightarrow{R_1 \rightarrow \frac{1}{3}R_1} \\ &\begin{pmatrix} 1 & 1 & 1 & -1/3 \\ 0 & -1 & -1 & 0 \\ 2 & 1 & 4 & -1 \\ 0 & 0 & 0 & 0 \end{pmatrix} \xrightarrow{R_3 \rightarrow R_3 - 2R_1} \begin{pmatrix} 1 & 1 & 1 & -1/3 \\ 0 & -1 & -1 & 0 \\ 0 & -1 & 2 & -1/3 \\ 0 & 0 & 0 & 0 \end{pmatrix} \xrightarrow{R_2 \rightarrow -R_2} \begin{pmatrix} 1 & 1 & 1 & -1/3 \\ 0 & 1 & 1 & 0 \\ 0 & -1 & 2 & -1/3 \\ 0 & 0 & 0 & 0 \end{pmatrix} \end{aligned}$$

$$\begin{array}{l}
 R_3 \rightarrow R_3 + R_2 \quad \left( \begin{array}{cccc} 1 & 1 & 1 & -1/3 \\ 0 & 1 & 1 & 0 \\ 0 & 0 & 3 & -1/3 \\ 0 & 0 & 0 & 0 \end{array} \right) \xrightarrow{R_3 \rightarrow \frac{1}{3}R_3} \left( \begin{array}{cccc} 1 & 1 & 1 & -1/3 \\ 0 & 1 & 1 & 0 \\ 0 & 0 & 1 & -1/9 \\ 0 & 0 & 0 & 0 \end{array} \right) \xrightarrow{R_1 \rightarrow R_1 - R_2} \left( \begin{array}{cccc} 1 & 0 & 0 & -1/3 \\ 0 & 1 & 1 & 0 \\ 0 & 0 & 1 & -1/9 \\ 0 & 0 & 0 & 0 \end{array} \right) \\
 R_2 \rightarrow R_2 - R_3 \quad \left( \begin{array}{cccc} 1 & 0 & 0 & -1/3 \\ 0 & 1 & 0 & 1/9 \\ 0 & 0 & 1 & -1/9 \\ 0 & 0 & 0 & 0 \end{array} \right).
 \end{array}$$

Once more we can verify this expression in Sage quickly, by adding the cell

```
AEmrref=(A+E).rref(); show(AEmrref)
```

This results in the system  $\{x_1 - \frac{1}{3}x_4 = 0, x_2 + \frac{1}{9}x_4 = 0, x_3 - \frac{1}{9}x_4 = 0\}$ , where  $x_4$  is a free parameter. Thus

$$V_{\lambda_2} = V_{-1} = \ker(A + E) = \left\{ t \left( \frac{1}{3}, -\frac{1}{9}, \frac{1}{9}, 1 \right) : t \in \mathbb{R} \right\}.$$

Therefore the corresponding eigenvector is given (up to a scalar) by  $v_1 = (\frac{1}{3}, -\frac{1}{9}, \frac{1}{9}, 1)^T$ .

(ii) We will use Sage to study the matrices  $(A-E)^2$ ,  $(A-E)^3$ , and so on. We proceed with the following block:

```
A=matrix([[ -1, -1, -1, 0], [3, 2, 3, -1], [2, 1, 3, -1], [2, 1, 4, -2]])
E=identity_matrix(4)
bb=(A-E)*(A-E)
show("\nThe matrix (A-E)^2 is given by:",bb)
cc=bb*(A-E)
show("\nThe matrix (A-E)^3 is given by:",cc)
dd=cc*(A-E)
show("\nThe matrix (A-E)^4 is given by:",dd)
ee=dd*(A-E)
show("\nThe matrix (A-E)^5 is given by:",ee)
```

Executing this block, we obtain

$$\begin{array}{l}
 \text{The matrix } (A-E)^2 \text{ is given by: } \begin{pmatrix} -1 & 0 & -3 & 2 \\ 1 & 0 & 2 & -1 \\ 1 & 0 & 1 & 0 \\ 1 & 0 & -3 & 4 \end{pmatrix} \\
 \text{The matrix } (A-E)^3 \text{ is given by: } \begin{pmatrix} 0 & 0 & 3 & -3 \\ 0 & 0 & -1 & 1 \\ 0 & 0 & 1 & -1 \\ 0 & 0 & 9 & -9 \end{pmatrix} \\
 \text{The matrix } (A-E)^4 \text{ is given by: } \begin{pmatrix} 0 & 0 & -6 & 6 \\ 0 & 0 & 2 & -2 \\ 0 & 0 & -2 & 2 \\ 0 & 0 & -18 & 18 \end{pmatrix} \\
 \text{The matrix } (A-E)^5 \text{ is given by: } \begin{pmatrix} 0 & 0 & 12 & -12 \\ 0 & 0 & -4 & 4 \\ 0 & 0 & 4 & -4 \\ 0 & 0 & 36 & -36 \end{pmatrix}
 \end{array}$$

This shows that the matrices  $(A-E)^4$  and  $(A-E)^5$  are (even) multiples of the matrix  $(A-E)^3$ . Thus, as we expected, the dimensions of the null subspaces  $\ker((A-E)^j)$  will not increase for  $j > 3 = \alpha(\lambda_1)$ . To compute the rank of the matrix  $(A-E)^3$  we can continue typing in the previous block the following syntax:

```
show("The rank of (A-E)^3 is given by:", cc.rank())
```

Sage's output has the form:

```
The rank of (A-E)^3 is given by:1.
```

Thus  $\text{rank}((A-E)^3) = 1$  and  $\dim \ker((A-E)^3) = 4 - 1 = 3 = \dim \mathcal{R}_{\lambda_1}$ , as it should be, since  $\alpha(\lambda_1) = 3$ .

(iii) Let us now determine generalized eigenvectors  $u_2, u_3 \in \mathcal{R}_{\lambda_1}$  for the first eigenvalue, where the algebraic multiplicity exceeds the geometric multiplicity. To do this, start with the matrix equation  $(A-E)u_2 = u_1$ , i.e.,

$$\begin{pmatrix} -2 & -1 & -1 & 0 \\ 3 & 1 & 3 & -1 \\ 2 & 1 & 2 & -1 \\ 2 & 1 & 4 & -3 \end{pmatrix} \begin{pmatrix} x_1 \\ x_2 \\ x_3 \\ x_3 \end{pmatrix} = \begin{pmatrix} -1 \\ 1 \\ 1 \\ 1 \end{pmatrix},$$

where  $u_2 = (x_1, x_2, x_3, x_4)^T$  is the unknown. We will use Sage to obtain the reduced row echelon form of the augmented matrix  $(A - E \mid v_1)$ . It is sufficient to continue typing in our previous block and add the following cell

```
v1=vector([-1, 1, 1, 1])
B=(A-E).augment(v1, subdivide="True")
show(B.rref())
```

We see that

$$\left( \begin{array}{cccc|c} -2 & -1 & -1 & 0 & -1 \\ 3 & 1 & 3 & -1 & 1 \\ 2 & 1 & 2 & -1 & 1 \\ 2 & 1 & 4 & -3 & 1 \end{array} \right) \sim \left( \begin{array}{cccc|c} 1 & 0 & 0 & 1 & 0 \\ 0 & 1 & 0 & -1 & 1 \\ 0 & 0 & 1 & -1 & 0 \\ 0 & 0 & 0 & 0 & 0 \end{array} \right).$$

Now you may conclude that the solution space of the induced linear system has the form  $\{(x_1, x_2, x_3, x_4)^T = (-s, 1 + s, s, s)^T\}$ , where  $s$  is a free parameter. Therefore, without loss of generality we may assume that  $u_2 = (0, 1, 0, 0)^T$ . Next, using the matrix expression  $(A - E)^3$  provided above, we can easily verify that  $(A - E)^3 u_2 = 0$ .

Similarly, by solving the matrix equation  $(A - E)u_3 = u_2$  we find that  $u_3 = (1, -2, 0, 0)^T$  (up to a scalar). Verification of this result is left as an exercise for the reader. To summarize, the eigenvalue  $\lambda_1 = 1$  has the eigenvector  $u_1 = (-1, 1, 1, 1)^T$  and the generalized eigenvectors  $u_2 = (0, 1, 0, 0)^T$  and  $u_3 = (1, -2, 0, 0)^T$ .

(iv) It is easy to see that the generalized eigenvector  $u_3$  satisfies the additional relation  $(A - E)^2 u_3 = u_1$ . Hence the set

$$\{(A - E)^2 u_3, (A - E)u_3, u_3\} = \{u_1, u_2, u_3\}$$

is a Jordan chain of length 3 corresponding to  $\mathcal{R}_{\lambda_1}$ . Consequently, the Jordan form should contain a Jordan block of size 3 corresponding to  $\lambda_1$ ,  $J_1 = \begin{pmatrix} 1 & 1 & 0 \\ 0 & 1 & 1 \\ 0 & 0 & 1 \end{pmatrix}$ , and a Jordan block of size 1 corresponding to  $\lambda_2$ ,  $J_{-1} = (-1)$ . This yields the following expression:

$$J = J_1 \oplus J_{-1} = \begin{pmatrix} 1 & 1 & 0 \\ 0 & 1 & 1 \\ 0 & 0 & 1 \end{pmatrix} \oplus (-1) = \left( \begin{array}{ccc|c} 1 & 1 & 0 & 0 \\ 0 & 1 & 1 & 0 \\ 0 & 0 & 1 & 0 \\ \hline 0 & 0 & 0 & -1 \end{array} \right).$$

Recall that in Sage a verification of the Jordan canonical form (up to order of the Jordan blocks) occurs by adding the cell

```
J= A.jordan_form(transformation=True); show(J)
```

Now, a similarity matrix  $P$  satisfying the condition  $P^{-1}AP = J$  has as columns the vectors  $\{u_1, u_2, u_3, v_1\}$  derived in (i) and (iii), i.e.,

$$P = \begin{pmatrix} -1 & 0 & 1 & 1/3 \\ 1 & 1 & -2 & -1/9 \\ 1 & 0 & 0 & 1/9 \\ 1 & 0 & 0 & 1 \end{pmatrix}.$$

In particular,  $P$  is invertible since these vectors are linearly independent. While the computation of  $P^{-1}$  is left as an exercise, we use Sage to verify that  $P^{-1}AP = J$ :

```
J=matrix([[1, 1, 0, 0], [0, 1, 1, 0], [0, 0, 1, 0], [0, 0, 0, -1]])
P=matrix([[-1, 0, 1, 1/3], [1, 1, -2, -1/9], [1, 0, 0, 1/9], [1, 0, 0, 1]])
P.inverse()*A*P == J
```

Sage's output is True. Finally, recall from Chapter 2 that in Sage a quick way to verify the linear independence of the vectors  $u_1, u_2, u_3$  and  $v_1$  is by computing the determinant of  $P$ , via the command  $P.det()$ . Alternatively, you might prefer to use the cell provided below:

```

u1=vector([-1, 1, 1, 1])
u2=vector([0, 1, 0, 0])
u3=vector([1, -2, 0, 0])
v1=vector([1/3, -1/9, 1/9, 1])
V=RR^4; V.linear_dependence([u1, u2, u3, v1])==[]
    
```

(v) We have seen that  $\dim \mathcal{R}_1 = 3$  and  $\dim \mathcal{R}_{-1} = \dim V_{-1} = 1$ . Since the total dimension of  $\mathbb{R}^4$  equals 4, the generalized eigenspaces together have enough “space” to cover all of  $\mathbb{R}^4$ . In fact, above we saw that joining the bases  $\{u_1, u_2, u_3\}$  of  $\mathcal{R}_1$  and  $\{v_1\}$  of  $\mathcal{R}_{-1} \cong V_{-1}$  we obtain a basis of  $\mathbb{R}^4$ , and this already provides a proof. Alternatively, the relations  $\mathbb{R}^4 = \mathcal{R}_1 + \mathcal{R}_{-1}$  and  $\mathcal{R}_1 \cap \mathcal{R}_{-1} = \{0\}$  imply the direct sum decomposition

$$\mathbb{R}^4 = \mathcal{R}_{\lambda_1} \oplus \mathcal{R}_{\lambda_2} = \mathcal{R}_1 \oplus \mathcal{R}_{-1} = \ker((A - E)^3) \oplus \ker(A + E).$$

## E) MATERIAL ON LINEAR ALGEBRA – MATRIX DECOMPOSITIONS

**3.F.60.** Find the  $LU$ -decomposition of the matrix

$$A = \begin{pmatrix} 2 & 8 & 0 \\ 2 & 2 & -3 \\ 1 & 2 & 6 \end{pmatrix}.$$

**Solution.** An answer goes as follows:

$$A = \begin{pmatrix} 2 & 8 & 0 \\ 2 & 2 & -3 \\ 1 & 2 & 6 \end{pmatrix} = LU = \begin{pmatrix} 1 & 0 & 0 \\ 1 & 1 & 0 \\ 1/2 & 1/3 & 1 \end{pmatrix} \begin{pmatrix} 2 & 8 & 0 \\ 0 & -6 & -3 \\ 0 & 0 & 7 \end{pmatrix}.$$

□

**3.F.61.** Provide the  $QR$ -decomposition of the following matrices:

$$A = \begin{pmatrix} 1 & 0 & 0 \\ 1 & 1 & 0 \\ 1 & 1 & 1 \\ 1 & 1 & 1 \end{pmatrix}, \quad B = \begin{pmatrix} 1 & 1 & 0 \\ 1 & 0 & 1 \\ 0 & 1 & 1 \end{pmatrix}.$$

**Solution.** The  $QR$ -factorizations under question are given as follows:

$$A = QR = \begin{pmatrix} 1/2 & -\sqrt{12}/4 & 0 \\ 1/2 & \sqrt{12}/12 & -\sqrt{6}/3 \\ 1/2 & \sqrt{12}/12 & \sqrt{6}/6 \\ 1/2 & \sqrt{12}/12 & \sqrt{6}/6 \end{pmatrix} \begin{pmatrix} 2 & 3/2 & 1 \\ 0 & \sqrt{12}/4 & \sqrt{12}/6 \\ 0 & 0 & \sqrt{6}/3 \end{pmatrix},$$

$$B = QR = \begin{pmatrix} \sqrt{2}/2 & \sqrt{6}/6 & -\sqrt{3}/3 \\ \sqrt{2}/2 & -\sqrt{6}/6 & \sqrt{3}/3 \\ 0 & \sqrt{6}/3 & \sqrt{3}/3 \end{pmatrix} \begin{pmatrix} \sqrt{2} & \sqrt{2}/2 & \sqrt{2}/2 \\ 0 & \sqrt{6}/2 & \sqrt{6}/6 \\ 0 & 0 & 2\sqrt{3}/3 \end{pmatrix}.$$

□

**3.F.62. Ray-tracing.** In computer 3D-graphics the image is very often displayed using the Ray-tracing algorithm. The basis of this algorithm is an approximation of the light waves by a ray (line) and an approximation of the displayed objects by polyhedrons. These are bounded by planes and it is necessary to compute where exactly the light rays are reflected from these planes. From physics we know how the rays are reflected – the angle of impact equals the angle of reflection. We have already met this topic in the exercise ??.

The ray of light in the direction  $v = (1, 2, 3)$  hits the plane given by the equation  $x + y + z = 1$ . In what direction is it reflected?

**Solution.** The unit normal vector to the plane is  $n = \frac{1}{\sqrt{3}}(1, 1, 1)$ . The vector that gives the direction of the reflected ray  $v_R$  lies in the plane given by the vectors  $v, n$ . We can express it as a linear combination of these vectors. Furthermore, the rule for the angle of reflection says that  $\langle v, n \rangle = -\langle v_R, n \rangle$ . From there we obtain a quadratic equation for the coefficient of the linear combination.

This exercise can be solved in an easier, more geometric way. From the diagram we can derive directly that

$$v_R = v - 2\langle v, n \rangle n$$

. In our case,  $v_R = (-3, -2, -1)$ .

□

Solutions to the problems

**3.A.3.** We see that  $h = c^T x$ , where  $c = (-1, 2)^T$ . By multiplying the first inequality by  $-1$  we obtain the following equivalent system of constraints:

$$x_2 - x_1 \leq 1, \quad -0.5x_1 + x_2 \leq 2, \quad x_1 \geq 0, \quad x_2 \geq 0.$$

An illustration of this LP problem goes as follows:

The feasible region (the grey region in this diagram) is unbounded. However, the drawn thick semi-line starting from the point  $(2, 3)$  give us infinitely many optimal solutions.

**3.A.5.** The daily diet should contain 3.9 kg of hay and 4.3 kg of oat. Then the costs per foal are €13.82.

**3.A.9.** (a) Multiply both sides of the second inequality by  $-1$  to get  $-x_1 - x_2 \leq 1$ . Also, replace the relation  $x_1 - 2x_2 = 1$  by the inequalities  $x_1 - 2x_1 \leq 1$  and  $x_1 - 2x_2 \geq 1$ . A multiplication of the latter by  $-1$  yields the standard form of the initial problem: maximize  $h = x_1 + 2.5x_2$  with respect to the conditions

$$2x_1 + 3x_2 \leq 20, \quad -x_1 - x_2 \leq 1, \quad x_1 - 2x_2 \leq 1, \quad -x_1 + 2x_2 \leq -1, \quad x_1 \geq 0, \quad x_2 \geq 0.$$

Hence the dual problem is the minimization of  $20y_1 + y_2 + y_3 - y_4$  subject to the conditions

$$2y_1 - y_2 + y_3 - y_4 \geq 1, \quad 3y_1 - y_2 - 2y_3 + 2y_4 \geq 2.5, \quad y_i \geq 0, \quad \text{for all } i = 1, \dots, 4.$$

However, in the primal problem we had a constraint given by an equality, and so in the dual problem this should correspond to an unrestricted variable. Indeed, by setting  $y_5 = y_3 - y_4$  we result to the minimization of  $20y_1 + y_2 + y_5$  subject to

$$2y_1 - y_2 + y_5 \geq 1, \quad 3y_1 - y_2 - 2y_5 \geq 2.5, \quad y_1 \geq 0, \quad y_2 \geq 0,$$

with  $y_5$  unrestricted in sign.

(b) The standard form of the primal problem is the minimization of  $h = 2x_1 + 3x_2 + 2x_4$  subject to

$$-x_1 - 2x_2 - 2x_3 \geq 6, \quad -x_1 - 4x_2 + 2x_4 \geq -5, \quad x_1 + 4x_2 - 2x_4 \geq 5, \quad x_2 - x_3 + 4x_4 \geq 2, \quad x_i \geq 0, \quad \text{for all } i = 1, \dots, 4.$$

The dual problem reads as follows: maximize  $6y_1 - 5y_2 + 5y_3 + 2y_4$  subject to

$$-y_1 - y_2 + y_3 \leq 2, \quad -2y_1 - 4y_2 + 4y_3 + y_4 \leq 3, \quad -2y_1 - y_4 \leq 0, \quad 2y_2 - 2y_3 + 4y_4 \leq 2, \quad y_i \geq 0, \quad \text{for all } i = 1, \dots, 4.$$

By setting  $y_5 = y_2 - y_3$  we finally result to the maximization of  $6y_1 + 2y_4 - 5y_5$  with respect to

$$-y_1 - y_5 \leq 2, \quad -2y_1 + y_4 - 4y_5 \leq 3, \quad -2y_1 - y_4 \leq 0, \quad 4y_4 + 2y_5 \leq 2, \quad y_1 \geq 0, \quad y_4 \geq 0,$$

with  $y_5$  unrestricted in sign.

**3.B.4.** Let us proceed with Sage for now, although we recommend readers to follow the discussion in Section 3.2.2, and perform the formal computations alone. For the given recurrence relation, the corresponding code is as follows:

```
from sympy import Function, rsolve
from sympy.abc import n
a = Function("a")
f = a(n+2) - 3*a(n+1) - 3*a(n)
initial = {a(1):1, a(2):3}
rsolve(f, a(n), initial)
```

As an answer, Sage returns the following:

$$-\sqrt{21} * (3/2 - \sqrt{21}/2) * n/21 + \sqrt{21} * (3/2 + \sqrt{21}/2) * n/21.$$

In other words, the solution is given by

$$x_n = \frac{1}{\sqrt{21}} \left( \frac{3 + \sqrt{21}}{2} \right)^n - \frac{1}{\sqrt{21}} \left( \frac{3 - \sqrt{21}}{2} \right)^n.$$

**3.B.7.** A verification in Sage can be obtained as follows:

```
from sympy import Function, rsolve
from sympy.abc import n
a = Function('a')
f = a(n+2) - 2*a(n+1) - 3*a(n)
initial = {a(0) : 0, a(1) : 1}
rsolve(f, a(n), initial)
```

Sage's output has the form  $-(-1) * n/4 + 3 * n/4$ .

**3.B.8.** To treat this task we begin with the characteristic equation, given by  $r^4 - r^3 - r + 1 = 0$ , or equivalently by  $(r - 1)^2(r^2 + r + 1) = 0$ . This has two complex roots given by

$$r_1 = -\frac{1}{2} + i\frac{\sqrt{3}}{2} = \cos(2\pi/3) + i\sin(2\pi/3), \quad r_2 = -\frac{1}{2} - i\frac{\sqrt{3}}{2} = \cos(2\pi/3) - i\sin(2\pi/3),$$

and the real root 1 which is double. Thus we can find basis of the solution space; this consists of the sequences

$$\{a_n\} := \left\{ \left( -\frac{1}{2} + i\frac{\sqrt{3}}{2} \right)^n \right\}_{n=1}^{\infty}, \quad \{b_n\} := \left\{ \left( -\frac{1}{2} - i\frac{\sqrt{3}}{2} \right)^n \right\}_{n=1}^{\infty},$$

together with  $\{n\}_{n=1}^{\infty}$  and the constant sequence  $\{1\}_{n=1}^{\infty}$ .

Our focus now shifts to establishing a real basis for the solution space, by replacing the two complex generators from the previous basis with sequences that are entirely real. These generators are “power series” whose elements are complex conjugates. We will discuss power series in Chapter 5. Now, it suffices to take as generators appropriate linear combinations of  $a_n, b_n$ , as in the Problem 3.B.5. This yields the following real basis:  $\{1\}_{n=1}^{\infty}, \{n\}_{n=1}^{\infty}, \{\cos(2n\pi/3)\}_{n=1}^{\infty}, \{\sin(2n\pi/3)\}_{n=1}^{\infty}$ .

**3.B.9.** The answer is given by the sequence  $(x_n)$  with general term  $x_n = -3(-1)^n - 2\cos(n \cdot (2\pi/3)) - 2\sqrt{3}\sin(n \cdot (2\pi/3))$ .

**3.B.11.** The general solution of the homogeneous equation is of the form  $a(-1)^n + b2^n$ . A particular solution is the constant  $-1/2$ . Therefore, the general solution of the given non-homogeneous equation without initial conditions has the form

$$a(-1)^n + b2^n - \frac{1}{2}.$$

Substituting in the initial conditions we obtain the constants  $a = -5/6, b = 5/6$ . Thus, the desired solution is given by the sequence  $x_n = -\frac{5}{6}(-1)^n + \frac{5}{6}2^n - \frac{1}{2}$ . To confirm this result by Sage use the block

```
from sympy import Function, rsolve
from sympy.abc import n
a = Function("a")
f = a(n+2) - a(n+1) - 2*a(n) - 1
int = {a(1) : 2, a(2) : 2}
rsolve(f, a(n), int)
```

**3.C.5.** In this case we have  $b_1 = 0, b_2 = 2 = b_3, b_4 = 1$ , and thus the Leslie matrix has the form

$$A = \begin{pmatrix} 0 & 2 & 2 & 1 \\ 0.4 & 0 & 0 & 0 \\ 0 & 0.5 & 0 & 0 \\ 0 & 0 & 0.2 & 0 \end{pmatrix}.$$

Its unique dominant eigenvalue is  $\lambda_1 \approx 1.09486$ . Since  $\lambda_1 > 0$ , the population increases with growth rate  $1.09486^t$ , in contrast with the population of bushbabies in 3.C.3. The normalized eigenvector associated with  $\lambda_1$  is given by  $X_1 \approx (0.639, 0.233, 0.106, 0.019)^T$ , hence the long term trends of the female population are as follows: 63.9% of age class A, 23.3% of age class B, 10.6% of age class C and 1.9% of age class D. Finally, we compute

$$A^{10} \approx \begin{pmatrix} 1.047 & 2.872 & 2.094 & 0.96 \\ 0.384 & 1.047 & 0.761 & 0.348 \\ 0.174 & 0.48 & 0.349 & 0.16 \\ 0.032 & 0.087 & 0.064 & 0.029 \end{pmatrix}, \quad p_{10} = A^{10}p_0 \approx (150.813, 54.956, 25.171, 4.598)^T.$$

Therefore, the female population after ten years will consist of approximately 235 members (this is the sum of the entries of  $p_{10}$ ), and the total population of the colony (both females and males) after the same period will approximately reach the level

of 470 galagos. Below is the required diagram representing the exponential growth of the female population for a duration of thirty years.

**3.D.1.** Let us first recall that the norm of an arbitrary vector  $z \in \mathbb{C}^n$  with respect the standard Hermitian form  $\langle \cdot, \cdot \rangle$  reads by  $\|z\|^2 = \sum_{j=1}^n z_j \bar{z}_j$ . For the vectors  $x = (3 + 2i, 1 - i, -i)^T$  and  $y = (2 - 2i, 1 - i, 2 + i)^T$  in  $\mathbb{C}^3$  one computes

$$\langle x, y \rangle = y^* x = \begin{pmatrix} 2 + 2i & 1 + i & 2 - i \end{pmatrix} \begin{pmatrix} 3 + 2i \\ 1 - i \\ -i \end{pmatrix} = (3 + 2i)(2 + 2i) + (1 - i)(1 + i) - i(2 - i) = 3 + 8i.$$

Moreover, we see that

$$\begin{aligned} \|x\| &= \sqrt{(3 + 2i)(3 - 2i) + (1 - i)(1 + i) - i^2} = 4, \\ \|y\| &= \sqrt{(2 - 2i)(2 + 2i) + (1 - i)(1 + i) + (2 + i)(2 - i)} = \sqrt{15}. \end{aligned}$$

On the other hand, the vector  $x - y$  has the expression  $x - y = (1 + 4i, 0, -(2 + 2i))^T$ . Therefore,  $d(x, y) = \sqrt{(1 + 4i)(1 - 4i) + (2 + 2i)(2 - 2i)} = 5$ . Since  $\|x\| = 4$  and  $\|y\| = \sqrt{15}$ , the normalized vectors with  $\|\hat{x}\| = 1 = \|\hat{y}\|$  are given by  $\hat{x} = \frac{1}{4}(3 + 2i, 1 - i, -i)$  and  $\hat{y} = \frac{1}{\sqrt{15}}(2 - 2i, 1 - i, 2 + i)$ , respectively. See the Problem 3.D.2 how one can verify these results in Sage.

**3.D.3.** (a) For the vectors  $v = (1 + i, 2 - i)^T$  and  $w = (3 - 2i, 1 + i)^T$  in  $\mathbb{C}^2$  we compute

$$\langle v, w \rangle = w^* v = \begin{pmatrix} 3 + 2i & 1 - i \end{pmatrix} \begin{pmatrix} 1 + i \\ 2 - i \end{pmatrix} = (3 + 2i)(1 + i) + (1 - i)(2 - i) = 2 + 2i.$$

Moreover, we see that

$$\|v\|^2 = v^* v = (1 + i)(1 - i) + (2 - i)(2 + i) = 7, \quad \|w\|^2 = w^* w = (3 - 2i)(3 + 2i) + (1 + i)(1 - i) = 15.$$

Recall that the angle  $\theta$  between  $v, w$  is defined by the equation (compare with the formula given in 2.3.22 for the real case)

$$\cos \theta = \frac{\operatorname{Re}(\langle v, w \rangle)}{\|v\| \|w\|},$$

where  $\operatorname{Re}(z)$  denotes the real part of a complex number  $z \in \mathbb{C}$ . Hence it follows that  $\theta = \cos^{-1} \left( \frac{2}{\sqrt{7}\sqrt{15}} \right) \approx 1.37435 \approx 78.75^\circ$ . To verify all these results in Sage one can use the following cell:

```
v = vector(CDF, [1+I, 2-I])
w = vector(CDF, [3-2*I, 1+I])
vinnerw=w.hermitian_inner_product(v)
print("The standard Hermitian product of the vectors v=",v,"
and w=",w," "equals to",vinnerw)
vn=N(v.norm()^2, digits=3)
print("The square norm of the vector v=", v, "" "equals to", vn)
wn=N(w.norm()^2, digits=3)
print("The square norm of the vector w=", w, "" "equals to", wn)
theta=arccos(w.hermitian_inner_product(v).real()/(norm(v)*norm (w)))
```

```

print("The angle between the vectors v and w equals to",
N(theta, digits = 4), "radians" )
print("The angle between the vectors v and w equals to",
N(theta*180/pi, digits = 4), "degrees")
    
```

In this block we used the option CDF (Complex Double Field) when introducing the vectors  $v, w$ , similarly with the description given in 3.D.2. Recall that CDF approximates the field of complex numbers using double-precision floating point numbers. Alternatively, we could use the option CC (for this task, the result would remain the same). The CDF option helps to save some space in the output, compared to CC. Finally, for your convenience, in this block Sage was programmed to provide more detailed responses, than usual, as one can see in the output below:

```

The standard Hermitian product of the vectors v= (1.0 + 1.0*I, 2.0 - 1.0*I)
and w= (3.0 - 2.0*I, 1.0 + 1.0*I) equals to 2.0 + 2.0*I
The square norm of the vector v= (1.0 + 1.0*I, 2.0 - 1.0*I) equals to 7.00
The square norm of the vector w= (3.0 - 2.0*I, 1.0 + 1.0*I) equals to 15.0
The angle between the vectors v and w equals to 1.374 radians
The angle between the vectors v and w equals to 78.75 degrees
    
```

Similarly can be treated the cases (b) and (c) for which we only present the results.

(b)  $\langle v, w \rangle = 5 + 4i$ ,  $\|v\|^2 = 10$ ,  $\|w\|^2 = 7$ ,  $\cos \theta \approx 0.59$ ,  $\theta \approx 0.93 \approx 53.5^\circ$ .

(c)  $\langle v, w \rangle = 2 - 4i$ ,  $\|v\|^2 = 5$ ,  $\|w\|^2 = 19$ ,  $\cos \theta \approx 0.205$ ,  $\theta \approx 1.364 \approx 78.1^\circ$ .

**3.D.4.** One can easily check the following properties of  $f$ ;  $f(u + w, v) = f(u, v) + f(w, v)$ ,  $f(au, v) = af(u, v)$  and  $\overline{f(v, u)} = f(u, v)$ , for all  $u, v \in V = \mathbb{F}^2$  and  $a \in \mathbb{F}$ . Moreover, if  $u = (x_1, x_2)^T$  we have

$$f(u, u) = x_1\bar{x}_1 + 4x_1\bar{x}_2 + 4x_2\bar{x}_1 + x_2\bar{x}_2 = |x_1|^2 + 4(x_1\bar{x}_2 + x_2\bar{x}_1) + |x_2|^2,$$

where we used the relation  $z\bar{z} = |z|^2$  with  $z \in \mathbb{F}$ . However,  $x_1\bar{x}_2 + x_2\bar{x}_1 = |x_1 + x_2|^2 - |x_1|^2 - |x_2|^2$ , and hence the above relation reduces to  $f(u, u) = -3|x_1|^2 + 4|x_1 + x_2|^2 - 3|x_2|^2$ . Therefore, we may have  $f(u, u) < 0$  for some  $u \neq 0$ . For example,  $f(u, u) = -6$  for  $u = (1, -1)^T$ . This shows that  $f$  cannot be a scalar product on  $V$ .

**3.D.6.** We see that  $\rho_{a,b}(u, u) = au_1^2 + bu_2^2 \geq 0$  and the only way that this is zero is when  $u = 0$ , that is,  $u_1 = u_2 = 0$ . This proves positive definiteness. Moreover, by the commutativity of real numbers we get

$$\overline{\rho_{a,b}(v, u)} = \rho_{a,b}(v, u) = av_1u_1 + bv_2u_2 = \rho_{a,b}(u, v).$$

Hence  $\rho_{a,b}$  is Hermitian symmetric. Next,

$$\rho_{a,b}(u, v + w) = au_1(v_1 + w_1) + bu_2(v_2 + w_2) = (au_1v_1 + bu_2v_2) + (au_1w_2 + bu_2w_2) = \rho_{a,b}(u, v) + \rho_{a,b}(u, w),$$

and moreover  $\rho_{a,b}(cu, v) = \rho_{a,b}(u, cv) = c\rho_{a,b}(u, v)$  for any  $c \in \mathbb{R}$ . This proves that  $\rho_{a,b}$  is a scalar product on  $\mathbb{R}^2$ . Then the angle between  $u, v$  satisfies

$$\cos \theta = \frac{\rho_{a,b}(u, v)}{\|u\|_{\rho_{a,b}} \|v\|_{\rho_{a,b}}}.$$

For  $a = 2$  and  $b = 1$  we compute  $\rho_{2,1}(u, v) = 2 \cdot 1 + 1 \cdot (-1) = 1$ , and  $\|u\|_{\rho_{2,1}} = \sqrt{2 \cdot 1 + 1 \cdot 1} = \sqrt{3} = \|v\|_{\rho_{2,1}}$ . Thus  $\cos \theta = 1/3$  and so  $\theta = \arccos(1/3)$ . With respect to the dot product the vector  $u, v$  are orthogonal,  $u \cdot v = 0$ , hence they obviously form a different angle in comparison with the one appearing with respect to  $\rho_{2,1}$ .

**3.D.7.** For any vector  $x \in \mathbb{C}^n$  we see that  $\rho_A(x, x) = x^* A^* A x = (Ax)^* A x = \langle Ax, Ax \rangle \geq 0$ , where  $\langle \cdot, \cdot \rangle$  is the standard Hermitian form on  $\mathbb{C}^n$ . Thus  $\rho_A(x, x) \geq 0$  with the equality holding if and only if  $Ax = 0$ . Let us denote by  $A_1, \dots, A_n$  the  $n$  columns of  $A$ , such that  $A = (A_1 \ A_2 \ \dots \ A_n)$  with  $A_i = (a_{1i}, a_{2i}, \dots, a_{mi})^T$ , for any  $1 \leq i \leq n$ . Recall the column space of  $A$ :

$$C(A) = \{w \in \mathbb{C}^m : w = \sum_{i=1}^n x_i A_i, \text{ with } x_i \in \mathbb{C}\} = \{w \in \mathbb{C}^m : w = Ax\},$$

where  $x = (x_1, \dots, x_n)^T \in \mathbb{C}^n$ , and the second relation holds since the vector  $Ax \in \mathbb{C}^m$  is given by a linear combination of the columns of  $A$  with elements of  $x$ , i.e.,  $Ax = \sum_{i=1}^n x_i A_i$ . Hence our assumption that  $C(A)$  is  $n$ -dimensional, is equivalent to say that  $A$  consists of  $n$  linearly independent column vectors, or that the conditions  $Ax = 0$  and  $x = 0$  are equivalent each other. This shows that  $\rho_A$  is positive definite. Also, since  $\rho_A(x, y) \in \mathbb{C}$  for any  $x, y \in \mathbb{C}^n$  and so  $(\rho_A(x, y))^* = \overline{\rho_A(x, y)}$  we see that

$$\rho_A(x, y) = (Ay)^*(Ax) = ((Ax)^*(Ay))^* = (x^* A^* Ay)^* = (\rho_A(y, x))^* = \overline{\rho_A(y, x)},$$

for any  $x, y \in \mathbb{C}^n$ . Moreover,  $\rho_A(x, y + z) = (y + z)^*(A^* Ax) = y^* A^* Ax + z^* A^* Ax = \rho_A(x, y) + \rho_A(x, z)$  for any three vectors  $x, y, z$ , while for some  $a \in \mathbb{C}$  and any  $x, y \in \mathbb{C}^n$  we get  $\rho_A(ax, y) = (Ay)^* A ax = a(Ay)^* Ax = a\rho_A(x, y)$ . Thus  $\rho$  is an inner product.

We should mention that by the definition of  $\rho_A$  one gets  $\rho_A(x, y) = y^* A^* A x = (A y)^*(A x) = \langle A x, A y \rangle$ , where  $A x$  is viewed as a (column) vector. This provides of course an alternative and much shorter verification of the claim, but for the convenience of the reader we kept both arguments. Finally observe that when  $A$  is the identity matrix, then  $\rho_A$  is nothing than the standard Hermitian form on  $\mathbb{C}^n$ .

**3.D.9.** (a) For a real scalar product space  $(V, \langle \cdot, \cdot \rangle)$  we have  $\langle u, w \rangle = \langle w, u \rangle$ , for all  $u, w \in V$  and hence

$$\|u + w\|^2 = \langle u + w, u + w \rangle = \|u\|^2 + \|w\|^2 + 2\langle u, w \rangle, \quad u, w \in V.$$

The first claim is now direct.

For a complex scalar product space  $(V, \langle \cdot, \cdot \rangle)$  the bilinear form  $\langle \cdot, \cdot \rangle$  should satisfy  $\langle u, w \rangle = \overline{\langle w, u \rangle}$ , for all  $u, w \in V$ . This requirement prevents the form  $\langle \cdot, \cdot \rangle$  from having the same symmetry, as in the real case. For example, consider  $\mathbb{C}^2$  endowed with the standard (positive) Hermitian form  $\langle u, w \rangle = u_1 \bar{w}_1 + u_2 \bar{w}_2$ , with  $u, w \in \mathbb{C}^2$ . Given the vectors  $u = (0, i)^T \in \mathbb{C}^2$  and  $w = (0, 1)^T \in \mathbb{C}^2$  we see that  $\langle u, w \rangle = i$  and  $\|u + w\|^2 = 2$ ,  $\|u\|^2 = i\bar{i} = 1$ ,  $\|w\|^2 = 1$ . Hence we have  $\|u + w\|^2 = \|u\|^2 + \|w\|^2$  but  $u, w$  are not orthogonal (observe however that if  $\langle u, w \rangle = 0$ , then  $\|u + w\|^2 = \|u\|^2 + \|w\|^2$  still makes sense on a complex inner product space, see the proof of the theorem in 3.4.2).

(b) If  $u + w \perp u - w$  then  $0 = \langle u + w, u - w \rangle = \|u\|^2 - \|w\|^2$ . Thus  $\|u\|^2 = \|w\|^2$ , which gives  $\|u\| = \|w\|$ . Conversely, let  $u, w \in V$  such that  $\|u\| = \|w\|$ . Then  $\langle u + w, u - w \rangle = \|u\|^2 - \|w\|^2 = 0$ , hence  $u + w \perp u - w$ .

**3.D.10.** (a) From the definition of a unitary space given in 3.4.1, we see that

$$\|u + av\|^2 = \langle u + av, u + av \rangle = \langle u, u \rangle + \bar{a}\langle u, v \rangle + a\langle v, u \rangle + a\bar{a}\langle v, v \rangle = \|u\|^2 + 2\operatorname{Re}(\bar{a}\langle u, v \rangle) + |a|^2\|v\|^2$$

and similarly  $\|u - av\|^2 = \|u\|^2 - 2\operatorname{Re}(\bar{a}\langle u, v \rangle) + |a|^2\|v\|^2$ , for any two vector  $u, v \in V$  and scalar  $a$ . Thus,  $\|u + av\| = \|u - av\|$  if and only if  $\operatorname{Re}(\bar{a}\langle u, v \rangle) = 0$ . Since the latter relation should hold for any scalar  $a$ , taking  $a = 1$  for the real case, and  $a = i$  for the complex case, we see that  $\langle u, v \rangle = 0$ .

(b) The proof is similar and we leave it for practice.

**3.D.13.** According to part (4) of the main theorem in Section 3.4.2, for any two vectors  $x, y \in V$  we have the (Fourier) expansions  $x = \sum_j \langle x, E_j \rangle E_j$  and  $y = \sum_k \langle y, E_k \rangle E_k$ . Thus

$$\langle x, y \rangle = \left\langle \sum_j \langle x, E_j \rangle E_j, \sum_k \langle y, E_k \rangle E_k \right\rangle = \sum_{j,k} \langle x, E_j \rangle \overline{\langle y, E_k \rangle} \langle E_j, E_k \rangle = \sum_j \langle x, E_j \rangle \overline{\langle y, E_j \rangle}.$$

**3.D.14.** We can easily check that the given set  $\{E_1 = (-1, 1, 2), E_2 = (2, 0, 1), E_3 = (1, 5, -2)\}$  is an orthogonal basis of  $\mathbb{R}^3$ . We only prove orthogonality by Sage and leave a formal verification of the claim to the reader. Let us program Sage to do this quickly, as follows:

```
E1 = vector(QQbar, [-1, 1, 2])
E2 = vector(QQbar, [2, 0, 1])
E3 = vector(QQbar, [1, 5, -2])
B = [E1, E2, E3]
ips = [B[i].dot_product(B[j])
for i in range(2) for j in range(i+1, 2)]
all([ip == 0 for ip in ips])
```

Sage's answer is True. Notice in the same way we can also verify that the vectors  $E_i$  are *not* of unit length for all  $i = 1, 2, 3$ . This can be done by adding the cell

```
ips2 = [B[i].dot_product(B[i])
for i in range(2)]
all([ip2 == 1 for ip2 in ips2])
```

and in this case Sage prints out False.

Now recall that if  $\{u_1, \dots, u_m\}$  is an orthogonal basis of a unitary space  $(V, \langle \cdot, \cdot \rangle)$ , then any vector  $u \in V$  is expressed by

$$u = \sum_{k=1}^m \frac{\langle u, u_k \rangle}{\|u_k\|^2} u_k.$$

Let us apply this rule for our task. We compute

$$\langle u, E_1 \rangle = -12, \quad \langle u, E_2 \rangle = 8, \quad \langle u, E_3 \rangle = 24, \quad \|E_1\|^2 = 6, \quad \|E_2\|^2 = 5, \quad \|E_3\|^2 = 30.$$

Thus  $u = -\frac{12}{6}E_1 + \frac{8}{5}E_2 + \frac{24}{30}E_3$ .

**3.D.15.** We will apply a method that relies on the Cauchy-Schwarz inequality, see 3.4.3, as it is suggested in the statement. Set  $u = (\sqrt{a+2b}, \sqrt{b+2c}, \sqrt{c+2a})^T$ ,  $v = (1, 1, 1)^T$  and view  $u, v$  as vectors in  $\mathbb{R}^3$ . Their dot product is given by

$\langle u, v \rangle = v^T u = \sqrt{a+2b} + \sqrt{b+2c} + \sqrt{c+2a}$ , while  $\|u\|^2 = (a+2b) + (b+2c) + (c+2a) = 3(a+b+c)$  and  $\|v\|^2 = 3$ . An application of the Cauchy-Schwarz inequality  $\langle u, v \rangle \leq \|u\| \|v\|$  yields the expression

$$\sqrt{a+2b} + \sqrt{b+2c} + \sqrt{c+2a} \leq 3\sqrt{a+b+c},$$

which gives the result after dividing with  $\sqrt{a+b+c}$  (which is non-zero by the assumption in the statement).

**3.D.16.** The standard basis  $\underline{e}$  is an orthonormal basis of  $(\mathbb{C}^3, \langle \cdot, \cdot \rangle)$  and hence we see that

$$u = \sum_{j=1}^3 \langle u, e_j \rangle e_j = (2+i)e_1 + (-1+2i)e_2 + (3-i)e_3,$$

that is,  $\langle u, e_1 \rangle = 2+i$ ,  $\langle u, e_2 \rangle = -1+2i$  and  $\langle u, e_3 \rangle = 3-i$ . Now, according to Parseval's equality (see 3.4.3) we should have

$$\|u\|^2 = \sum_{j=1}^n |\langle u, e_j \rangle|^2 = |2+i|^2 + |-1+2i|^2 + |3-i|^2 = (2+i)(2-i) + (-1+2i)(-1-2i) + (3-i)(3+i) = 20,$$

where we applied the rule  $|z|^2 = z\bar{z}$ , with  $z \in \mathbb{C}$ . On the other hand, we also see that  $\|u\|^2 = \langle u, u \rangle = (2+i)\overline{(2+i)} + (-1+2i)\overline{(-1+2i)} + (3-i)\overline{(3-i)} = 20$ , and we are done.

**3.D.19.** When we rotate a point in  $\mathbb{R}^3$  about a particular axis, the coordinate corresponding to that axis remains unchanged. The remaining two coordinates are given by the well known rotation in the plane (see Chapter 1). This yields the matrices

$$R_x(\theta) = \begin{pmatrix} 1 & 0 & 0 \\ 0 & \cos \theta & -\sin \theta \\ 0 & \sin \theta & \cos \theta \end{pmatrix}, \quad R_y(\theta) = \begin{pmatrix} \cos \theta & 0 & \sin \theta \\ 0 & 1 & 0 \\ -\sin \theta & 0 & \cos \theta \end{pmatrix}, \quad R_z(\theta) = \begin{pmatrix} \cos \theta & -\sin \theta & 0 \\ \sin \theta & \cos \theta & 0 \\ 0 & 0 & 1 \end{pmatrix}$$

which represent the rotation about the  $x$ -axis, the  $y$ -axis and the  $z$ -axis, respectively.

Note the sign of  $\theta$  in the rotation matrix about the  $y$ -axis. As with any other rotation, we want the rotation about the  $y$ -axis to be in the "positive sense". This means that when viewed from the negative  $y$ -axis direction, the rotation should appear anti-clockwise. Consequently, the signs in the rotation matrices depend on the orientation of our coordinate system.

Usually, in the 3-dimensional space the "right-handed coordinate system" is chosen, also known as "dextrorotary coordinate system". In a right-handed coordinate system, if you orient your right hand so that your thumb points along the positive  $x$ -axis and curl your fingers naturally, your fingers will point in the direction of the  $y$ -axis, followed by the  $z$ -axis. In particular, the index finger will point the positive  $y$ -axis and the middle finger will point the positive  $z$ -axis. For example, a positive rotation  $R_x(\theta)$  about the  $x$ -axis occurs perpendicular to the  $yz$ -plane, and a negative rotation will occur in the  $yz$ -plane, with opposite direction to the positive rotation. Notice when looking from positive  $x$  towards the origin, a positive rotation is counterclockwise. This configuration visually confirms the order  $x \rightarrow y \rightarrow z$  and its cyclical nature is evident in how axes are sequentially rotated:  $x \rightarrow y \rightarrow z \rightarrow x \rightarrow \dots$  for a positive cycle and  $x \rightarrow z \rightarrow y \rightarrow x \rightarrow \dots$  for a negative one.

**3.D.20.** The first task has been analyzed for unitary transformations in 3.4.4. Let us present an alternative proof. Suppose that  $U \in \text{Mat}_n(\mathbb{C})$  is unitary and consider the scalar product  $\langle Ux, y \rangle$ . Based on the relation  $E = UU^{-1} = U^{-1}U$ , where  $E$  is the identity  $n \times n$  matrix, we get  $\langle Ux, y \rangle = \langle Ux, UU^{-1}y \rangle = \langle x, U^{-1}y \rangle$ . On the other hand, by the definition of the conjugate transpose matrix we have  $\langle Ux, y \rangle = \langle x, U^*y \rangle$  for any  $x, y \in \mathbb{C}^n$ . By comparing these two relations and using bilinearity, we arrive at the following relation:

$$\langle x, (U^{-1} - U^*)y \rangle = 0, \quad (*)$$

for any  $x, y \in \mathbb{C}^n$ . We can now utilize the fact that  $\langle \cdot, \cdot \rangle$  is a non-degenerate bilinear form. Hence, by the relation (\*) we deduce that  $U^{-1} - U^* = 0$ , which implies that  $U^{-1} = U^*$ .

Conversely, assume that  $U^*U = E$ . Then, for any  $x \in \mathbb{C}^n$  we have  $\|Ux\|^2 = \langle Ux, Ux \rangle = \langle x, U^*Ux \rangle = \langle x, x \rangle = \|x\|^2$ , and hence  $U$  is unitary.

To prove that  $U(n)$  is a group, we can proceed similarly to the case of  $O(n)$ . Hence we need to verify that the composition of two unitary transformations and the inverse of a unitary transformation, both retain the same property. Let  $A, B \in U(n)$ . Then  $A^{-1} = A^*$  and  $B^{-1} = B^*$ , respectively. Moreover  $(AB)^* = B^*A^* = B^{-1}A^{-1} = (AB)^{-1}$ , and hence  $AB$  is also unitary. The verification of the second property is left as an exercise for the reader.

Finally, the claim for the determinant occurs by the relation  $\det(E) = 1 = \det(U^*U) = \det(U^*)\det(U) = \overline{\det(U)}\det(U) = |\det(U)|^2$ . This implies that the absolute value of the determinant of any unitary matrix is equal to one.

**3.D.22.** Consider linear maps  $\varphi, \psi : V \rightarrow V$  as in the statement, and let  $A, B$  be their matrices. In Problem 2.E.56 we proved that  $A, B$  must satisfy all the analogous properties listed in the statement. Since  $\varphi, \psi$  are determined by their matrices, all the formulas follow. Alternatively, one can work in terms of endomorphisms and prove all the relations based on the definition of the adjoint map. We leave such a description to the reader.

**3.D.25.** For  $A$  we have  $A^* = A$  and hence  $A$  is Hermitian (i.e., self-adjoint). We can directly verify this by Sage, as follows:

```
A=matrix(CC, [[sqrt(2), I, 1-I], [-I, 10, sqrt(2)+I], [1+I, sqrt(2)-I, 0]])
A.is_hermitian()
```

This command returns True. Alternatively, we can check this by verifying if  $A$  equals its conjugate transpose:

```
A=matrix(CC, [[sqrt(2), I, 1-I], [-I, 10, sqrt(2)+I], [1+I, sqrt(2)-I, 0]])
A == A.conjugate_transpose()
```

which again returns True.

Among the remaining matrices,  $B$  and  $C$  are Hermitian, while  $D$  is not. For the matrix  $B$ , verifying this property using Sage may take more time compared to a manual computation, but it is useful for handling parametric matrices. The verification process is as follows:

```
a = var("a"); b = var("b")
assume(a, "real"); assume(b, "real")
B = matrix(SR, 2, 2, [[a, I+b], [-I+b, sqrt(abs(a))]])
B.is_hermitian()
```

We leave the verification for the matrices  $C$  and  $D$  to the reader.

**3.D.26.** Under our assumptions for the matrices  $A, B$ , we need to show  $\text{tr}(A^*A) = \text{tr}(B^*B)$ . This is equivalent to proving that  $\sum_{i,j=1}^n |a_{ij}|^2 = \sum_{i,j=1}^n |b_{ij}|^2$ , providing an alternative reformulation of the problem. Since  $B = U^*AU$ , we have  $B^* = (U^*AU)^* = U^*A^*U$ . Therefore

$$\text{tr}(B^*B) = \text{tr}(U^*A^*UU^*AU) = \text{tr}(U^*A^*AU) = \text{tr}(A^*A).$$

This follows from the property that similar matrices  $X, Y$ , i.e.,  $X = P^{-1}YP$ , have the same trace,  $\text{tr}(X) = \text{tr}(Y)$ , and from the fact that  $U$  is unitary, i.e.,  $U^{-1} = U^*$ .

**3.D.27.** To compute its adjoint operator  $\varphi^* : \mathbb{R}^3 \rightarrow \mathbb{R}^2$ , we need to find the matrix representation of  $\varphi^*$  with respect to the standard bases of  $\mathbb{R}^3$  and  $\mathbb{R}^2$ . In matrix form we have

$$\varphi \left( \begin{pmatrix} x \\ y \end{pmatrix} \right) = \begin{pmatrix} \sqrt{2} & 1 \\ 1 & -1 \\ 0 & 2 \end{pmatrix} \begin{pmatrix} x \\ y \end{pmatrix}.$$

Thus, the matrix of  $\varphi$  with respect to the standard orthonormal bases is given by

$$A = \begin{pmatrix} \sqrt{2} & 1 \\ 1 & -1 \\ 0 & 2 \end{pmatrix}.$$

Now, to compute  $\varphi^*$  we can take the conjugate transpose of  $A$ , but since  $A$  has only real entries, this simplifies to just the transpose of  $A$ : We compute

$$A^* = A^T = \begin{pmatrix} \sqrt{2} & 1 & 0 \\ 1 & -1 & 2 \end{pmatrix}.$$

and hence  $\varphi^* \left( \begin{pmatrix} x \\ y \\ z \end{pmatrix} \right) = \begin{pmatrix} \sqrt{2}x + y \\ x - y + 2z \end{pmatrix}$ , with  $x, y, z \in \mathbb{R}$ .

For the second task, we need to verify that  $B = B^*$ . The conjugate transpose of the matrix  $B$  is given by

$$B^* = \bar{B}^T = \begin{pmatrix} 10 & 5 + 5i & 3 + 2i \\ 5 - 5i & 5 & \sqrt{2}i \\ 3 - 2i & -\sqrt{2}i & 0 \end{pmatrix}.$$

Hence  $B = B^*$  and consequently  $\psi$  is a self-adjoint operator.

**3.D.28.** The adjoint operator of  $\text{tr} : \text{Mat}_m(\mathbb{F}) \rightarrow \mathbb{F}$  is a linear map  $\text{tr}^* : \mathbb{F} \rightarrow \text{Mat}_m(\mathbb{F})$ , assigning to any scalar  $z \in \mathbb{F}$  a  $m \times m$  matrix over  $\mathbb{F}$ . It is determined by the relation

$$\mathcal{B}(\text{tr}(A), z) = \mathcal{B}(A, \text{tr}^*(z)),$$

for any  $z \in \mathbb{F}$  and  $A \in \text{Mat}_m(\mathbb{F})$ . Observe here that on the left-hand side  $\mathcal{B}$  acts on scalars (viewed as trivial  $1 \times 1$  matrices). By the definition of  $\mathcal{B}$ , we have

$$\mathcal{B}(\text{tr}(A), z) = \bar{z} \text{tr}(A).$$

Setting  $\text{tr}^*(z) = B$  for some matrix  $B \in \text{Mat}_m(\mathbb{F})$ , we also obtain  $\mathcal{B}(A, \text{tr}^*(z)) = \text{tr}(B^*A)$ . Hence, we need  $\bar{z} \text{tr}(A) = \text{tr}(B^*A)$ . Based on the properties of the trace described in 2.C.38, we see that  $\bar{z} \text{tr}(A) = \text{tr}(\bar{z}A) = \text{tr}(\bar{z}EA)$ , where  $E$  denotes the  $m \times m$  matrix. By comparing these two relations and using the non-degeneracy of  $\mathcal{B}$ , we find that  $B^* = \bar{z}E$ . Therefore

$$B = (B^*)^* = (\bar{z}E)^* = E^* \bar{z} = Ez,$$

which means that  $\text{tr}^*(z) = zE$  from any  $z \in \mathbb{F}$ .

**3.D.29.** By definition, the linear map  $\text{proj}_W : V \rightarrow V$  sends  $u \in V$  to its orthogonal projection  $\text{proj}_W u$  on  $W$ . Let  $W^\perp$  be the orthogonal complement of  $W$  with respect to  $\langle \cdot, \cdot \rangle$ . Recall by Chapter 2 the direct sum decomposition  $V = W \oplus W^\perp$ , which for any  $u \in V$  implies that

$$u = \text{proj}_W u + \text{proj}_{W^\perp} u = \text{proj}_W u + (u - \text{proj}_W u) = P(u) + (u - P(u)),$$

where  $P(u) := \text{proj}_W u$ . Then, by linearity we see that

$$\langle P(u), w \rangle = \langle P(u), P(w) + (w - P(w)) \rangle = \langle P(u), P(w) \rangle + \langle P(u), w - P(w) \rangle,$$

for any  $u, w \in V$ . However, by assumption  $P(u) \in W$  and  $(w - P(w)) \in W^\perp$ . Thus, the second component in the right-hand side of the previous relation vanishes, which yields the relation  $\langle P(u), w \rangle = \langle P(u), P(w) \rangle$ . In a similar way one computes  $\langle u, P(w) \rangle = \langle P(u), P(w) \rangle$ , and the result follows.

**3.D.30.** The first claim is direct. To present a counterexample, use the matrix  $A = \begin{pmatrix} 1 & 1 & 0 \\ 0 & 1 & 1 \\ 1 & 0 & 1 \end{pmatrix} \in \text{Mat}_3(\mathbb{R})$ . Then a direct computation shows that

$$A^* = A^T = \begin{pmatrix} 1 & 0 & 1 \\ 1 & 1 & 0 \\ 0 & 1 & 1 \end{pmatrix}, \quad AA^* = A^*A = \begin{pmatrix} 2 & 1 & 1 \\ 1 & 2 & 1 \\ 1 & 1 & 2 \end{pmatrix}.$$

Hence  $A$  is normal, but is not orthogonal since  $AA^T = A^T A \neq E$ .

**3.D.32.** We present directly the code including some comments within the code:

```
# Define the matrix phi symbolically
phi = Matrix(SR, [[2, 1+I, 0],
                 [1-I, 3, 0],
                 [0, 0, 1]])
# Verify that phi is normal
is_normal = phi*phi.conjugate_transpose() == phi.conjugate_transpose() * phi
print("Is phi normal?:", is_normal)
# Compute eigenvalues and eigenvectors symbolically
eigenvalues = phi.eigenvalues()
eigenvectors = phi.eigenvectors_right()
# Display eigenvalues and eigenvectors
print("Eigenvalues:", eigenvalues)
print("Eigenvectors:")
for eig in eigenvectors:
    print(f"Eigenvalue: {eig[0]}, Eigenvectors: {eig[1]}")
# Extract eigenvectors corresponding to distinct eigenvalues
if len(eigenvectors) >= 2:
    v1 = eigenvectors[0][1][0] # Eigenvector for the first eigenvalue
    v2 = eigenvectors[1][1][0] # Eigenvector for the second eigenvalue

    # Compute the inner product of the eigenvectors
    inner_product = v1.inner_product(v2)
    print("Inner product of v1 and v2:", inner_product)

    # Verify if they are orthogonal
    is_orthogonal = inner_product == 0
    print("Are v1 and v2 orthogonal?:", is_orthogonal)
else:
    print("Not enough distinct eigenvalues to check orthogonality.")
```

Let us also display Sage's output:

```
Is phi normal?: True
Eigenvalues: [1, 1, 4]
Eigenvectors:
Eigenvalue: 1, Eigenvectors: [(1, 1/2*I - 1/2, 0), (0, 0, 1)]
Eigenvalue: 4, Eigenvectors: [(1, -I + 1, 0)]
Inner product of v1 and v2: I + 1
Are v1 and v2 orthogonal?: (I + 1) == 0
```

Notice the comparison  $(I + 1) == 0$  is used to determine if the computed inner product is zero. Since  $1 + i \neq 0$  the result of the comparison is `False`, indicating that the eigenvectors are not orthogonal. We leave a formal computation for practice.

**3.D.34.** Such an example is given by the matrix  $A = \begin{pmatrix} 0 & 1-i \\ 1-i & 0 \end{pmatrix}$ . Indeed, since  $A^* = \bar{A}^T = \begin{pmatrix} 0 & 1+i \\ 1+i & 0 \end{pmatrix} \neq \pm A$ , the matrix at hand is neither Hermitian, nor skew-Hermitian. However,  $A$  is a normal matrix since

$$AA^* = \begin{pmatrix} 0 & 1-i \\ 1-i & 0 \end{pmatrix} \begin{pmatrix} 0 & 1+i \\ 1+i & 0 \end{pmatrix} = \begin{pmatrix} 2 & 0 \\ 0 & 2 \end{pmatrix} = \begin{pmatrix} 0 & 1+i \\ 1+i & 0 \end{pmatrix} \begin{pmatrix} 0 & 1-i \\ 1-i & 0 \end{pmatrix} = A^*A.$$

Here is a detailed verification with Sage:

```
# Define the matrix
A = Matrix([[0, 1 - I], [1 - I, 0]])
# Compute the conjugate transpose (Hermitian transpose) of A
A_H = A.H
# Check if A is Hermitian
is_hermitian = A == A_H
# Check if A is skew-Hermitian
is_skew_hermitian = A == -A_H
# Compute A * A^H
A_AH = A * A_H
# Compute A^H * A
AH_A = A_H * A
# Check if A is normal
is_normal = A_AH == AH_A
# Print the results
print("Matrix A:")
print(A)
print("\nConjugate Transpose of A:")
print(A_H)
print("\nIs A Hermitian?")
print(is_hermitian)
print("\nIs A Skew-Hermitian?")
print(is_skew_hermitian)
print("\nIs A Normal?")
print(is_normal)
```

**3.D.35.** We will mainly use Sage and leave the formal computations for practice. The given matrix  $A$  is symmetric,  $A = A^T$ . The following cell verifies this statement in Sage:

```
A = matrix(SR, [[1, 2, 6], [2, 0, 2], [6, 2, 1]])
A.T == A
```

Recall also that the eigenvalues of  $A$  occur by the command

```
A.eigenvalues()
```

They are given by  $\lambda_1 = 8$ ,  $\lambda_2 = -5$  and  $\lambda_3 = -1$ . As for the eigenvectors, use the cell

```
A.eigenvectors_right()
```

Sage's output is the list

```
[(8, [(1, 1/2, 1)], 1), (-1, [(1, -4, 1)], 1), (-5, [(1, 0, -1)], 1)]
```

Thus the vectors  $u_1 = (2, 1, 2)^T$ ,  $u_2 = (1, 0, -1)^T$  and  $u_3 = (1, -4, 1)^T$  are eigenvectors of  $A$ , corresponding to the eigenvalues  $\lambda_1$ ,  $\lambda_2$ , and  $\lambda_3$ , respectively. Observe that  $\langle u_1, u_2 \rangle = 0$ ,  $\langle u_1, u_3 \rangle = 0$ , and  $\langle u_2, u_3 \rangle = 0$  where  $\langle \cdot, \cdot \rangle$  is the dot product on  $\mathbb{R}^3$ . Thus, the eigenvectors of  $A$  are orthogonal to each other. We also compute  $\|u_1\| = 3$ ,  $\|u_2\| = \sqrt{2}$  and  $\|u_3\| = 3\sqrt{2}$ . Consequently, the orthogonal matrix  $P$  has the form

$$P = \begin{pmatrix} \frac{2}{3} & \frac{1}{\sqrt{2}} & \frac{1}{3\sqrt{2}} \\ \frac{1}{3} & 0 & -\frac{4}{3\sqrt{2}} \\ \frac{2}{3} & -\frac{1}{\sqrt{2}} & \frac{1}{3\sqrt{2}} \end{pmatrix}.$$

Note that  $P$  is not uniquely defined. It remains to verify the relations  $P^{-1} = P^T$ , and  $P^{-1}AP = \text{diag}(\lambda_1, \lambda_2, \lambda_3)$ . In Sage this can be done easily:

```
A = matrix(SR, [[1, 2, 6], [2, 0, 2], [6, 2, 1]])
D = diagonal_matrix([8, -5, -1])
P = matrix(SR, [[2/3, 1/sqrt(2), 1/(3*sqrt(2))], [1/3, 0, -4/(3*sqrt(2))],
[2/3, -1/sqrt(2), 1/(3*sqrt(2))]])
print(P.inverse()==P.T); print(P.inverse()*A*P==D)
```

**3.D.36.** The one direction starting with  $A$  orthogonally diagonalizable is easy. Then we have  $P^TAP = D$  for some orthogonal  $n \times n$  matrix  $P$  and a diagonal  $n \times n$  matrix  $D$ . Thus  $A = PDP^T$  and since  $D$  being diagonal satisfies  $D = D^T$ , we obtain

$$A^T = (PDP^T)^T = PD^T P^T = PDP^T = A.$$

Hence  $A$  is symmetric. The converse is more difficult. Assume that  $A$  is a symmetric  $n \times n$  matrix. If  $n = 1$  the statement is trivial, i.e. the pair  $(P = 1, D = A)$  satisfies the statement. We will proceed by induction on the size of  $A$ . The induction hypothesis assumes that every  $(n-1) \times (n-1)$  symmetric matrix is orthogonally diagonalizable. Consider now the symmetric matrix  $A$  and let  $\lambda \in \mathbb{R}$  be an eigenvalue of  $A$  with eigenvector  $u \in \mathbb{R}^n$ , i.e.,  $Au = \lambda u$ . Set  $p_1 = u/\|u\|$  and extend  $\{p_1\}$  to an orthonormal basis  $\{p_1, \dots, p_n\}$  of  $\mathbb{R}^n$ . Let  $P$  be the orthogonal matrix whose column vectors are the vectors  $p_i$ , that is,  $P = (p_1 \ p_2 \ \dots \ p_n)$ . Then, in terms of block matrices for the multiplication  $AP$  we get the expression

$$AP = (\lambda p_1 \ Ap_2 \ \dots \ Ap_n) = P \begin{pmatrix} \lambda & C \\ 0 & A_1 \end{pmatrix},$$

for some  $C \in \text{Mat}_{1, n-1}(\mathbb{R})$  and  $A_1 \in \text{Mat}_{n-1}(\mathbb{R})$ . However,  $P^{-1} = P^T$  and hence this equivalently can be rewritten as

$$P^TAP = \begin{pmatrix} \lambda & C \\ 0 & A_1 \end{pmatrix}. \quad (*)$$

Since  $A$  is symmetric, we see that  $(P^TAP)^T = P^TAP$ , hence the matrix  $P^TAP$  is also symmetric. Thus, the relation given in  $(*)$  will make sense only when  $C = 0$  and  $A_1$  is symmetric. Since  $A_1$  has size  $(n-1) \times (n-1)$ , the induction hypothesis applies, so there exist an orthogonal matrix  $B$  and a diagonal matrix  $D_1$  of the same size with  $A_1$ , satisfying  $B^T A_1 B = D_1$ .

Consider now the block matrix  $P' = \begin{pmatrix} 1 & 0 \\ 0 & B \end{pmatrix}$ , whose size is  $n \times n$ . Since  $B$  is orthogonal,  $P'$  is also orthogonal and hence we see that

$$(PP')^T A (PP') = (P')^T (P^TAP) P' = \begin{pmatrix} 1 & 0 \\ 0 & B^T \end{pmatrix} \begin{pmatrix} \lambda & 0 \\ 0 & A_1 \end{pmatrix} \begin{pmatrix} 1 & 0 \\ 0 & B \end{pmatrix} = \begin{pmatrix} \lambda & 0 \\ 0 & B^T A_1 B \end{pmatrix} = \begin{pmatrix} \lambda & 0 \\ 0 & D_1 \end{pmatrix}.$$

Since the last matrix is diagonal and  $PP'$  is orthogonal, the proof is complete.

**3.D.38.** Both matrices  $A$  and  $B$  are Hermitian, i.e.,  $A = A^*$  and  $B = B^*$ , and hence also normal. Thus, they are unitary diagonalizable. Moreover, since Hermitian matrices have only real eigenvalues, both  $A$  and  $B$  possess only real eigenvalues, as we will see also below. Let us begin with the matrix  $A$ . The characteristic polynomial of  $A$  is given by

$$\begin{aligned} \chi_A(\lambda) &= |A - \lambda E| = \begin{vmatrix} -(1+\lambda) & 0 & i \\ 0 & 1-\lambda & 0 \\ -i & 0 & 1-\lambda \end{vmatrix} = -(1+\lambda) \begin{vmatrix} 1-\lambda & 0 \\ 0 & 1-\lambda \end{vmatrix} + i \begin{vmatrix} 0 & 1-\lambda \\ -i & 0 \end{vmatrix} \\ &= -(1+\lambda)(1-\lambda)^2 + i^2(1-\lambda) = -(1+\lambda)(1-\lambda^2+1) = (1-\lambda)(\lambda^2-2) = (1-\lambda)(\lambda-\sqrt{2})(\lambda+\sqrt{2}). \end{aligned}$$

Or one may try to express the  $3 \times 3$  determinant with respect to the second row, which has less computations. Hence the eigenvalues of  $A$  are given by  $\lambda = 1$  and  $\lambda_{\pm} = \pm\sqrt{2}$ , all with multiplicity one. Hence their geometric multiplicity is also one. Let us derive generators of the corresponding eigenspaces  $V_{\lambda}$ ,  $V_{\lambda_+}$  and  $V_{\lambda_-}$ , which are subspaces of  $\mathbb{C}^3$ .

• For  $\lambda = 1$  we have the matrix equation  $Au = \lambda u = u$ , for some vector  $u = (u_1, u_2, u_3)^T \in \mathbb{C}^3$ , i.e.,

$$\begin{pmatrix} -u_1 + iu_3 \\ u_2 \\ -iu_1 + u_3 \end{pmatrix} = \begin{pmatrix} u_1 \\ u_2 \\ u_3 \end{pmatrix}.$$

It is easy to see that the solutions of the corresponding linear system are given by  $u_1 = u_3 = 0$ , with  $u_2 \in \mathbb{C}$  free. Thus we may assume that  $u = (0, 1, 0)^T$ .

• For  $\lambda_+ = \sqrt{2}$  we need to solve the matrix equation  $Au_+ = \sqrt{2}u_+$ , for some  $u_+ = (w_1, w_2, w_3) \in \mathbb{C}^3$ , i.e.,

$$\begin{pmatrix} -w_1 + iw_3 \\ w_2 \\ -iw_1 + w_3 \end{pmatrix} = \begin{pmatrix} \sqrt{2}w_1 \\ \sqrt{2}w_2 \\ \sqrt{2}w_3 \end{pmatrix}.$$

This induces the linear system

$$\begin{cases} (\sqrt{2} + 1)w_1 - iw_3 = 0, \\ (\sqrt{2} - 1)w_2 = 0, \\ iw_1 + (\sqrt{2} - 1)w_3 = 0, \end{cases}$$

whose solutions are given by  $\{w_1 = i(\sqrt{2} - 1)r, w_2 = 0, w_3 = r \in \mathbb{C}\}$ . Thus, setting  $r = 1$  we may assume that  $u_+ = (i(\sqrt{2} - 1), 0, 1)^T \in \mathbb{C}^3$ .

• For  $\lambda_- = -\sqrt{2}$  we need to solve the matrix equation  $Au_- = -\sqrt{2}u_-$ , for some vector  $u_- = (v_1, v_2, v_3) \in \mathbb{C}^3$ . In a similar way we find that the solution of the corresponding linear system is given by  $\{v_1 = -i(\sqrt{2} + 1)s, v_2 = 0, v_3 = s \in \mathbb{C}\}$ . Thus, up to a multiple, the eigenvector  $u_-$  is given by  $u_- = (-i(\sqrt{2} + 1), 0, 1)^T \in \mathbb{C}^3$ .

We recommend formally verifying that the eigenvectors are orthogonal with respect to the standard Hermitian form  $\langle \cdot, \cdot \rangle$  on  $\mathbb{C}^3$ . We have achieved this using Sage, as presented below:

```
u=vector([0, 1, 0])
u_plus=vector([1-sqrt(2), 0, i])
u_minus=vector([1+sqrt(2), 0, i])
a=u.dot_product(u_plus.conjugate())
print(a.simplify_full())
b=u.dot_product(u_minus.conjugate())
print(b.simplify_full())
c=u_plus.dot_product(u_minus.conjugate())
print(c.simplify_full())
```

Now, without loss of generality, we can multiply both  $u_{\pm}$  by  $i$  and hence consider the eigenvectors

$$\tilde{u}_+ = \begin{pmatrix} 1 - \sqrt{2} \\ 0 \\ i \end{pmatrix} \in V_+, \quad \text{and} \quad \tilde{u}_- = \begin{pmatrix} 1 + \sqrt{2} \\ 0 \\ i \end{pmatrix} \in V_-.$$

We need to compute the norms of the eigenvectors  $u$ , and  $\tilde{u}_{\pm}$  with respect the standard Hermitian form  $\langle \cdot, \cdot \rangle$  on  $\mathbb{C}^3$ . Obviously,  $\|u\| = 1$  and

$$\begin{aligned} \|\tilde{u}_+\|^2 &= \langle \tilde{u}_+, \tilde{u}_+ \rangle = \tilde{u}_+^* \tilde{u}_+ = \begin{pmatrix} 1 - \sqrt{2} & 0 & -i \end{pmatrix} \cdot \begin{pmatrix} 1 - \sqrt{2} \\ 0 \\ i \end{pmatrix} = (1 - \sqrt{2})^2 - i^2 = 4 - 2\sqrt{2}, \\ \|\tilde{u}_-\|^2 &= \langle \tilde{u}_-, \tilde{u}_- \rangle = \tilde{u}_-^* \tilde{u}_- = \begin{pmatrix} 1 + \sqrt{2} & 0 & -i \end{pmatrix} \cdot \begin{pmatrix} 1 + \sqrt{2} \\ 0 \\ i \end{pmatrix} = (1 + \sqrt{2})^2 - i^2 = 4 + 2\sqrt{2}, \end{aligned}$$

where “ $\cdot$ ” denotes matrix multiplication. Thus  $\|\tilde{u}_+\| = \sqrt{4 - 2\sqrt{2}}$ ,  $\|\tilde{u}_-\| = \sqrt{4 + 2\sqrt{2}}$ , and the normalized eigenvectors are given by

$$\hat{u} = u = \begin{pmatrix} 0 \\ 1 \\ 0 \end{pmatrix}, \quad \hat{u}_+ = \frac{\tilde{u}_+}{\|\tilde{u}_+\|} = \frac{1}{\sqrt{4 - 2\sqrt{2}}} \begin{pmatrix} 1 - \sqrt{2} \\ 0 \\ i \end{pmatrix}, \quad \hat{u}_- = \frac{\tilde{u}_-}{\|\tilde{u}_-\|} = \frac{1}{\sqrt{4 + 2\sqrt{2}}} \begin{pmatrix} 1 + \sqrt{2} \\ 0 \\ i \end{pmatrix}.$$

We can now derive the matrices  $U$ ,  $U^*$  (and  $D$ )

$$U = \begin{pmatrix} 0 & \frac{1 - \sqrt{2}}{\sqrt{4 - 2\sqrt{2}}} & \frac{1 + \sqrt{2}}{\sqrt{4 + 2\sqrt{2}}} \\ 1 & 0 & 0 \\ 0 & \frac{i}{\sqrt{4 - 2\sqrt{2}}} & \frac{i}{\sqrt{4 + 2\sqrt{2}}} \end{pmatrix}, \quad U^* = \begin{pmatrix} 0 & 1 & 0 \\ \frac{1 - \sqrt{2}}{\sqrt{4 - 2\sqrt{2}}} & 0 & \frac{-i}{\sqrt{4 - 2\sqrt{2}}} \\ \frac{1 + \sqrt{2}}{\sqrt{4 + 2\sqrt{2}}} & 0 & \frac{-i}{\sqrt{4 + 2\sqrt{2}}} \end{pmatrix}, \quad D = \begin{pmatrix} 1 & 0 & 0 \\ 0 & \sqrt{2} & 0 \\ 0 & 0 & -\sqrt{2} \end{pmatrix}.$$

Verifying the relation  $U^*AU = D$  by hand can be both time-consuming and challenging. To streamline this process we will use Sage in the following straightforward manner:

```
A=matrix([[ -1, 0, i], [0, 1, 0], [ -i, 0, 1]])
U=matrix([[0, (1-sqrt(2))/sqrt(4-2*sqrt(2)), (1+sqrt(2))/sqrt(4+2*sqrt(2))],
[1, 0, 0], [0, i/sqrt(4-2*sqrt(2)), i/sqrt(4+2*sqrt(2))]])
D=diagonal_matrix([1, sqrt(2), -sqrt(2)])
U.H*A*U==D
```

Verify that Sage's response is rapid, and effectively confirms the desired relation  $U^*AU = D$ .

For the matrix  $B$  we will rely solely on Sage to obtain a solution. Using the cell

```
B = matrix(QQbar, [[3, I], [-I, 3]])
B.eigenvalues()
B.eigenvectors_right()
```

we obtain the eigenvalues of  $B$ :  $\lambda_1 = 2$  and  $\lambda_2 = 4$ , both with multiplicity one. This code also returns the corresponding eigenvectors:  $(1, i)^T$  for  $\lambda_1$  and  $(1, -i)^T$  for  $\lambda_2$ . We may multiply the second vector by  $i$  and set  $u_1 = (1, i)^T$  and  $u_2 = (i, 1)^T$ . With respect to the standard Hermitian form on  $\mathbb{C}^2$  it is easy to verify that  $\langle u_1, u_2 \rangle = 0$ . Thus the eigenvectors are orthogonal, as it should be, and moreover  $\|u_1\| = \sqrt{2} = \|u_2\|$ . By taking the orthonormal vectors  $\hat{u}_1 = \frac{1}{\sqrt{2}}u_1$  and  $\hat{u}_2 = \frac{1}{\sqrt{2}}u_2$  we arrive to the unitary matrix  $U$  given by

$$U = \frac{1}{\sqrt{2}} \begin{pmatrix} 1 & i \\ i & 1 \end{pmatrix}.$$

Recall that Sage can verify this claim via the command `U.is_unitary`, where the same cell should include the definition of the matrix  $U$ . To verify that this matrix  $U$  diagonalizes the given matrix  $B$ , i.e.  $U^*BU = D$ , where  $D = \text{diag}(\lambda_1, \lambda_2) = \text{diag}(2, 4)$ , use the following block:

```
B = matrix(QQbar, [[3, I], [-I, 3]])
U = matrix(QQbar, [[1/sqrt(2), I*(1/sqrt(2))], [I*(1/sqrt(2)), 1/sqrt(2)]])
D = matrix(QQbar, [[2, 0], [0, 4]])
U.conjugate_transpose()*B*U == D
```

**3.D.39.** Suppose that  $A$  is a normal matrix with purely imaginary eigenvalues. Then we can find a unitary matrix  $U$  satisfying  $U^*AU = D$ , where  $D$  is a diagonal matrix with purely imaginary (diagonal) entries. From this we get  $A = UDU^*$  and since  $D^* = -D$ , we see that

$$A^* = (UDU^*)^* = UD^*U^* = -UDU^* = -A.$$

**3.D.41.** The matrices that represent Jordan canonical forms are  $G_1, G_2, G_5$  and  $G_6$ .

**3.D.43.** We saw that only the matrices  $G_1, G_2, G_5$  and  $G_6$  represent a Jordan canonical form. Let us denote by  $A_k$  the corresponding matrices and by  $P_k$  the corresponding similarity matrices. Both  $A_k$  and  $P_k$  have the same size as  $G_k$  for all these  $k$ . Since  $A_k = P_k G_k P_k^{-1}$ , i.e., the matrices  $A_k$  and  $G_k$  are similar for all  $k = 1, 2, 5, 6$ , they have the same characteristic polynomial. Thus  $\chi_{A_k}(\lambda) = \chi_{G_k}(\lambda)$  for all these four cases and from the expressions of  $G_k$  is direct that

- $\chi_{G_1}(\lambda) = \chi_{A_1}(\lambda) = \lambda^2(\lambda - 2)^2$ ;
- $\chi_{G_2}(\lambda) = \chi_{A_2}(\lambda) = (\lambda - 3)(\lambda - 1)^2$ ;
- $\chi_{G_5}(\lambda) = \chi_{A_5}(\lambda) = (\lambda - \pi)$ ;
- $\chi_{G_6}(\lambda) = \chi_{A_6}(\lambda) = (\lambda - 2)^2(\lambda - 1)^2\lambda^2$ .

**3.D.45.** (a) Let us compute the characteristic polynomial of the given matrix  $A = \begin{pmatrix} 3 & 1 \\ -1 & 1 \end{pmatrix}$ :

$$\chi_A(\lambda) = |A - \lambda E| = \begin{vmatrix} 3 - \lambda & 1 \\ -1 & 1 - \lambda \end{vmatrix} = (3 - \lambda)(1 - \lambda) + 1 = \lambda^2 - 4\lambda + 4 = (\lambda - 2)^2.$$

Thus,  $\lambda = 2$  is the unique eigenvalue of  $A$ , and has algebraic multiplicity  $\alpha(\lambda) = 2$ . To determine the eigenvectors, we need to solve the matrix equation  $(A - 2E)u = 0$  for some vector  $u = (x, y)^T$ . This gives the linear system  $\{x + y = 0, -x - y = 0\}$  with 1-dimensional solution space  $\left\{ \begin{pmatrix} x \\ y \end{pmatrix} = \begin{pmatrix} -s \\ s \end{pmatrix} : s \in \mathbb{R} \right\}$ . Therefore, we may assume that the eigenspace  $V_\lambda = V_2$  is generated by the eigenvector  $u = (1, -1)^T$  (this occurs for  $s = -1$ ). For the geometric multiplicity of  $\lambda$  this fact implies that  $\gamma(\lambda) = 1$ . Hence  $\gamma(\lambda) \neq \alpha(\lambda)$  and  $A$  cannot be diagonalizable. Since  $A$  is  $2 \times 2$ ,  $\alpha(\lambda) = 2$ ,  $\gamma(\lambda) = 1$ , and  $\lambda$  is the unique eigenvalue of  $A$ , the Jordan canonical form of  $A$  is the matrix  $J = \begin{pmatrix} 2 & 1 \\ 0 & 2 \end{pmatrix}$ .

Observe now that  $(A - 2E)^2 = 0$ , where 0 denotes the  $2 \times 2$  matrix. To find the generalized eigenvector corresponding to  $\lambda$  we need to solve the matrix equation  $(A - 2E)w = u$ . If we assume that  $w$  has the expression  $w = (w_1, w_2)^T$ , the solution space of the corresponding linear system has the form  $\left\{ \begin{pmatrix} w_1 \\ w_2 \end{pmatrix} = \begin{pmatrix} 1-t \\ t \end{pmatrix} : t \in \mathbb{R} \right\}$ . Thus we may assume that the generalized eigenvector  $w$  has the form  $w = (1, 0)^T$  (this occurs for  $t = 0$ ). Consequently, the basis with respect to which  $J$  has the above form is given by  $\{u, w\}$  and  $P$  has the form  $P = \begin{pmatrix} 1 & 1 \\ -1 & 0 \end{pmatrix}$ . We also compute  $P^{-1} = \begin{pmatrix} 0 & -1 \\ 1 & 1 \end{pmatrix}$  and it is straightforward to verify the relation  $P^{-1}AP = J$ . In Sage this verification can be done as usual, i.e.,

```
A=matrix(SR, [[3, 1], [-1, 1]])
J=matrix(SR, [[2, 1], [0, 2]])
P=matrix(SR, [[1, 1], [-1, 0]])
Pinv=P.inverse(); Pinv*A*P==J
```

As mentioned in 3.D.44, an alternative has the form

```
A=matrix(SR, [[3, 1], [-1, 1]])
J, P = A.jordan_form(transformation=True)
show(J, P)
```

In this case Sage directly prints out the derived expression for  $J$  and  $P$ .

(b) For this task, observe that the  $k$ th power  $A^k$  of  $A$  satisfies the relation

$$A^k = \underbrace{(PJP^{-1})(PJP^{-1}) \cdots (PJP^{-1})}_{k\text{-factors}} = PJ^k P^{-1}.$$

Now, we easily compute  $J^4 = \begin{pmatrix} 16 & 32 \\ 0 & 16 \end{pmatrix}$  and by applying the relation  $A^4 = PJ^4 P^{-1}$ , we obtain  $A^4 = \begin{pmatrix} 48 & 32 \\ -32 & 16 \end{pmatrix}$ .

**3.D.46.** The matrix  $A$  is upper triangular, meaning that all entries below the main diagonal are zero. For an upper triangular matrix the characteristic polynomial is factorized into linear factors by inspecting the diagonal elements. For our case we get the expression  $\chi_A(\lambda) = (5 - \lambda)^4$ . Therefore,  $\lambda = 5$  is the unique eigenvalue of  $A$  and has algebraic multiplicity 4,  $\alpha(\lambda) = 4$ . To determine the size of the Jordan blocks, we need to find the geometric multiplicity of  $\lambda$ . The matrix  $A - 5E$  is given by

$$A - 5E = \begin{pmatrix} 0 & 4 & 2 & 1 \\ 0 & 0 & 1 & 1 \\ 0 & 0 & 0 & 2 \\ 0 & 0 & 0 & 0 \end{pmatrix},$$

and it is easy to see that its rank equals 3. We can verify this statement in Sage, by the following block,

```
A = Matrix([[5, 4, 2, 1], [0, 5, 1, 1], [0, 0, 5, 2], [0, 0, 0, 5]])
E=identity_matrix(4)
AA=A-5*E; show(AA)
show(AA.rref())
print("The rank of A-4E is given by:", AA.rank())
```

Since  $\text{rank}(A - 4E) = 3$ , the dimension of  $\text{Ker}(A - 5E)$  equals 1.<sup>23</sup> Hence we conclude that the geometric multiplicity of  $\lambda = 5$  equals 1. Since  $\gamma(\lambda) = 1$ ,  $\alpha(\lambda) = 4$  and  $\lambda = 5$  is the unique eigenvalue of  $A$ , the Jordan form is composed of a single Jordan block of size 4 (see also below for a Jordan chain of length 4)

$$J = \begin{pmatrix} 5 & 1 & 0 & 0 \\ 0 & 5 & 1 & 0 \\ 0 & 0 & 5 & 1 \\ 0 & 0 & 0 & 5 \end{pmatrix}.$$

Let us now describe an eigenvector of  $\lambda$ . The previous block also provides the REEF of  $A - 4E$ , given by

$$A - 5E = \begin{pmatrix} 0 & 4 & 2 & 1 \\ 0 & 0 & 1 & 1 \\ 0 & 0 & 0 & 2 \\ 0 & 0 & 0 & 0 \end{pmatrix} \sim \begin{pmatrix} 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & 0 \end{pmatrix}.$$

<sup>23</sup>Recall that according to the rank-nullity theorem we have  $\text{rank}(T) + \dim \text{Ker}(T) = \dim V$  for any linear transformation  $T : V \rightarrow W$  defined on a finite-dimensional vector space  $V$ .

Thus, the general solution of the linear system corresponding to the matrix equation  $(A - 4E)u_1 = 0$  is given by  $\{(x_1, x_2, x_3, x_4)^T = (t, 0, 0, 0)^T\}$ , where  $t$  is a free parameter. Hence, without loss of generality, we may assume that the eigenspace  $V_\lambda = V_5 = \text{Ker}(A - 5E)$  is generated by the eigenvector  $u_1 = (1, 0, 0, 0)^T$ . Using Sage we can confirm that  $(A - 5E)^4 = 0$  and compute

$$(A - 5E)^2 = \begin{pmatrix} 0 & 0 & 4 & 8 \\ 0 & 0 & 0 & 2 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix}, \quad (A - 5E)^3 = \begin{pmatrix} 0 & 0 & 0 & 8 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix}.$$

Therefore it is easy to derive the dimensions of the null spaces  $\text{Ker}((A - 5E)^2)$  and  $\text{Ker}((A - 5E)^3)$ :

$$\begin{aligned} \text{rank}((A - 5E)^2) = 2 &\implies \dim \text{Ker}((A - 5E)^2) = 4 - 2 = 2, \\ \text{rank}((A - 5E)^3) = 1 &\implies \dim \text{Ker}((A - 5E)^3) = 4 - 1 = 3. \end{aligned}$$

Since  $(A - 5E)^4 = 0$  it is immediate that  $\dim \text{Ker}((A - 5E)^4) = 4$  and hence  $\text{Ker}((A - 5E)^4)$  is the whole  $\mathbb{R}^4$ .

Let us compute a generalized eigenvector for the unique eigenvalue of  $A$ , which we will denote by  $u_2 = (x_1, x_2, x_3, x_4)^T$ . The matrix equation  $(A - 5E)u_2 = u_1$  corresponds to the linear system  $\{4x_2 + 2x_3 + x_4 = 1, x_3 + x_4 = 0, 2x_4 = 0\}$  and its solutions are given by  $\{(x_1, x_2, x_3, x_4)^T = (s, \frac{1}{4}, 0, 0)^T\}$ , where  $s$  is a free parameter. Thus, we may assume that  $u_2 = (0, \frac{1}{4}, 0, 0)^T$ , and it is easy to see that  $u_2 \in \text{Ker}((A - 5E)^2)$  but  $u_2 \notin \text{Ker}(A - 5E)$ . In particular, the vectors  $u_1, u_2$  span the subspace  $\text{Ker}((A - 5E)^2)$ . Next we need to solve the matrix equation  $(A - 5E)u_3 = u_2$  for some vector  $u_3 = (x_1, x_2, x_3, x_4)^T$ , which induces the system  $\{4x_2 + 2x_3 + x_4 = 0, x_3 + x_4 = 1/4, 2x_4 = 0\}$ . Its solutions are given by  $\{(x_1, x_2, x_3, x_4)^T = (r, -\frac{1}{8}, \frac{1}{4}, 0)^T\}$ , where  $r$  is a free parameter. Thus we may assume that  $u_3 = (0, -\frac{1}{8}, \frac{1}{4}, 0)^T$  and it is easy to see that  $u_3 \in \text{Ker}((A - 5E)^3)$  but  $u_3 \notin \text{Ker}((A - 5E)^2)$ . It follows that vectors  $u_1, u_2, u_3$  generate  $\text{Ker}((A - 5E)^3)$ . Finally, solving the matrix equation  $(A - 5E)u_4 = u_3$  for some unknown  $u_4 = (x_1, x_2, x_3, x_4)^T$ , we get the generalized eigenvector  $u_4 = (0, \frac{3}{32}, -\frac{1}{4}, \frac{1}{8})^T$ . Putting all information together, we deduce that  $\text{Ker}((A - 5E)^4) = \text{span}\{u_1, u_2, u_3, u_4\}$ .

To summarize, we saw that the vectors  $u_4, u_3, u_2$  and  $u_1$  satisfy the relations

$$\begin{array}{l} (A - 5E)^4 u_4 = 0 \mid (A - 5E)^3 u_3 = 0 \mid (A - 5E)^2 u_2 = 0 \mid (A - 5E)u_1 = 0, \\ (A - 5E)u_4 = u_3 \mid (A - 5E)u_3 = u_2 \mid (A - 5E)u_2 = u_1. \end{array}$$

Moreover, a direct computations shows that

$$(A - 5E)^3 u_4 = u_1, \quad (A - 5E)^2 u_4 = u_2, \quad (A - 5E)u_4 = u_3.$$

Thus  $\{(A - 5E)^3 u_4, (A - 5E)^2 u_4, (A - 5E)u_4, u_4\} = \{u_1, u_2, u_3, u_4\}$  is a Jordan chain of full length 4. This implies that the generalized eigenspace  $\mathcal{R}_\lambda$  corresponding to the eigenvalue  $\lambda$  has dimension 4 and it encompasses all vectors that map to zero under the fourth power of  $(A - 5E)$ . Thus,

$$\mathcal{R}_\lambda = \text{Ker}((A - 5E)^4) \cong \mathbb{R}^4.$$

Actually  $\mathcal{R}_\lambda$  is the union of the subspaces  $\text{Ker}((A - 5E)^\ell)$  for all  $1 \leq \ell \leq 4$ .

As another consequence of this chain we can derive a representative of the matrix  $P$ :

$$P = (u_1 \mid u_2 \mid u_3 \mid u_4) = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 1/4 & -1/8 & 3/32 \\ 0 & 0 & 1/4 & -1/4 \\ 0 & 0 & 0 & 1/8 \end{pmatrix}.$$

Check yourselves using Sage via the following block that  $P$  satisfies  $P^{-1}AP = J$ .

```
A = matrix(SR, [[5, 4, 2, 1], [0, 5, 1, 1], [0, 0, 5, 2], [0, 0, 0, 5]])
J = matrix(SR, [[5, 1, 0, 0], [0, 5, 1, 0], [0, 0, 5, 1], [0, 0, 0, 5]])
P = matrix(SR, [[1, 0, 0, 0], [0, 1/4, -1/8, 3/32], [0, 0, 1/4, -1/4],
[0, 0, 0, 1/8]])
#Verify P^(-1)AP = J
print(P.inverse()*A*P == J)
```

**3.E.5.** (i) In 3.E.1 the matrix  $U$  was derived from the matrix  $A$  by successively applying the elementary row operations  $R_2 \rightarrow R_2 - 2R_1$ ,  $R_3 \rightarrow R_3 - 3R_1$  and  $R_3 \rightarrow R_3 + R_2$ . To obtain the corresponding elementary matrices, we apply each of these row operations to the  $3 \times 3$  identity matrix. This results in the following matrices:

$$E_1 = \begin{pmatrix} 1 & 0 & 0 \\ -2 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix}, \quad E_2 = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ -3 & 0 & 1 \end{pmatrix}, \quad E_3 = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 1 & 1 \end{pmatrix},$$

and the Gauss elimination in terms of matrices has the form

$$E_3 E_2 E_1 A = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 1 & 1 \end{pmatrix} \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ -3 & 0 & 1 \end{pmatrix} \begin{pmatrix} 1 & 0 & 0 \\ -2 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix} \begin{pmatrix} -2 & 1 & 0 \\ -4 & 4 & 2 \\ -6 & 1 & -1 \end{pmatrix} = \begin{pmatrix} -2 & 1 & 0 \\ 0 & 2 & 2 \\ 0 & 0 & 1 \end{pmatrix} = U.$$

Since the elementary matrices are always invertible, we obtain  $A = E_1^{-1} E_2^{-1} E_3^{-1} U$ , which implies that  $L = E_1^{-1} E_2^{-1} E_3^{-1}$ . The inverses of the elementary matrices are easily computed, leading to the expected result:

$$L = E_1^{-1} E_2^{-1} E_3^{-1} = \begin{pmatrix} 1 & 0 & 0 \\ 2 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix} \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 3 & 0 & 1 \end{pmatrix} \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & -1 & 1 \end{pmatrix} = \begin{pmatrix} 1 & 0 & 0 \\ 2 & 1 & 0 \\ 3 & -1 & 1 \end{pmatrix}.$$

We also compute

$$L^{-1} = E_3 E_2 E_1 = \begin{pmatrix} 1 & 0 & 0 \\ -2 & 1 & 0 \\ -5 & 1 & 1 \end{pmatrix}.$$

For a verification using Sage, type the cell

```
L=matrix([[1, 0, 0], [2, 1, 0], [3, -1, 1]]); show(L.inverse())
```

(ii) To find the inverse of the matrix  $U$  via the Gauss elimination method, we begin by forming the augmented matrix  $(U | E)$ , where  $E$  is the  $3 \times 3$  identity matrix. We then successively apply the following elementary row operations:  $R_1 \rightarrow -\frac{1}{2}R_1$ ,  $R_1 \rightarrow R_1 + \frac{1}{4}R_2$ ,  $R_1 \rightarrow R_1 - \frac{1}{2}R_3$ ,  $R_2 \rightarrow \frac{1}{2}R_2$  and  $R_2 \rightarrow R_2 - R_3$ . You should be able to verify on your own that this results in the matrix

$$U^{-1} = \begin{pmatrix} -1/2 & 1/4 & -1/2 \\ 0 & 1/2 & -1 \\ 0 & 0 & 1 \end{pmatrix}.$$

Here is a quick verification using Sage:

```
U=matrix([[-2, 1, 0], [0, 2, 2], [0, 0, 1]]); show(U.inverse())
```

(iii) We have  $\det(A) = \det(L) \det(U) = 1 \cdot (-4) = -4 \neq 0$ , and hence  $A$  is invertible. Now, using the expressions of  $L^{-1}$  and  $U^{-1}$  obtained above, the matrix  $A^{-1}$  occurs very easily:

$$A^{-1} = (LU)^{-1} = U^{-1}L^{-1} = \begin{pmatrix} -1/2 & 1/4 & -1/2 \\ 0 & 1/2 & -1 \\ 0 & 0 & 1 \end{pmatrix} \begin{pmatrix} 1 & 0 & 0 \\ -2 & 1 & 0 \\ -5 & 1 & 1 \end{pmatrix} = \begin{pmatrix} 3/2 & -1/4 & -1/2 \\ 4 & -1/2 & -1 \\ -5 & 1 & 1 \end{pmatrix}.$$

Verify this result in Sage with the same basic method applied for  $L$  or  $U$ .

**3.E.6.** It is easy to see that  $\text{rank}(A) = 2$  and hence there exist two non-zero singular values. Since  $A^T A = \begin{pmatrix} 25 & 15 \\ 15 & 25 \end{pmatrix}$ , the characteristic polynomial of  $A^T A$  is given by  $\chi_{A^T A}(\lambda) = (40 - \lambda)(10 - \lambda)$ . Hence we conclude that the eigenvalues of  $A^T A$  are  $\lambda_1 = 40$  and  $\lambda_2 = 10$ , so the singular values of  $A$  are  $\sigma_1 = \sqrt{40} = 2\sqrt{10}$  and  $\sigma_2 = \sqrt{10}$ , with  $\sigma_1 > \sigma_2$ .

**3.E.7.** We see that  $A^T A$  is a diagonal matrix:

$$A^T A = \begin{pmatrix} 0 & -1 & 0 \\ 0 & 0 & 0 \\ -\frac{1}{2} & 0 & 0 \end{pmatrix} \begin{pmatrix} 0 & 0 & -\frac{1}{2} \\ -1 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix} = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & \frac{1}{4} \end{pmatrix}.$$

From this we deduce that  $A^T A$  has three eigenvalues,  $\lambda_1 = 1$ ,  $\lambda_2 = 1/4$  and  $\lambda_3 = 0$ . and two non-zero singular values (note that  $\text{rank}(A) = 2$ ), the latter given by  $\sigma_1 = \sqrt{\lambda_1} = 1$  and  $\sigma_2 = \sqrt{\lambda_2} = 1/2$ , with  $\sigma_1 > \sigma_2$ . Therefore, the matrix  $\Sigma$  has the form  $\Sigma = \text{diag}(1, 1/2, 0)$ .

**3.E.9.** According to 3.5.5 we will have  $P := U\Sigma U^T$  and  $U_p := UV^T$ , where  $A = U\Sigma V^T$  is the SVD decomposition of  $A$ . We compute

$$P = \begin{pmatrix} 0 & -1 & 0 \\ -1 & 0 & 0 \\ 0 & 0 & -1 \end{pmatrix} \begin{pmatrix} 1 & 0 & 0 \\ 0 & \frac{1}{2} & 0 \\ 0 & 0 & 0 \end{pmatrix} \begin{pmatrix} 0 & -1 & 0 \\ -1 & 0 & 0 \\ 0 & 0 & -1 \end{pmatrix} = \begin{pmatrix} \frac{1}{2} & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 0 \end{pmatrix},$$

and

$$U_p = \begin{pmatrix} 0 & -1 & 0 \\ -1 & 0 & 0 \\ 0 & 0 & -1 \end{pmatrix} \begin{pmatrix} 1 & 0 & 0 \\ 0 & 0 & 1 \\ 0 & 1 & 0 \end{pmatrix} = \begin{pmatrix} 0 & 0 & -1 \\ -1 & 0 & 0 \\ 0 & -1 & 0 \end{pmatrix}.$$

Thus, the polar decomposition of the matrix  $A$  has the form

$$A = \begin{pmatrix} 0 & 0 & -\frac{1}{2} \\ -1 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix} = PU_p = \begin{pmatrix} \frac{1}{2} & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 0 \end{pmatrix} \begin{pmatrix} 0 & 0 & -1 \\ -1 & 0 & 0 \\ 0 & -1 & 0 \end{pmatrix}.$$

A verification using Sage is easy:

```
A=matrix([[0, 0, -1/2], [-1, 0, 0], [0, 0, 0]])
S=diagonal_matrix([1, 1/2, 0])
V=matrix([[1, 0, 0], [0, 0, 1], [0, 1, 0]])
U=matrix([[0, -1, 0], [-1, 0, 0], [0, 0, -1]])
P=U*S*(U.T)
show(P)
Upolar=U*(V.T)
show(Upolar)
A==P*Upolar
```

The polar decomposition is not unique, since  $A$  is singular. Next it easy to see that  $P$  is Hermitian and positive semi-definite. For example, for the second claim we see that  $P$  has three non-negative eigenvalues: 1, 1/2 and 0. In Sage you can confirm these claims by the adding the cell

```
show(P.eigenvalues())
P.is_hermitian()
```

**3.F.10.** The answer is given by  $x_n = (-1)^n(-2n^2 + 8n - 7)$ .

**3.F.23.** The required matrix has the form  $\begin{pmatrix} \frac{5}{6} & \frac{1}{5} \\ \frac{1}{6} & \frac{5}{5} \end{pmatrix}$ . This matrix has the dominant eigenvalue 1, with corresponding eigenvector given by  $(\frac{6}{5}, 1)^T$ . Because the eigenvalue is dominant, the ratio of the viewers stabilises on 6 : 5.

**3.F.25.** The game ends after three bets (the same as in 3.F.24). Thus, all the powers of  $A$ , starting with  $A^3$ , are identical. Consequently the answer is given as follows:

$$A^{100} = A^3 = \begin{pmatrix} 1 & 7/8 & 3/4 & 1/2 & 0 \\ 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 \\ 0 & 1/8 & 1/4 & 1/2 & 1 \end{pmatrix}.$$

**3.F.31.** It is easy to see that  $F$  is linear. Also we compute  $\ker(F) = \left\{ \begin{pmatrix} a & -a \\ a & -a \end{pmatrix} : a \in \mathbb{R} \right\}$  hence  $\dim_{\mathbb{R}}(\ker(F)) = 1$  and a basis of  $\ker(F)$  consists of the matrix  $u = \begin{pmatrix} 1 & -1 \\ 1 & -1 \end{pmatrix}$ . Since  $\mathcal{B}(u, u) = 4$ , we deduce that  $\{\hat{u} = \frac{1}{2}u\}$  is an orthonormal basis of  $\ker(F)$ .

**3.F.36.** The given rotation is easily obtained by composing the following three mappings:

- rotation through the angle  $\pi/4$  in the negative sense about the axis  $z$  (the axis of the rotation goes over on the  $x$  axis);
- rotation through the angle  $\pi/3$  in the positive sense about the  $x$  axis;
- rotation through the angle  $\pi/4$  in the positive sense about the  $z$  axis (the  $x$  axis goes over on the axis of the rotation).

The matrix of the resulting rotation is the product of the matrices corresponding to the given three mappings, while the order of the matrices is given by the order of application of the mappings – the first mapping applied is in the product the rightmost one. Thus we obtain the desired matrix

$$\begin{pmatrix} \frac{\sqrt{2}}{2} & -\frac{\sqrt{2}}{2} & 0 \\ \frac{\sqrt{2}}{2} & \frac{\sqrt{2}}{2} & 0 \\ 0 & 0 & 1 \end{pmatrix} \cdot \begin{pmatrix} 1 & 0 & 0 \\ 0 & \frac{1}{2} & -\frac{\sqrt{3}}{2} \\ 0 & \frac{\sqrt{3}}{2} & \frac{1}{2} \end{pmatrix} \cdot \begin{pmatrix} \frac{\sqrt{2}}{2} & \frac{\sqrt{2}}{2} & 0 \\ -\frac{\sqrt{2}}{2} & \frac{\sqrt{2}}{2} & 0 \\ 0 & 0 & 1 \end{pmatrix} = \begin{pmatrix} \frac{3}{4} & \frac{1}{4} & \frac{\sqrt{6}}{4} \\ \frac{1}{4} & \frac{3}{4} & -\frac{\sqrt{6}}{4} \\ -\frac{\sqrt{6}}{4} & \frac{\sqrt{6}}{4} & \frac{1}{2} \end{pmatrix}.$$

Note that the resulting rotation could be also obtained for instance by taking the composition of the three following mappings:

- rotation through the angle  $\pi/4$  in the positive sense about the axis  $z$  (the axis of rotation goes over on the axis  $y$ );
- rotation through the angle  $\pi/3$  in the positive sense about the axis  $y$ ;
- rotation through the angle  $\pi/4$  in the negative sense about the axis  $z$  (the axis  $y$  goes over to the axis of rotation).

Analogously we obtain

$$\begin{pmatrix} \frac{\sqrt{2}}{2} & \frac{\sqrt{2}}{2} & 0 \\ -\frac{\sqrt{2}}{2} & \frac{\sqrt{2}}{2} & 0 \\ 0 & 0 & 1 \end{pmatrix} \cdot \begin{pmatrix} \frac{1}{2} & 0 & \frac{\sqrt{3}}{2} \\ 0 & 1 & 0 \\ -\frac{\sqrt{3}}{2} & 0 & \frac{1}{2} \end{pmatrix} \cdot \begin{pmatrix} \frac{\sqrt{2}}{2} & -\frac{\sqrt{2}}{2} & 0 \\ \frac{\sqrt{2}}{2} & \frac{\sqrt{2}}{2} & 0 \\ 0 & 0 & 1 \end{pmatrix} = \begin{pmatrix} \frac{3}{4} & \frac{1}{4} & \frac{\sqrt{6}}{4} \\ \frac{1}{4} & \frac{3}{4} & -\frac{\sqrt{6}}{4} \\ -\frac{\sqrt{6}}{4} & \frac{\sqrt{6}}{4} & \frac{1}{2} \end{pmatrix}.$$

**3.F.39.** For any  $x, y \in \mathbb{R}^n$  and with respect to the standard dot product on  $\mathbb{R}^n$  we compute

$$\langle L_A x, y \rangle = \langle Ax, y \rangle = y^T Ax = y^T (A^T)^T x = (A^T y)^T x = \langle x, A^T y \rangle = \langle x, Ay \rangle$$

where the last equality follows since by assumption  $A = A^T$ .

**3.F.40.** First notice that the operator  $L_A : \text{Mat}_{m,n}(\mathbb{F}) \rightarrow \text{Mat}_{m,n}(\mathbb{F})$  is linear since  $L_A(B+C) = A(B+C) = AB+AC = L_A(B) + L_A(C)$  and  $L_A(zB) = A(zB) = z(AB) = zL_A(B)$  for any  $B, C \in \text{Mat}_{m,n}(\mathbb{F})$  and  $z \in \mathbb{F}$ . Its adjoint operator  $L_A^*$  is the linear map  $L_A^* : \text{Mat}_{m,n}(\mathbb{F}) \rightarrow \text{Mat}_{m,n}(\mathbb{F})$  satisfying

$$\mathcal{B}(L_A(B), C) = \mathcal{B}(B, L_A^*(C)), \quad B, C \in \text{Mat}_{m,n}(\mathbb{F}).$$

We will show that for  $L_A^* = A^*$  this holds like an identity. We compute

$$\mathcal{B}(L_A(B), C) = \text{tr}(C^*(AB)) = \text{tr}(C^*AB),$$

$$\mathcal{B}(B, L_A^*(C)) = \mathcal{B}(B, A^*C) = \text{tr}((A^*C)^*B) = \text{tr}((C^*(A^*)^*)B) = \text{tr}(C^*AB).$$

Since  $L_A^* = A^*$  and  $A$  is by assumption Hermitian, our claim follows.

**3.F.41.** Let  $y \in V$ . Then we have the following equivalences:

$$\begin{aligned} y \in \ker(f^*) &\iff f^*(y) = 0, \\ &\iff \langle x, f^*(y) \rangle = 0, \text{ for any } x \in V, \\ &\iff \langle f(x), y \rangle = 0, \text{ for any } x \in V, \\ &\iff y \perp f(x), \text{ for any } x \in V, \\ &\iff y \in (\text{Im}(f))^\perp. \end{aligned}$$

Thus  $\ker(f^*) = (\text{Im}(f))^\perp$ . Similarly is treated the second relation.

**3.F.42.** Reflections matrices are unitary since they preserve the length of vectors. In particular,

$$[\varphi_u][\varphi_u]^* = (2uu^T - E)(2uu^T - E)^* = (2uu^T - E)(2uu^T - E) = 4u(u^T u)u^T - 4uu^T + E = 4uu^T - 4uu^T + E = E,$$

since  $u$  is a unit vector, i.e.,  $\langle u, u \rangle = u^T u = 1$ .

**3.F.43.** Observe that  $(A^*A)^* = A^*A$  hence the matrix  $B = A^*A$  is Hermitian,  $B = B^*$ . Then the result follows since any Hermitian matrix has real eigenvalues, see 3.4.7. For the second statement, we have  $AA^* = U^*DU(U^*DU)^* = U^*DUU^*D^*U = U^*DD^*U$  and  $A^*A = (U^*DU)^*U^*DU = U^*D^*UU^*DU = U^*D^*DU$ . Now the result follows since  $D$  is diagonal and hence we have  $DD^* = D^*D$  (as one can easily verify).

**3.F.44.** It should be  $a = 2 + 2i$ ,  $b = 1 - i$  and  $c = i$ . One can verify this answer in Sage as follows:

```
A=matrix(SR, 3, 3, [[1, 2+2*I, -1], [2-2*I, 0, 1-I], [1, 1+I, 0]])
A.is_hermitian()
```

Could you suggest an alternative method in Sage to verify the same result?

**3.F.51.** The answer is  $\dim \text{Mat}_n(\mathbb{R}) = n^2$ .

## Analytic geometry

*position, incidence, projection*  
 – and we return to matrices again...

### A. Affine geometry

**4.A.1.** Find a parametric equation for a line in  $\mathbb{R}^3$  given by the equations

$$\begin{aligned} x - 2y + z &= 2, \\ 2x + y - z &= 5. \end{aligned}$$

**Solution.** It is sufficient to solve the equation system. However, there is an alternative approach. Find a non-zero direction vector orthogonal to the normal vectors  $(1, -2, 1)$ ,  $(2, 1, -1)$ . The cross product

$$(1, -2, 1) \times (2, 1, -1) = (1, 3, 5)$$

is such a vector. The triple

$$[x, y, z] = [2, -1, -2]$$

satisfies the respective system, so a solution is

$$[2, -1, -2] + t(1, 3, 5), \quad t \in \mathbb{R}.$$

□

**4.A.2.** A plane in  $\mathbb{R}^4$  is given by its parametric equation

$$\varrho : [0, 3, 2, 5] + t(1, 0, 1, 0) + s(2, -1, -2, 2), \quad t, s \in \mathbb{R}$$

Find its implicit equation.

**Solution.** The task is to find a system of equations with 4 variables  $x, y, z, u$  (the dimension of the space is 4) which are satisfied by the coordinates of those points which lie in the plane. The desired system must contain  $2 = 4 - 2$  linearly

We return to the view on geometry that we had when we studied positions of points in the plane in the 5th part of the first chapter, c.f. 1.5.1. We are interested in the properties of objects in the Euclidean space, delimited by points, straight lines, planes etc. The essential point is to clarify how their properties are related to the notion of vectors, and whether they depend on the notion of the length of vectors.

Later in the book, we use linear and multi-linear algebra to study objects defined in a nonlinear way. In order to facilitate this we provide some insight in the so called analytic geometry, based on the application of matrix calculus. This point of view is most useful in discussion of the technique of optimization, e.g. when searching for (constrained) extrema of functions.

At the end of this chapter we show how the projectivization of affine spaces helps us to obtain simplification and stability of algorithms typical for computer graphics.

### 1. Affine and Euclidean geometry

While clarifying the structure of solutions of linear equations in the second chapter we find in paragraph 2.3.5 that the set of all solutions of a nonhomogeneous system of linear equations does not form a vector space. However, the solutions always arise in such a way that to one particular solution we can add the vector space of solutions to the corresponding homogeneous system. On the other hand, the difference of any two solutions of the nonhomogeneous system is always a solution of the homogeneous system. This behaviour is similar to the behaviour of linear difference equations. We see this already in paragraph 3.2.6.

**4.1.1. Affine spaces.** Going back to paragraph 1.5.3 (and further on) provides a hint how to deal with the theory in any finite dimension. There we describe straight lines and points as sets of solutions of systems of linear equations. A line is considered as a one-dimensional subspace, although its points are described by two coordinates. Parametrically, the line is defined by the sum of a single point (that is, a pair of coordinates) and multiples of a fixed direction vector. We proceed now in the same way for arbitrary dimensions.

independent equations. Solve the problem by elimination of parameters. The points  $[x, y, z, u] \in \varrho$  satisfy

$$\begin{aligned} x &= t + 2s, \\ y &= 3 - s, \\ z &= 2 + t - 2s, \\ u &= 5 + 2s, \end{aligned}$$

where  $t, s \in \mathbb{R}$ . Write the system as a matrix

$$\left( \begin{array}{cc|cccc|c} 1 & 2 & -1 & 0 & 0 & 0 & 0 \\ 0 & -1 & 0 & -1 & 0 & 0 & 3 \\ 1 & -2 & 0 & 0 & -1 & 0 & 2 \\ 0 & 2 & 0 & 0 & 0 & -1 & 5 \end{array} \right).$$

The first two columns are direction vectors of the plane, followed by the negative identity matrix. The last column is the vector of coordinates of the point  $[0, 3, 2, 5]$ . This is now a system in  $t, s, x, y, z, u$ . Transform the obtained matrix using elementary row operations in order to have as many zero-rows on the left-hand side of the first vertical line as possible. Adding  $(-1)$ -times the first row and  $(-4)$ -times the second row to the third row and adding twice the second row to the first row gives

$$\left( \begin{array}{cc|cccc|c} 1 & 2 & -1 & 0 & 0 & 0 & 0 \\ 0 & -1 & 0 & -1 & 0 & 0 & 3 \\ 0 & 0 & 1 & 4 & -1 & 0 & -10 \\ 0 & 0 & 0 & -2 & 0 & -1 & 11 \end{array} \right).$$

The bottom two rows, both with only zeros to the left of the first vertical line, imply

$$\begin{aligned} x + 4y - z - 10 &= 0, \\ -2y - u + 11 &= 0. \end{aligned}$$

Note that the original system can be written as

$$\left( \begin{array}{cccc|cc|c} 1 & 0 & 0 & 0 & 1 & 2 & 0 \\ 0 & 1 & 0 & 0 & 0 & -1 & 3 \\ 0 & 0 & 1 & 0 & 1 & -2 & 2 \\ 0 & 0 & 0 & 1 & 0 & 2 & 5 \end{array} \right),$$

where  $x, y, z, u$  remains on the left-hand side of the equations. A similar transformation gives

$$\left( \begin{array}{cccc|cc|c} 1 & 0 & 0 & 0 & 1 & 2 & 0 \\ 0 & 1 & 0 & 0 & 0 & -1 & 3 \\ -1 & -4 & 1 & 0 & 0 & 0 & -10 \\ 0 & 2 & 0 & 1 & 0 & 0 & 11 \end{array} \right)$$

from which

$$\begin{aligned} -x - 4y + z &= -10, \\ 2y + u &= 11. \end{aligned}$$

As seen in this exercise, parameter elimination can be long-winded. It is not difficult to make a mistake along the way.

**Another solution** All that is needed are two linearly independent vectors perpendicular to  $(1, 0, 1, 0)$ ,  $(2, -1, -2, 2)$ . If we “guessed” that these vectors could be for example  $(0, 2, 0, 1)$ ,  $(-1, 0, 1, 2)$ , then putting  $x = 0$ ,  $y = 3$ ,  $z = 2$ ,  $u = 5$  to the equations

$$\begin{aligned} 2y + u &= a, \\ -x + z + 2u &= b \end{aligned}$$

STANDARD AFFINE SPACE

*Standard affine space*  $\mathcal{A}_n$  is a set of all points in  $\mathbb{R}^n = \mathcal{A}_n$  together with an operation “+” which assigns the point

$$A + v = (a_1 + v_1, \dots, a_n + v_n) \in \mathbb{R}^n = \mathcal{A}_n$$

to a point  $A = (a_1, \dots, a_n) \in \mathcal{A}_n$  and a vector  $v = (v_1, \dots, v_n) \in \mathbb{R}^n = V$ .

This operation satisfies the following three properties:

- (1)  $A + 0 = A$  for all points  $A \in \mathcal{A}_n$  and the null vector  $0 \in V$ ,
- (2)  $A + (v + w) = (A + v) + w$  for all vectors  $v, w \in V$  and points  $A \in \mathcal{A}_n$ ,
- (3) for every two points  $A, B \in \mathcal{A}_n$  there exists exactly one vector  $v \in V$  such that  $A + v = B$ . This vector is denoted by  $v = B - A$ , sometimes also  $\overline{AB}$ .

The underlying vector space  $\mathbb{R}^n$  is called the *difference space* of the standard affine space  $\mathcal{A}_n$ .

Notice that care is needed about several formal ambiguities. In particular, the symbol “+” is used for two different operations. “+” is used for adding a vector from the difference space to a point in the affine space. “+” is also used for summing vectors in the difference space  $V = \mathbb{R}^n$ . Further, notice that the operation “-” assigns a vector to a couple of points and cannot be understood as inverse of the addition (although in the standard affine space it is given by the difference of the  $n$ -tuples  $B$  and  $A$ ). We do not introduce specific letters for the set of points in the affine space.  $\mathcal{A}_n$  denotes both this set of points as well as the whole structure defining the affine space.

Why distinguish between the set of points in the affine space  $\mathcal{A}_n$  and its difference space  $V$  when both spaces can be viewed as  $\mathbb{R}^n$ ? It is a fundamental formal step to understanding the geometry in  $\mathbb{R}^n$ : The issue is that geometric objects, namely straight lines, points, planes etc. do not depend directly on the vector space structure of the set  $\mathbb{R}^n$ . They do not depend at all on the fact that we work with  $n$ -tuples of scalars. We need to know only what it means to move “straight in a given direction”. For instance, we can consider the affine plane as an unbounded board without chosen coordinates, but with the possibility of moving about a given vector. When we switch to such an abstract view, we can discuss the “plane geometry” for two-dimensional subspaces, without the need to work with  $k$ -tuples of coordinates.

This point of view underlies the following definition:

**4.1.2. Definition.** The affine space  $\mathcal{A}$  with the difference space  $V$  is a set of *points*  $\mathcal{P}$ , together with the map

$$\mathcal{P} \times V \rightarrow \mathcal{P}, \quad (A, v) \mapsto A + v.$$

$V$  is a vector space. The map satisfies the properties (1)–(3) from the definition of the standard affine space.

For a fixed vector  $v \in V$ , there is a *translation*  $\tau_v : \mathcal{A} \rightarrow \mathcal{A}$  as the restricted map

$$\tau_v : \mathcal{P} \simeq \mathcal{P} \times \{v\} \rightarrow \mathcal{P}, \quad A \mapsto A + v.$$

yields  $a = 11, b = 12$ . The desired implicit expression is

$$\begin{aligned} 2y &+ u = 11, \\ -x &+ z + 2u = 12. \end{aligned}$$

**Another solution** Since

$$\begin{aligned} x &= t + 2s, \\ y &= 3 - s, \\ z &= 2 + t - 2s, \\ u &= 5 + 2s, \end{aligned}$$

Eliminate  $t$  to get

$$\begin{aligned} x - z &= 2 - 4s, \\ y &= 3 - s, \\ u &= 5 + 2s, \end{aligned}$$

Eliminate  $s$  to obtain two equations, namely

$$\begin{aligned} z - x + 2u &= 12 \\ u + 2y &= 11, \end{aligned}$$

which solves the problem.  $\square$

**4.A.3.** Find a parametric equation of the plane passing through the points

$$A = [2, 1, 1], \quad B = [3, 4, 5], \quad C = [4, -2, 3].$$

Hence find a parametric equation of the open half-plane containing the point  $C$  and bounded by the line passing through the points  $A, B$ .

**Solution.** We need one point and two (linearly independent) vectors lying in the plane. It is enough to choose  $A$  together with the vectors  $B - A = (1, 3, 4)$  and  $C - A = (2, -3, 2)$ , which are clearly independent. A point  $[x, y, z]$  lies in the plane if and only if there exist numbers  $t, s \in \mathbb{R}$  so that

$$x = 2 + 1 \cdot t + 2 \cdot s, \quad y = 1 + 3 \cdot t - 3 \cdot s, \quad z = 1 + 4 \cdot t + 2 \cdot s.$$

Consequently a parametric equation is

$$[x, y, z] = [2, 1, 1] + t(1, 3, 4) + s(2, -3, 2), \quad t, s \in \mathbb{R}.$$

Setting  $s = 0$  gives a line passing through the points  $A$  and  $B$ .  $t = 0$  and  $s \geq 0$ , defines a ray passing through  $C$  with an initial point  $A$ . A particular but arbitrarily chosen  $t \in \mathbb{R}$  and variable  $s \geq 0$  gives a ray initiated on the border line, going through the half-plane in which the point  $C$  lies. That means that the desired open half-plane can be expressed parametrically as

$$[x, y, z] = [2, 1, 1] + t(1, 3, 4) + s(2, -3, 2), \quad t \in \mathbb{R}, s > 0. \quad \square$$

**4.A.4.** Determine the relative position of the lines

$$\begin{aligned} p &: [1, 0, 3] + t(2, -1, -3), \quad t \in \mathbb{R}, \\ q &: [1, 1, 3] + s(1, -1, -2), \quad s \in \mathbb{R}. \end{aligned}$$

**Solution.** Search for common points of the given lines (subspaces intersection). We have a system

$$\begin{aligned} 1 + 2t &= 1 + s, \\ 0 - t &= 1 - s, \\ 3 - 3t &= 3 - 2s. \end{aligned}$$

By the *dimension* of an affine space  $\mathcal{A}$ , is meant the dimension of its difference space.

In the sequel, we do not distinguish accurately between  $\mathcal{A}$  and the set of points  $\mathcal{P}$ . We talk instead about points and vectors of the affine space  $\mathcal{A}$ .

It follows immediately from the axioms that for arbitrary points  $A, B, C$  in the affine space  $\mathcal{A}$

$$\begin{aligned} (1) \quad A - A &= 0 \in V \\ (2) \quad B - A &= -(A - B) \\ (3) \quad (C - B) + (B - A) &= C - A. \end{aligned}$$

Indeed, (1) follows from the fact that  $A + 0 = A$  and that such a vector is unique (the first and third defining property). By adding successively  $B - A$  and  $A - B$  to  $A$ , according to the second defining property we obtain  $A$  again. Add the null vector to prove (2). Similarly, (3) follows from the defining property 4.1.1 (2) and the uniqueness.

Notice that the choice of one fixed point  $A_0 \in \mathcal{A}$  determines a bijection between  $V$  and  $\mathcal{A}$ . So for a fixed basis  $\underline{u}$  in  $V$  there is a unique expression

$$A = A_0 + x_1 u_1 + \cdots + x_n u_n$$

for every point  $A \in \mathcal{A}$ . We talk about an *affine coordinate system*  $(A_0; u_1, \dots, u_n)$  given by the *origin of the affine coordinate system*  $A_0$  and the basis  $\underline{u}$  of the corresponding difference space. This is sometimes called an *affine frame*  $(A_0, \underline{u})$ .

To summarize: Affine coordinates of a point  $A$  in the frame  $(A_0, \underline{u})$  are the coordinates of the vector  $A - A_0$  in the basis  $\underline{u}$  of the difference space  $V$ .

The choice of an affine coordinate system identifies each  $n$ -dimensional affine space  $\mathcal{A}$  with the standard affine space  $\mathcal{A}_n$ .

**4.1.3. Affine subspaces.** If we consider some coordinate system on  $\mathcal{A}$  and choose only such points in  $\mathcal{A}$  which have some chosen coordinates equal to zero (for instance the last one), we obtain again a set which behaves as an affine space. This is the spirit of the following definition of the affine subspaces.

SUBSPACES OF AN AFFINE SPACE

**Definition.** The nonempty subset  $\mathcal{Q} \subset \mathcal{A}$  of an affine space  $\mathcal{A}$  with a difference space  $V$  is called an *affine subspace* in  $\mathcal{A}$  if the subset  $W = \{B - A; A, B \in \mathcal{Q}\} \subset V$  is a vector subspace and  $A + v \in \mathcal{Q}$  for any  $A \in \mathcal{Q}, v \in W$ .

It is important to include both of the conditions in the definition, since there are examples of sets which satisfy the first condition but not the second. One such set consists of a straight line in the plane with one point removed.

For an arbitrary set of points  $M \subset \mathcal{A}$  in an affine space with a difference space  $V$ , we define the vector space

$$Z(M) = \text{span}\{B - A; B, A \in M\} \subset V$$

of all vectors generated by the differences of points in  $M$ .

From the first two equations,  $t = 1, s = 2$ . This does not satisfy the third equation. Thus the system does not have a solution. The direction vector  $(2, -1, -3)$  of the line  $p$  is not a multiple of the direction vector  $(1, -1, -2)$  of the line  $q$ . Hence the lines are not parallel. Hence, the lines are skew.  $\square$

**4.A.5.** Find all numbers  $a \in \mathbb{R}$  so that the lines

$$p : [4, -4, 8] + t(2, 1, -4), \quad t \in \mathbb{R},$$

$$q : [a, 6, -5] + s(1, -3, 3), \quad s \in \mathbb{R}$$

intersect.

**Solution.** The lines intersect if and only if the system

$$\begin{aligned} 4 + 2t &= a + s, \\ -4 + t &= 6 - 3s, \\ 8 - 4t &= -5 + 3s \end{aligned}$$

has a solution. Express the system as a matrix (the first column corresponding to  $t$ , the second to  $s$ ), and solve

$$\begin{aligned} \left( \begin{array}{cc|c} 2 & -1 & a-4 \\ 1 & 3 & 10 \\ -4 & -3 & -13 \end{array} \right) &\sim \left( \begin{array}{cc|c} 1 & 3 & 10 \\ 2 & -1 & a-4 \\ -4 & -3 & -13 \end{array} \right) \\ &\sim \left( \begin{array}{cc|c} 1 & 3 & 10 \\ 0 & -7 & a-24 \\ 0 & 1 & 3 \end{array} \right). \end{aligned}$$

The system has a solution if and only if the second row is a multiple of the third row. This property is satisfied only for  $a = 3$ . The point of intersection of the lines is  $[6, -3, 4]$ .  $\square$

**4.A.6.** In  $\mathbb{R}^3$ , determine the relative position of the line  $p$  defined implicitly by

$$\begin{aligned} x + y - z &= 4, \\ x - 2y + z &= -3 \end{aligned}$$

and the plane  $\varrho : y = 2x - 1$ .

**Solution.** A normal vector to the plane is  $\varrho$  is  $(2, -1, 0)$  (consider  $\varrho : 2x - y + 0z = 1$ ). Since

$$(1, 1, -1) + (1, -2, 1) = (2, -1, 0),$$

the normal vector to the plane  $\varrho$  is a linear combination of the  $p$  normal vectors. A vector defining the line lies in a subspace of the plane  $\varrho$ . It remains to discover whether or not they intersect. The system of equations

$$\begin{aligned} x + y - z &= 4, \\ x - 2y + z &= -3, \\ 2x - y &= 1 \end{aligned}$$

has infinitely many solutions, because the first two equations add to give the third one. So the line  $p$  lies in the plane  $\varrho$ .  $\square$

The following exercise is a typical vector spaces intersection exercise. The reader should be able to solve this. Otherwise we recommend not continuing with this book.

In particular,  $V = Z(\mathcal{A})$ . Every affine subspace  $\mathcal{Q} \subset \mathcal{A}$  itself satisfies the axioms for an affine space with the difference space  $Z(\mathcal{Q})$ .

The intersection of any set of affine subspaces is either an affine subspace or is the empty set. This follows directly from the definitions.

The affine subspace  $\langle M \rangle$  in  $\mathcal{A}$  generated by a nonempty set  $M \subset \mathcal{A}$  is the intersection of all affine subspaces which contain all points of  $M$ .

#### AFFINE HULL AND PARAMETRIC DESCRIPTION

Affine subspaces can be described by their difference spaces after choosing a point  $A_0 \in M$  in a generating set  $M$ . Indeed, to generate the affine subspace, take the vector subspace  $Z(M) \subset Z(\mathcal{A})$  generated by all differences of points in  $M$ , and add this vector space to an arbitrary point in  $M$ , i.e.,  $\langle M \rangle = \{A_0 + v; v \in Z(M) \subset Z(\mathcal{A})\}$ . We talk about the *affine hull* of the set of points  $M$  in  $\mathcal{A}$ .

On the other hand, whenever a subspace  $U$  in the difference space  $Z(\mathcal{A})$  and a fixed point  $A \in \mathcal{A}$  is chosen, the subset  $A + U$ , created by all possible sums of  $A$  and all vectors in  $U$ , is an affine subspace. This approach leads to the notion of parametrization of subspaces:

Let  $\mathcal{Q} = A + Z(\mathcal{Q})$  be an affine subspace in  $\mathcal{A}_n$ . Let  $(u_1, \dots, u_k)$  be a basis of  $Z(\mathcal{Q}) \subset \mathbb{R}^n$ . Then the expression of the subspace

$$\mathcal{Q} = \{A + t_1u_1 + \dots + t_ku_k; t_1, \dots, t_k \in \mathbb{R}\}$$

is called the *parametric description* of the subspace  $\mathcal{Q}$ .

In the sequel, we shall use the same notation  $\langle \rangle$  for the affine hulls in the affine spaces and linear hulls in their difference vector spaces.

There is another way of prescribing affine spaces: If we choose affine coordinates, then the difference space may be described by a homogeneous system of linear equations in these coordinates. By inserting the coordinates of one point of the subspace  $\mathcal{Q}$  into the system of equations, we obtain the right-hand side of the non-homogeneous system with the same matrix. The subspace  $\mathcal{Q}$  is exactly the set of solutions of this system. The description of the subspace  $\mathcal{Q}$  by a system of equations in given coordinates is called an *implicit description* of the subspace  $\mathcal{Q}$ .

The following proposition says that we can prescribe all affine subspaces in this way. It shows the geometric nature of the solutions of systems of linear equations.

**4.1.4. Theorem.** Let  $(A_0; \underline{u})$  be an affine coordinate system in an  $n$ -dimensional affine space  $\mathcal{A}$ . In these coordinates, affine subspaces of dimension  $k$  in  $\mathcal{A}$  are exactly the sets of solutions of solvable systems of  $n - k$  linearly independent equations in  $n$  variables.

**PROOF.** Consider an arbitrary solvable system of  $n - k$  linearly independent equations  $\alpha_i(x) = b_i$ , where  $b_i \in \mathbb{R}$ ,  $i = 1, \dots, n - k$ . Suppose  $A = (a_1, \dots, a_n)^T \in \mathbb{R}^n$  is a

**4.A.7.** Find the intersection of the subspaces  $Q_1$  and  $Q_2$ , where

$$Q_1 : [4, -5, 1, -2] + t_1(3, 5, 4, 2) + t_2(2, 4, 5, 1) + t_3(0, 3, 1, 2),$$

$$Q_2 : [4, 4, 4, 4] + s_1(0, -6, -2, -4) + s_2(-1, -5, -3, -3),$$

for  $t_1, t_2, t_3, s_1, s_2 \in \mathbb{R}$ .

**Solution.** The point  $X = [x_1, x_2, x_3, x_4] \in \mathbb{R}^4$  lies in  $Q_1$  if and only if

$$\begin{bmatrix} x_1 \\ x_2 \\ x_3 \\ x_4 \end{bmatrix} = \begin{bmatrix} 4 \\ -5 \\ 1 \\ -2 \end{bmatrix} + t_1 \begin{bmatrix} 3 \\ 5 \\ 4 \\ 2 \end{bmatrix} + t_2 \begin{bmatrix} 2 \\ 4 \\ 5 \\ 1 \end{bmatrix} + t_3 \begin{bmatrix} 0 \\ 3 \\ 1 \\ 2 \end{bmatrix}$$

for some numbers  $t_1, t_2, t_3 \in \mathbb{R}$ . The point  $X = [x_1, x_2, x_3, x_4] \in \mathbb{R}^4$  lies in  $Q_2$  if and only if

$$\begin{bmatrix} x_1 \\ x_2 \\ x_3 \\ x_4 \end{bmatrix} = \begin{bmatrix} 4 \\ 4 \\ 4 \\ 4 \end{bmatrix} + s_1 \begin{bmatrix} 0 \\ -6 \\ -2 \\ -4 \end{bmatrix} + s_2 \begin{bmatrix} -1 \\ -5 \\ -3 \\ -3 \end{bmatrix}$$

for some  $s_1, s_2 \in \mathbb{R}$ . Hence if  $X$  lies in  $Q_1 \cap Q_2$  then the equation

$$t_1 \begin{bmatrix} 3 \\ 5 \\ 4 \\ 2 \end{bmatrix} + t_2 \begin{bmatrix} 2 \\ 4 \\ 5 \\ 1 \end{bmatrix} + t_3 \begin{bmatrix} 0 \\ 3 \\ 1 \\ 2 \end{bmatrix} = \begin{bmatrix} 4-4 \\ 4+5 \\ 4-1 \\ 4+2 \end{bmatrix} + s_1 \begin{bmatrix} 0 \\ -6 \\ -2 \\ -4 \end{bmatrix} + s_2 \begin{bmatrix} -1 \\ -5 \\ -3 \\ -3 \end{bmatrix}.$$

has a solution for  $t_1, t_2, t_3, s_1, s_2$ .

Move the vectors corresponding to  $s_1$  and  $s_2$  to the left-hand side. Write the equations in matrix form and reduce to echelon form. There follows

$$\begin{pmatrix} 3 & 2 & 0 & 0 & 1 & 0 \\ 5 & 4 & 3 & 6 & 5 & 9 \\ 4 & 5 & 1 & 2 & 3 & 3 \\ 2 & 1 & 2 & 4 & 3 & 6 \end{pmatrix} \sim \begin{pmatrix} 3 & 2 & 0 & 0 & 1 & 0 \\ 0 & 2 & 9 & 18 & 10 & 27 \\ 0 & 7 & 3 & 6 & 5 & 9 \\ 0 & -1 & 6 & 12 & 7 & 18 \end{pmatrix}$$

$$\sim \dots \sim \left( \begin{array}{cccccc|c} 3 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 2 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 2 & 0 & 3 & 0 \\ 0 & 0 & 0 & 0 & 1 & 0 & 0 \end{array} \right).$$

So  $t_1 = t_2 = s_2 = 0$  and for  $s_1 = t \in \mathbb{R}$  we have  $t_3 = 3 - 2t$ . Note that for the determination of  $Q_1 \cap Q_2$ , it is sufficient to know either  $t_1, t_2, t_3$ , or  $s_1, s_2$ . So

$$\begin{bmatrix} x_1 \\ x_2 \\ x_3 \\ x_4 \end{bmatrix} = \begin{bmatrix} 4 \\ 4 \\ 4 \\ 4 \end{bmatrix} + s_1 \begin{bmatrix} 0 \\ -6 \\ -2 \\ -4 \end{bmatrix} + s_2 \begin{bmatrix} -1 \\ -5 \\ -3 \\ -3 \end{bmatrix} = \begin{bmatrix} 4 \\ 4 \\ 4 \\ 4 \end{bmatrix} + t \begin{bmatrix} 0 \\ -6 \\ -2 \\ -4 \end{bmatrix}.$$

This should be checked using  $t_1 = t_2 = 0$  and  $t_3 = 3 - 2t$ . The solution is a line lying in both planes. It is  $Q_1 \cap Q_2$ .  $\square$

fixed solution of this (non-homogeneous) system. Suppose also that  $U \subset \mathbb{R}^n$  is the vector space of all solutions of the homogenized system  $\alpha_i(x) = 0$ . Then the dimension of  $U$  is  $k$ . The set of all solutions of the given system is of the form  $\{B; B = A + (y_1, \dots, y_n)^T, y = (y_1, \dots, y_n)^T \in U\} \subset \mathbb{R}^n$ , c.f. 2.3.5. So the corresponding affine subspace is described parametrically by the initial coordinates  $(A_0; \underline{u})$ .

Conversely, consider an arbitrary affine subspace  $Q \subset \mathbb{A}^n$ . Choose a point  $B$  therein, and consider this point to be the origin of an affine coordinate system  $(B, \underline{v})$  for the affine space  $\mathcal{A}$ . Since  $Q = B + Z(Q)$ , it is necessary to describe the difference space of the subspace  $Q$  as a subspace of solutions of a homogeneous system of linear equations. Therefore, choose a basis  $\underline{v}$  of  $Z(\mathcal{A})$  such that the first  $k$  vectors form a basis of  $Z(Q)$ . In these coordinates, the vectors  $v \in Z(Q)$  are given by equations

$$\alpha_j(v) = 0, \quad j = k + 1, \dots, n.$$

The  $\alpha_i$  are linear forms from the dual basis to  $\underline{v}$ . They are the functions which assign to a vector the corresponding coordinates in the basis  $\underline{v}$ .

Hence the vector subspace  $Z(Q)$  of dimension  $k$  in the  $n$ -dimensional space  $\mathbb{R}^n$  is given as a solution of a homogeneous system of  $n - k$  independent equations. The description of the chosen affine subspace in the newly chosen coordinate system  $(B; \underline{v})$  is therefore given by a system of homogeneous linear equations.

It remains to consider the consequences of the transition from the former coordinate system  $(A; \underline{u})$  to the new adapted system  $(B; \underline{v})$ . It follows from a general consideration about transformations of coordinates in the following paragraph that the final description of the subspace is again a system of linear equations. This time it is non-homogeneous in general.  $\square$

**4.1.5. Coordinate transformations.** Any two arbitrarily chosen affine coordinate systems  $(A_0, \underline{u})$ ,

$(B_0, \underline{v})$  differ in the basis of the difference spaces and the origin of the latter one is translated about the vector  $(B_0 - A_0)$ . Hence the equations for the corresponding coordinate transformations can be read off from the rule for a transformation of a point  $X \in \mathcal{A}$

$$X = B_0 + x'_1 v_1 + \dots + x'_n v_n$$

$$= B_0 + (A_0 - B_0) + x_1 u_1 + \dots + x_n u_n.$$

Let  $y = (y_1, \dots, y_n)^T$  denote the column of coordinates of the vector  $(A_0 - B_0)$  in the basis  $\underline{v}$ . Let  $M = (a_{ij})$  be the matrix expressing the basis  $\underline{u}$  in terms of the basis  $\underline{v}$ . Then

$$x'_1 = y_1 + a_{11}x_1 + \dots + a_{1n}x_n$$

$$\vdots$$

$$x'_n = y_n + a_{n1}x_1 + \dots + a_{nn}x_n.$$

In matrix notation

$$x' = y + M \cdot x.$$

**4.A.8.** Determine whether or not the points  $[0, 2, 1]$ ,  $[-1, 2, 0]$ ,  $[-2, 5, 2]$  and  $[0, 5, 4]$  in  $\mathbb{R}^3$  all lie in the same plane.

**Solution.** Consider the vectors  $[0, 2, 1] - [-1, 2, 0] = (1, 0, 1)$ ,  $[0, 2, 1] - [-2, 5, 2] = (2, -3, -1)$  and  $[0, 2, 1] - [0, 5, 4] = (0, -3, -3)$ . They are linearly dependent since the matrix

$$\begin{pmatrix} 1 & 0 & 1 \\ 2 & -3 & -1 \\ 0 & -3 & -3 \end{pmatrix},$$

has rank 2. Hence, the given points lie in a plane.  $\square$

**4.A.9.** Into how many parts can three planes slice the space ( $\mathbb{R}^3$ )? Give an example of planes in a suitable position for every case.

**4.A.10.** Determine whether or not the point  $[2, 1, 0]$  lies within the convex hull of the points  $[0, 2, 1]$ ,  $[1, 0, 1]$ ,  $[3, -2, -1]$ ,  $[-1, 0, 1]$ .

**Solution.**  $[2, 1, 0]$  lies in the convex hull (see chapter 4.9) if and only if

$[2, 1, 0] = t_1[0, 2, 1] + t_2[1, 0, 1] + t_3[3, -2, -1] + t_4[-1, 0, 1]$  has a solution with  $t_1, t_2, t_3, t_4$ , all non-negative and  $t_1 + t_2 + t_3 + t_4 = 1$ . Equivalently,  $[2, 1, 0]$  lies in the convex hull if and only if

$$\begin{aligned} [2, 1, 0, 1] &= t_1[0, 2, 1, 1] + t_2[1, 0, 1, 1] + t_3[3, -2, -1, 1] \\ &\quad + t_4[-1, 0, 1, 1] \end{aligned}$$

has a solution with  $t_1, t_2, t_3, t_4$ , all non-negative. Solving these four equations, gives  $(t_1, t_2, t_3, t_4) = (1, 0, 1/2, -1/2)$ , so the given point does not lie in the convex hull.  $\square$

**4.A.11.** In  $\mathbb{R}^3$ , a tetrahedron has vertices  $ABCD$ , where  $A = [4, 0, 2]$ ,  $B = [-2, -3, 1]$ ,  $C = [1, -1, -3]$ ,  $D = [2, 4, -2]$ .

- Determine its volume.
- Decide whether or not the point  $X = [0, -3, 0]$  lies inside the tetrahedron.

**Solution.** a) The volume of the tetrahedron is one sixth of volume of a parallelepiped, of which three edges from the point  $A$  are  $B - A = (-6, -3, -1)$ ,  $C - A = (-3, -1, -5)$  and  $D - A = (-2, 4, -4)$ . It is given by the absolute value of the determinant

$$\begin{vmatrix} -6 & -3 & -1 \\ -3 & -1 & -5 \\ -2 & 4 & -4 \end{vmatrix} = -124.$$

Thus, the volume of the tetrahedron is  $\frac{124}{6}$ .

b) Write  $X$  as an affine combination of its vertices, by solving the system of four linear equation in four unknowns  $a, b, c, d$  given by the equality  $X = aA + bB + cC + dD$ . The solution is  $X = \frac{1}{4}A + \frac{1}{2}B + \frac{1}{2}C - \frac{1}{4}D$ . Since the coefficient of  $D$  is negative,  $X$  does not lie in the convex hull of the points  $A, B, C$  and  $D$ . Hence the given point does not lie inside the tetrahedron.  $\square$

Now, we can come back to the proof of the previous theorem. Suppose the system of linear equations in the “new” coordinates  $(B_0; \underline{v})$  has the form

$$S \cdot x' = b$$

where  $S$  is the matrix of the system. Then, in the original coordinates  $(A_0; \underline{u})$

$$S \cdot x' = S \cdot (y + M \cdot x) = b.$$

Thus in the original coordinates the system has the form

$$S \cdot M \cdot x = b - S \cdot y.$$

Therefore, if a subspace is described by a system of linear equations in one affine frame, then it is so described in all other affine frames. This completes the proof of the previous proposition.

**4.1.6. Examples of subspaces.** (1) The one-dimensional (standard) affine space is the set of all points of a real straight line  $\mathcal{A}_1$ . Its difference space is a one-dimensional vector space  $\mathbb{R}$ . The supporting set (i.e. the set of points in  $\mathcal{A}_1$ ) is also  $\mathbb{R}$ . The affine coordinates are obtained by the choice of an origin and a scale (i.e. a basis in the vector space  $\mathbb{R}$ ). All proper affine spaces are 0-dimensional. They are formed by all points of the real straight line  $\mathbb{R}$ .

(2) The two-dimensional (standard) affine space is a set of all points in the space  $\mathcal{A}_2$  with the difference space  $\mathbb{R}^2$ . The supporting set is  $\mathbb{R}^2$ . The affine coordinates are obtained by a choice of an origin and two linearly independent vectors (directions and scales). The proper subspaces are then all points and straight lines in the plane (0-dimensional and 1-dimensional). The lines are prescribed by the choice of a point and one vector from the corresponding difference space. The vector is a generator of direction as in the parametric definition of the straight line.

(3) The three-dimensional (standard) affine space is a set of all points in the space  $\mathcal{A}_3$  with the difference space  $\mathbb{R}^3$ . The affine coordinates are obtained by the choice of an origin and three linearly independent vectors (directions and scales). The proper affine subspaces are then all points, straight lines and planes (0-dimensional, 1-dimensional and 2-dimensional).

(4) Suppose there is given a nonzero vector of coefficients  $(a_1, \dots, a_n)$  and a scalar  $b \in \mathbb{R}$ . Compute the subspace of all solutions of one linear equation  $a \cdot x = b$  for the unknown point  $[x_1, \dots, x_n] \in \mathcal{A}_n$ . This is an affine subspace of dimension  $n - 1$ . We say that the subspace is of codimension 1, called a *hyperplane* in  $\mathcal{A}_n$ .

**4.1.7. Affine combinations of points.** We introduce an analogue of the linear combination of vectors. Let  $A_0, \dots, A_k$  be points in the affine space  $\mathcal{A}$ . Their affine hull  $\langle \{A_0, \dots, A_k\} \rangle$  can be written as the set of points

$$\{A_0 + t_1(A_1 - A_0) + \dots + t_k(A_k - A_0); t_1, \dots, t_k \in \mathbb{R}\}.$$

**4.A.12. Affine transformation of point coordinates**

The point  $X$  has coordinates expressed as  $[2, 2, 3]$  in an affine basis  $\{[1, 2, 3], (1, 1, 1), (1, -1, 2), (2, 1, 1)\}$  (in  $\mathbb{R}^3$ ). Determine its coordinates in the standard basis, i.e. in the basis  $\{[0, 0, 0], (1, 0, 0), (0, 1, 0), (0, 0, 1)\}$ .

**Solution.** The coordinates  $[2, 2, 3]$  in the given basis are by the definition

$$\begin{aligned} & [1, 2, 3] + 2 \cdot (1, 1, 1) + 2 \cdot (1, -1, 2) + 3 \cdot (2, 1, 1) \\ &= [11, 5, 12] \end{aligned}$$

coordinates for  $X$  in the standard basis.  $\square$

**4.A.13. Affine transformation of mapping.** Find the affine mapping  $f$  in the coordinate system with the basis  $\underline{u} = \{(1, 1), (-1, 1)\}$  and origin  $[2, 0]$ , defined as

$$f(x_1, x_2) = \begin{pmatrix} 2 & 1 \\ 0 & 1 \end{pmatrix} \begin{pmatrix} x_1 \\ x_2 \end{pmatrix} + \begin{pmatrix} 1 \\ 1 \end{pmatrix}$$

in the standard basis in  $\mathbb{R}^2$ .

**Solution.** The change of the basis matrix from the basis  $\underline{u}$  to the standard basis is

$$\begin{pmatrix} 1 & -1 \\ 1 & 1 \end{pmatrix}.$$

The transformation matrix in the basis  $([2, 0], \underline{u})$  is obtained by first transforming the coordinates in the basis  $([2, 0], \underline{u})$  to the standard basis, i.e. to the basis  $([0, 0], (1, 0), (0, 1))$ . Then the transformation matrix  $f$  is applied in the standard basis. Finally it is transformed back to the coordinates in the basis  $([2, 0], \underline{u})$ . The transformation equations for changing the coordinates  $y_1, y_2$  in the basis  $([2, 0], \underline{u})$  to the coordinates  $x_1, x_2$  in the standard basis are

$$\begin{pmatrix} x_1 \\ x_2 \end{pmatrix} = \begin{pmatrix} 1 & -1 \\ 1 & 1 \end{pmatrix} \begin{pmatrix} y_1 \\ y_2 \end{pmatrix} + \begin{pmatrix} 2 \\ 0 \end{pmatrix}.$$

Hereby

$$\begin{aligned} \begin{pmatrix} y_1 \\ y_2 \end{pmatrix} &= \begin{pmatrix} 1 & -1 \\ 1 & 1 \end{pmatrix}^{-1} \left( \begin{pmatrix} x_1 \\ x_2 \end{pmatrix} - \begin{pmatrix} 2 \\ 0 \end{pmatrix} \right) \\ &= \begin{pmatrix} \frac{1}{2} & \frac{1}{2} \\ -\frac{1}{2} & \frac{1}{2} \end{pmatrix} \begin{pmatrix} x_1 \\ x_2 \end{pmatrix} + \begin{pmatrix} -1 \\ 1 \end{pmatrix}. \end{aligned}$$

Hence the desired mapping is

$$\begin{aligned} & f(y_1, y_2) \\ &= \begin{pmatrix} \frac{1}{2} & \frac{1}{2} \\ -\frac{1}{2} & \frac{1}{2} \end{pmatrix} \left[ \begin{pmatrix} 2 & 1 \\ 0 & 1 \end{pmatrix} \left( \begin{pmatrix} 1 & -1 \\ 1 & 1 \end{pmatrix} \begin{pmatrix} y_1 \\ y_2 \end{pmatrix} + \begin{pmatrix} 2 \\ 0 \end{pmatrix} \right) + \begin{pmatrix} 1 \\ 1 \end{pmatrix} \right] + \begin{pmatrix} -1 \\ 1 \end{pmatrix} \\ &= \begin{pmatrix} 2 & 0 \\ -1 & 1 \end{pmatrix} \begin{pmatrix} y_1 \\ y_2 \end{pmatrix} + \begin{pmatrix} 2 \\ -1 \end{pmatrix} \end{aligned}$$

In any affine coordinates the same set can be written as

$$\{t_0 A_0 + \dots + t_k A_k; t_i \in \mathbb{R}, \sum_{i=0}^k t_i = 1\}.$$

**AFFINE COMBINATIONS OF POINTS**

In general, by the formula  $t_0 A_0 + t_1 A_1 + \dots + t_k A_k$  with coefficients satisfying  $\sum_{i=0}^k t_i = 1$  is meant the set of all points  $A_0 + \sum_{i=1}^k t_i (A_i - A_0)$ . They are called the *affine combinations of points*.

The points  $A_0, \dots, A_k$  are in *general position* if they generate a  $k$ -dimensional affine subspace. This happens if and only if for each  $A_i$ , the vectors which arise as differences of this point  $A_i$ , and all other vectors  $A_j$ , are linearly independent. Observe that an assignment of a series of  $(\dim \mathcal{A}) + 1$  points in general position is equivalent to the definition of an affine frame with the origin in the first of them.

**4.1.8. Simplexes.** For points in an affine space, the affine combination is a similar construction to the linear combination for vectors in a vector space. Indeed, the affine subspace generated by points  $A_0, \dots, A_k$  equals the set of all affine combinations of its generators. The notion “to lie on the line between two points” can be generalized. In the two-dimensional case, imagine the interior of a triangle. In general proceed as follows:

**$k$ -DIMENSIONAL SIMPLEXES**

Let  $A_0, \dots, A_k$  be  $k + 1$  points in general position in an affine space  $\mathcal{A}$ . The set  $\Delta = \Delta(A_0, \dots, A_k)$  is defined as the set of all affine combinations of points  $A_i$  with nonnegative coefficients only. This is

$$\Delta = \{t_0 A_0 + t_1 A_1 + \dots + t_k A_k; 0 \leq t_i, \sum_{i=0}^k t_i = 1\},$$

called a  $k$ -dimensional *simplex* generated by the points  $A_i$ .

A one-dimensional simplex is a *line segment*, a two-dimensional simplex is a *triangle*, while a zero-dimensional simplex is a point.

Notice that each  $k$ -dimensional simplex has exactly  $k + 1$  *faces* defined by equations  $t_i = 0, i = 0, \dots, k$ . The faces are also simplexes, and their dimension is  $k - 1$ . We talk about the *boundary* of the simplex. For instance, the boundary of a triangle is formed by the three edges, and the boundary of each edge is formed by the two vertices.

The description of a subspace as a set of affine combinations of points in general position is equivalent to the parametric description. We work similarly with the parametric description of simplexes.

**4.1.9. Convex sets.** The subset  $M$  of an affine space is called *convex* if and only if for any two points  $A, B \in M$  the set contains the line segment  $\Delta(A, B)$ . Directly from the definition, each convex set with  $k + 1$  points in general position contains  $\square$  also the entire simplex defined by these points

**4.A.14.** Let there be a standard coordinate system in  $\mathbb{R}^3$  space. Agent K lives at the point  $S$  with coordinates  $[0, 1, 2]$ . The headquarters gave him a coordinate system with origin  $S$  and basis  $\{(1, 1, 0), (-1, 0, 1), (0, 1, 2)\}$ . Agent Bond lives at the point  $D$  with coordinates  $[1, 1, 1]$  and uses a coordinate system with basis  $\{(0, 0, 1), (-1, 1, 2), (1, 0, 1)\}$ . Agent K has set an appointment with agent Bond in the old brickfield which is (according to K's coordinate system) at the point  $[1, 1, 0]$ . To where should Bond go (regarding his coordinate system)?

**Solution.** The change of basis matrix from agent K's basis to the Bond's basis (with the same origins) is

$$T = \begin{pmatrix} -4 & 2 & -1 \\ 1 & 0 & 1 \\ 2 & -1 & 1 \end{pmatrix}$$

The vector  $(0, 1, 2)$  thus has coordinates  $T \cdot (0, 1, 2)^T = (0, 2, 1)^T$ . Translate the origin (add the vector  $(-1, 0, 1)$ ) to obtain the result  $(-1, 2, 2)$ .  $\square$

**4.A.15.** Find a transversal of the lines (that is, a line passing through both given lines)

$$[1, 1, 1] + t(2, 1, 0), \quad q: [2, 2, 0] + t(1, 1, 1),$$

so that  $[1, 0, 0]$  lies on the transversal.

**Solution.** The transversal lies in the plane  $\rho$  defined by the point  $[1, 0, 0]$  and the line  $p$ . Hence it lies in the plane

$$[1, 1, 1] + t(2, 1, 0) + s(0, 1, 1).$$

Let the point  $Q$  be the intersection of this plane with the line  $q$ .  $Q$  is obtained by solving the system

$$\begin{aligned} 1 + 2t &= 2 + u \\ 1 + t + s &= 2 + u \\ 1 + s &= u \end{aligned}$$

The left-hand sides of the equations represent all three coordinates of an arbitrary point of the plane  $\rho$  respectively. The right-hand sides then represent the coordinates of an arbitrary point on  $q$  (the free variable is denoted  $u$  in order not to be ambiguous). Solving this system, yields  $s = 2$ ,  $t = 2$ ,  $u = 3$ . Putting  $u = 3$  into the line  $q$  equation, gives  $Q = [5, 5, 3]$ . The desired transversal is thus given by  $Q$  and the point  $[1, 0, 0]$ . The intersection of the transversal with  $p$  is at  $P = [7/3, 5/3, 1]$ .  $\square$

**4.A.16.** Find the common perpendicular between the two skew lines

$$\begin{aligned} p: & [3, 0, 3] + (0, 1, 2)t, \quad t \in \mathbb{R} \\ q: & [0, -1, -2] + (1, 2, 3)s \quad s \in \mathbb{R} \end{aligned}$$

**Solution.** The direction of the common perpendicular is given by the cross product of the two direction vectors. So the direction of the common perpendicular is  $(1, -2, 1)$ . Form a linear equation system which

Examples of convex sets are

- (1) the empty set,
- (2) affine subspaces,
- (3) line segments, rays  $p = \{P + t \cdot v; t \geq 0\}$ ,
- (4) more generally  $k$ -dimensional objects

$$\alpha = \{P + t_1 \cdot v_1 + \dots + t_k \cdot v_k; t_1, \dots, t_k \in \mathbb{R}, t_k \geq 0\},$$

- (5) angles in two-dimensional subspaces

$$\beta = \{P + t_1 \cdot v_1 + t_2 \cdot v_2; t_1 \geq 0, t_2 \geq 0\}.$$

The intersection of an arbitrary system of convex sets is a convex set. The intersection of all convex sets containing a given set  $M$  is called the *convex hull*  $\mathcal{K}(M)$  of the set  $M$ .

**Theorem.** The convex hull of any subset  $M \subset \mathcal{A}$  is

$$\mathcal{K}(M) = \{t_1 A_1 + \dots + t_s A_s; \sum_{i=1}^s t_i = 1, t_i \geq 0, A_i \in M\}$$

**PROOF.** Let  $S$  denote the set of all affine combinations on the right-hand side of the equation. To check that  $S$  is convex, choose two sets of parameters  $t_i, i = 1, \dots, s_1, t'_j, j = 1, \dots, s_2$  with the desired properties.

Without loss of generality, assume that  $s_1 = s_2$  and that the same points from  $M$  there appear in both combinations (otherwise simply add summands with zero coefficients). Consider an arbitrary point on the line segment given by the vertices defined by the two combinations:

$$\varepsilon(t_1 A_1 + \dots + t_s A_s) + (1 - \varepsilon)(t'_1 A_1 + \dots + t'_s A_s), \quad 0 \leq \varepsilon \leq 1.$$

Obviously any point of this line segment lies in  $S$ .

It remains to show that the convex hull of the points  $A_1, \dots, A_s$  cannot be smaller than  $S$ . The points  $A_i$  themselves correspond to the choice of parameters  $t_j = 0$  for all  $j \neq i$  and  $t_i = 1$ . Assume that the claim holds for all sets with at most  $s - 1$  points. Then the convex hull of the points  $A_1, \dots, A_{s-1}$  is (according to the assumption) formed exactly by the combinations from the right side of the equation to be proved, where  $t_s = 0$ . Now consider a point  $A = t_1 A_1 + \dots + t_s A_s \in S, t_s < 1$ , and affine combinations  $\varepsilon(t_1 A_1 + \dots + t_{s-1} A_{s-1}) + (1 - \varepsilon(1 - t_s)) A_s, 0 \leq \varepsilon \leq \frac{1}{1 - t_s}$ . It is a line segment with vertices given by parameters  $\varepsilon = 0$  (the point  $A_s$ ) and  $\varepsilon = 1/(1 - t_s)$  (a point in the convex hull of  $A_1, \dots, A_{s-1}$ ). The point  $A$  is an inner point of this line segment with the parameter  $\varepsilon = 1$ , and thus  $A$  lies in the convex hull of  $A_1, \dots, A_s$ .  $\square$

The convex hulls of finite sets are called *convex polyhedrons*.

We have a  $k$ -dimensional *simplex* if and only if the vertices  $A_0, \dots, A_k$  defining the convex polyhedron are in general position. In the case of a simplex, the expression of any of its points as an affine combination of the defining vertices is unique.

Specific examples are the convex polyhedrons defined by one point and a finite number of vectors. Let  $u_1, \dots, u_k$  be

expresses that a vector defined by two points, one lying on  $p$ , the other on  $q$ , is parallel to the direction  $(1, -2, 1)$ . We get the system  $P - Q = k(1, -2, 1)$ , or  $\underbrace{[3, 0, 3] + (0, 1, 2)t}_{P} - \underbrace{[0, -1, -2] + (1, 2, 3)s}_{Q} = k(1, -2, 1)$ .

Treat this equality component-wise to give

$$\begin{aligned} 3 - s &= k \\ 1 + t - 2s &= -2k \\ 5 + 2t - 3s &= k \end{aligned}$$

with the solution  $t = 1, s = 2, k = 1$ . Put  $t = 1$  into the line  $p$ , to obtain the point  $[3, 1, 5]$  on the common perpendicular. Put  $s = 2$  into the line  $q$  equation to obtain the point  $[3, 1, 5]$ . The common perpendicular is defined by the line joining these two points.  $\square$

### B. Euclidean geometry

**4.B.1.** Determine the distance between the lines in  $\mathbb{R}^3$ .

$p : [1, -1, 0] + t(-1, 2, 3)$ , and  $q : [2, 5, -1] + t(-1, -2, 1)$ .

**Solution.** The distance is defined as the distance of the orthogonal projection of arbitrary points on the respective lines to the orthogonal complement of the vector subspace generated by their directions. The orthogonal complement is spanned by the cross product:

$$\begin{aligned} \langle (-1, 2, 3), (-1, -2, 1) \rangle^\perp &= \langle (-1, 2, 3) \times (-1, -2, 1) \rangle \\ &= \langle (8, -2, 4) \rangle = \langle (4, -1, 2) \rangle. \end{aligned}$$

A transversal is (for example) the segment joining  $[1, -1, 0]$  to  $[2, 5, -1]$ . So the vector to be projected is  $[1, -1, 0] - [2, 5, -1] = (-1, -6, 1)$ . The distance between the lines is therefore:

$$\rho(p, q) = \frac{|(-1, -6, 1) \cdot (4, -1, 2)|}{\|(4, -1, 2)\|} = \frac{4}{\sqrt{21}}.$$

$\square$

**4.B.2.** Find a point  $A$  lying on the line

$$p : x + 2y + z - 1 = 0, \quad 3x - y + 4z - 29 = 0,$$

which is equidistant from both  $B = [3, 11, 4]$  and  $C = [-5, -13, -2]$ .

**Solution.** First, express the line  $p$  parametrically. Solve the system

$$\begin{aligned} x + 2y + z &= 1, \\ 3x - y + 4z &= 29. \end{aligned}$$

Rewrite the system as an augmented matrix and perform row operations

$$\begin{aligned} \left( \begin{array}{ccc|c} 1 & 2 & 1 & 1 \\ 3 & -1 & 4 & 29 \end{array} \right) &\sim \left( \begin{array}{ccc|c} 1 & 2 & 1 & 1 \\ 0 & -7 & 1 & 26 \end{array} \right) \\ &\sim \left( \begin{array}{ccc|c} 1 & 0 & 9/7 & 59/7 \\ 0 & 1 & -1/7 & -26/7 \end{array} \right). \end{aligned}$$

The line  $p$  is thus described by

$$p : \left[ \frac{59}{7}, -\frac{26}{7}, 0 \right] + t \left( -\frac{9}{7}, \frac{1}{7}, 1 \right), \quad t \in \mathbb{R}.$$

arbitrary vectors in the difference space  $\mathbb{R}^n$ ,  $A \in \mathcal{A}_n$  a point. A *parallelepiped*  $\mathcal{P}_k(A; u_1, \dots, u_k) \subset \mathcal{A}_n$  is the set

$$\mathcal{P}_k(A; u_1, \dots, u_k) = \{A + c_1u_1 + \dots + c_ku_k; 0 \leq c_i \leq 1\}.$$

If the vectors  $u_1, \dots, u_k$  are independent, we talk about a  $k$ -dimensional parallelepiped  $\mathcal{P}_k(A; u_1, \dots, u_k) \subset \mathcal{A}_n$ . It is clear from the definition that parallelepipeds are convex. They are the convex hulls of their vertices.

**4.1.10. Examples of standard affine tasks.** (1) *To find a parametric description of an implicitly given subspace and vice versa:*

Find a particular solution of a non-homogeneous system and a fundamental solution of the homogenized system. Then obtain (in the coordinates in which the equations have been set) the desired parametric description. In the opposite direction, write the parametric description in coordinates and then eliminate the free parameters  $t_1, \dots, t_k$ . This results in the equations defining the given subspace implicitly.

(2) *To find the subspace generated by several subspaces  $\mathcal{Q}_1, \dots, \mathcal{Q}_s$  (of different dimensions in general). For instance, to find a plane in  $\mathcal{A}_3$  given by a straight line and a point, or by three points). To define this subspace implicitly or parametrically:*

The resulting subspace  $\mathcal{Q}$  is always determined by one fixed point  $A_i$  in each subspace  $\mathcal{Q}_i$  and by the sum of all difference spaces. For instance,

$$\mathcal{Q} = A_1 + (Z(\{A_1, \dots, A_s\}) + Z(\mathcal{Q}_1) + \dots + Z(\mathcal{Q}_s)).$$

If the subspaces are given implicitly, it is possible to convert them into parametric form first. Nevertheless, different methods are advantageous in some concrete situations. Notice that it is really necessary to use one point from each of the subspaces. For example, two parallel lines in a plane generate the whole plane, but they share the same one-dimensional difference space.

(3) *To find the intersection of the subspaces  $\mathcal{Q}_1, \dots, \mathcal{Q}_s$ :*

If they are given in the implicit form, it is sufficient to unify all equations into one system, omitting any linearly dependent ones. If the resulting system has no solution, then the intersection is empty. Otherwise, an implicit description of the affine subspace is obtained. This is the intersection we are searching for.

If parametric forms are given, we may search directly for common points as solutions of the appropriate equations, similarly to the way we find the intersections of vector spaces. If the number of subspaces is greater than two, we must search for the intersection step by step.

If one of the subspaces is defined parametrically and the other implicitly, it suffices to substitute the parametrized coordinates and to solve the resulting system of equations.

(4) *To find a crossbar between two skew lines  $p, q$  in  $\mathcal{A}_3$  passing through a given point or having a given direction:*

By a *crossbar* we mean a straight line which has nonempty intersection with both skew lines. Thus the

It is convenient to avoid the fractions, by introducing the substitution  $t = 7s + 26$ .  $p$  is thus described by

$$p : [-25, 0, 26] + s(-9, 1, 7), \quad s \in \mathbb{R}.$$

The point  $A$  is obtained by requiring that the vectors

$$A - B = (-28 - 9s, -11 + s, 22 + 7s),$$

$$A - C = (-20 - 9s, 13 + s, 28 + 7s)$$

have the same length. Hence

$$\begin{aligned} & \sqrt{(-28 - 9s)^2 + (-11 + s)^2 + (22 + 7s)^2} \\ &= \sqrt{(-20 - 9s)^2 + (13 + s)^2 + (28 + 7s)^2}, \end{aligned}$$

or rather

$$\begin{aligned} & (-28 - 9s)^2 + (-11 + s)^2 + (22 + 7s)^2 \\ &= (-20 - 9s)^2 + (13 + s)^2 + (28 + 7s)^2. \end{aligned}$$

which has the unique solution  $s = -3$ . Therefore

$$A = [-25, 0, 26] - 3(-9, 1, 7) = [2, -3, 5].$$

□

**4.B.3.** Michael has a stick of length 4. Can he touch the lines  $p$  and  $q$  simultaneously with this stick, given that the stick must pass through  $[2, 1, 2]$ ?

$$\begin{aligned} p & : [-1, 4, 1] + t(-1, 2, 0), \\ q & : [4, 4, -1] + s(1, 2, -4)? \end{aligned}$$

**Solution.** Compute the transversal of those lines passing through  $[2, 1, 2]$ . It is the segment joining  $[1, 0, 1]$  to  $[3, 2, 3]$ . Its length is  $\sqrt{12}$ , which is less than 4. So Michael can touch the lines as required. □

**4.B.4.** In Euclidean space  $\mathbb{R}^4$ , determine the distance between the point  $A = [2, -5, 1, 4]$  and the subspace defined by the equations

$$\begin{aligned} U : 4x_1 - 2x_2 - 3x_3 - 2x_4 + 12 &= 0, \\ 2x_1 - x_2 - 2x_3 - 2x_4 + 9 &= 0. \end{aligned}$$

**Solution.** Find first a parametric expression of the subspace  $U$ . For example,

$$B = [0, 3, 0, 3] \in U.$$

The distance between  $A$  and  $U$  equals the length of the orthogonal projection of the vector  $A - B$  to the orthogonal complement of the direction of the subspace  $U$ . However, the orthogonal complement of the  $U$  direction (it defines this subspace) – as set (of linear combination of normal vectors)

$$V := \{t(4, -2, -3, -2) + s(2, -1, -2, -2); t, s \in \mathbb{R}\}.$$

We need to find the orthogonal projection  $P_{A-B}$  of vector  $A - B$  to  $V$ , which lies in  $V$ , and thus

$$P_{A-B} = a(4, -2, -3, -2) + b(2, -1, -2, -2)$$

for certain  $a, b \in \mathbb{R}$ . Clearly,  $(A - B - P_{A-B}) \perp V$ , thus

$$((A - B) - P_{A-B}) \perp (4, -2, -3, -2),$$

resulting crossbar  $r$  is a one-dimensional affine subspace. If we are given one point  $A \in r$ , then the affine subspace generated by  $p$  and  $A$  is either a straight line (if  $A \in p$ ) or a plane (if  $A \notin p$ ). In the first case, there are an infinite number of solutions, one for each point of  $q$ . In the second case, it suffices to find the intersection  $B$  of the plane  $\langle p \cup A \rangle$  with  $q$ , and  $r = \langle \{A, B\} \rangle$ . There is no solution if the intersection is empty. If  $q \subset \langle p \cup A \rangle$ , there are an infinite number of solutions. If the intersection has one element, there is exactly one solution.

If a direction  $u \in \mathbb{R}^n$  is given, then we consider the subspace  $Q$  generated by  $p$  and the difference space  $Z(p) + \langle u \rangle \subset \mathbb{R}^n$ . Again, we obtain an infinite number of solutions if  $q \subset Q$ . Otherwise we consider the intersection  $Q$  with  $q$  and we finish as before.

The solutions of other practical geometric problems are based mostly on the systematic use of the steps given above.

**4.1.11. Remark on linear programming.** In the beginning of the third chapter in paragraphs 3.1.1–3.1.7, we dealt with practical problems which are given by systems of linear inequalities. Each single inequality

$$a_1x_1 + \cdots + a_nx_n \leq b$$

defines a halfspace in the standard affine space  $\mathbb{R}^n$ . This is bounded by a hyperplane given by the corresponding equation (compare with the definition in paragraph 4.1.9(4)).

In particular, the set of all admissible vectors for the problem of the linear programming is always an intersection of a finite number of convex sets. Hence the set itself is either convex or empty.

If the intersection is both nonempty and bounded, then it is a convex polyhedron. As justified in 3.1.1 already, each linear form is either increasing or decreasing or constant along each parametrized straight line in the affine space. Thus if a given problem from linear programming is solvable and bounded, then it has the optimal solution at one of the vertices of the corresponding convex polyhedron. The reader should be able to imagine this claim in the case of two-dimensional or three-dimensional problems. Nevertheless, the straightforward explanation in these low dimensions holds for all finite-dimensional cases.

We have given a “geometric proof” of the existence part of the fundamental theorem 3.1.5. We have translated the initial problem into a finite problem of the given cost function.

**4.1.12. Euclidean point spaces.** So far, we do not need the notions of distance and length for geometric considerations. But the length of vectors and the angle between vectors, as defined in the second chapter (see 2.3.18 and elsewhere), play a significant role in many practical problems.

$$((A - B) - P_{A-B}) \perp (2, -1, -2, -2).$$

By substitution of  $A - B$  and  $P_{A-B}$ ,

$$((2, -8, 1, 1) - a(4, -2, -3, -2) - b(2, -1, -2, -2)) \cdot (4, -2, -3, -2) = 0,$$

$$((2, -8, 1, 1) - a(4, -2, -3, -2) - b(2, -1, -2, -2)) \cdot (2, -1, -2, -2) = 0;$$

so

$$\begin{aligned} &(2, -8, 1, 1) \cdot (4, -2, -3, -2) \\ &- a(4, -2, -3, -2) \cdot (4, -2, -3, -2) \\ &- b(2, -1, -2, -2) \cdot (4, -2, -3, -2) = 0, \end{aligned}$$

$$\begin{aligned} &((2, -8, 1, 1) \cdot (2, -1, -2, -2)) \\ &- a(4, -2, -3, -2) \cdot (2, -1, -2, -2) \\ &- b(2, -1, -2, -2) \cdot (2, -1, -2, -2) = 0. \end{aligned}$$

If we compute these dot products, we obtain the system

$$\begin{aligned} 19 - 33a - 20b &= 0, \\ 8 - 20a - 13b &= 0, \end{aligned}$$

with the only solution  $a = 3, b = -4$ . Hence

$$\begin{aligned} P_{A-B} &= 3(4, -2, -3, -2) - 4(2, -1, -2, -2) \\ &= (4, -2, -1, 2), \end{aligned}$$

where

$$\|P_{A-B}\| = \sqrt{4^2 + (-2)^2 + (-1)^2 + 2^2} = 5.$$

Hence the distance between  $A$  and  $U$  equals  $\|P_{A-B}\| = 5$ .

□

**4.B.5.** In the vector space  $\mathbb{R}^4$ , compute the distance  $v$  between the point  $[0, 0, 6, 0]$  and the vector subspace

$$U : [0, 0, 0, 0] + t_1(1, 0, 1, 1) + t_2(2, 1, 1, 0) + t_3(1, -1, 2, 3), \\ t_1, t_2, t_3 \in \mathbb{R}$$

**Solution.** We solve the problem by the least squares method. Write the generating vectors of  $U$  as the columns of the matrix

$$A = \begin{pmatrix} 1 & 2 & 1 \\ 0 & 1 & -1 \\ 1 & 1 & 2 \\ 1 & 0 & 3 \end{pmatrix}.$$

Substitute the point  $[0, 0, 6, 0]$  by the corresponding vector  $b = (0, 0, 6, 0)^T$ . Now solve  $A \cdot x = b$ . This is the linear equation system

$$\begin{aligned} x_1 + 2x_2 + x_3 &= 0, \\ &x_2 - x_3 = 0, \\ x_1 + x_2 + 2x_3 &= 6, \\ x_1 + 3x_3 &= 0, \end{aligned}$$

by the least squares method. (Note that the system does not have a solution – the distance would be 0 otherwise.) Multiply

EUCLIDEAN SPACES

The *standard Euclidean point space*  $\mathcal{E}_n$  is the affine space  $\mathcal{A}_n$  whose difference space is the standard *Euclidean space*  $\mathbb{R}^n$  with the scalar product

$$\langle x, y \rangle = y^T \cdot x.$$

The *Cartesian coordinate system* is the affine coordinate system  $(A_0; \underline{u})$  with the orthonormal basis  $\underline{u}$ .

The *Euclidean distance* between two points  $A, B \in \mathcal{E}_n$  is defined as the length of the vector  $\|B - A\|$ . This is denoted by  $\rho(A, B)$ .

*Euclidean subspaces* in  $\mathcal{E}_n$  are affine subspaces, where the corresponding difference spaces are considered with restricted scalar products.

By a *Euclidean point space*  $\mathcal{E}$  of dimension  $n$  is meant an affine space, whose difference space is a real  $n$ -dimensional Euclidean vector space. The notion of a Cartesian coordinate system has an obvious meaning. Since each choice of such a coordinate system identifies  $\mathcal{E}$  with the standard space  $\mathcal{E}_n$ , we deal with the standard Euclidean spaces and their subspaces, with no loss of generality.

From the geometric point of view, simple properties of the scalar product like the triangular inequality, the Cauchy inequality, Bessel's inequality, derived in the previous chapter (see 3.4.3), have useful consequences:

**4.1.13. Theorem.** For points  $A, B, C \in \mathcal{E}_n$  the following holds

- (1)  $\rho(A, B) = \rho(B, A)$
- (2)  $\rho(A, B) = 0$  if and only if  $A = B$
- (3)  $\rho(A, B) + \rho(B, C) \geq \rho(A, C)$
- (4) In each Cartesian coordinate system  $(A_0; \underline{e})$ , the distance between the points  $A = A_0 + a_1e_1 + \dots + a_n e_n$ ,  $B = A_0 + b_1e_1 + \dots + b_n e_n$  is  $\sqrt{\sum_{i=1}^n (a_i - b_i)^2}$ .
- (5) Given a point  $A$  and a subspace  $\mathcal{Q}$  in  $\mathcal{E}_n$ , there exists a point  $P \in \mathcal{Q}$  which minimizes the distance between  $A$  and points in  $\mathcal{Q}$ . The distance between  $A$  and  $P$  equals the length of the orthogonal projection of the vector  $A - B$  into  $Z(\mathcal{Q})^\perp$  for an arbitrary  $B \in \mathcal{Q}$ .
- (6) More generally, for subspaces  $\mathcal{Q}$  and  $\mathcal{R}$  in  $\mathcal{E}_n$  there exist points  $P \in \mathcal{Q}$  and  $Q \in \mathcal{R}$  which minimize the distance between points  $B \in \mathcal{Q}$  and  $A \in \mathcal{R}$ . The distance between the points  $P$  and  $Q$  is the length of the orthogonal projection of the vector  $A - B$  into  $(Z(\mathcal{Q}) + Z(\mathcal{R}))^\perp$  for arbitrary points  $B \in \mathcal{Q}$  and  $A \in \mathcal{R}$ .

**PROOF.** The first three properties follow directly from the properties of the length of vectors in spaces with a scalar product. The fourth follows from the expression of the scalar product in an orthonormal basis.

Consider the relation for the minimal distances  $\rho(A, B)$  for  $B \in \mathcal{Q}$ . The vector  $A - B$  decomposes uniquely as  $A - B = u_1 + u_2$ , where  $u_1 \in Z(\mathcal{Q})$ ,  $u_2 \in Z(\mathcal{Q})^\perp$ . The component  $u_2$  does not depend on the choice of  $B \in \mathcal{Q}$ . This

$A \cdot x = b$  by the matrix  $A^T$  from the left-hand side. Then the augmented matrix  $A^T \cdot A \cdot x = A^T \cdot b$  is

$$\left( \begin{array}{ccc|c} 3 & 3 & 6 & 6 \\ 3 & 6 & 3 & 6 \\ 6 & 3 & 15 & 12 \end{array} \right).$$

By elementary row operations, transform the matrix to the normal form

$$\begin{aligned} \left( \begin{array}{ccc|c} 3 & 3 & 6 & 6 \\ 3 & 6 & 3 & 6 \\ 6 & 3 & 15 & 12 \end{array} \right) &\sim \left( \begin{array}{ccc|c} 3 & 3 & 6 & 6 \\ 0 & 3 & -3 & 0 \\ 0 & -3 & 3 & 0 \end{array} \right) \\ &\sim \left( \begin{array}{ccc|c} 1 & 1 & 2 & 2 \\ 0 & 1 & -1 & 0 \\ 0 & 0 & 0 & 0 \end{array} \right). \end{aligned}$$

Continue with backward elimination

$$\left( \begin{array}{ccc|c} 1 & 1 & 2 & 2 \\ 0 & 1 & -1 & 0 \\ 0 & 0 & 0 & 0 \end{array} \right) \sim \left( \begin{array}{ccc|c} 1 & 0 & 3 & 2 \\ 0 & 1 & -1 & 0 \\ 0 & 0 & 0 & 0 \end{array} \right).$$

The solution is

$$x = (2 - 3t, t, t)^T, \quad t \in \mathbb{R}.$$

Note that the existence of infinitely many solutions is caused by third vector generating  $U$ , which is redundant because

$$3(1, 0, 1, 1) - (2, 1, 1, 0) = (1, -1, 2, 3).$$

An arbitrary ( $t \in \mathbb{R}$ ) linear combination

$$(2 - 3t)(1, 0, 1, 1) + t(2, 1, 1, 0) + t(1, -1, 2, 3) = (2, 0, 2, 2)$$

corresponds to a point  $[2, 0, 2, 2]$  in the subspace  $U$ , which is the nearest point to  $[0, 0, 6, 0]$ . The required distance is therefore

$$\begin{aligned} v &= \|[2, 0, 2, 2] - [0, 0, 6, 0]\| = \sqrt{2^2 + 0 + (-4)^2 + 2^2} \\ &= 2\sqrt{6}. \end{aligned}$$

□

**4.B.6.** Compute the volume of the parallelepiped in  $\mathbb{R}^3$  with base in the plane  $z = 0$  and with edges given by pairs of vertices  $[0, 0, 0]$ ,  $[-2, 3, 0]$ ;  $[0, 0, 0]$ ,  $[4, 1, 0]$  and  $[0, 0, 0]$ ,  $[5, 7, 3]$ .

**Solution.** The parallelepiped is given by vectors  $(4, 1, 0)$ ,  $(-2, 3, 0)$ ,  $(5, 7, 3)$ . Its volume is the determinant

$$\begin{vmatrix} 4 & -2 & 5 \\ 1 & 3 & 7 \\ 0 & 0 & 3 \end{vmatrix} = 3 \begin{vmatrix} 4 & -2 \\ 1 & 3 \end{vmatrix} = 3 \cdot 14 = 42.$$

Note that if the order of vectors is changed, we would get result  $\pm 42$ , because the determinant gives the *oriented* volume of parallelepiped. Note further that the volume would not change if the third vector was  $[a, b, 3]$  for arbitrary  $a, b \in \mathbb{R}$ . Its surface depends only on orthogonal distance between planes of its upper and lower base and their area

$$\begin{vmatrix} 4 & -2 \\ 1 & 3 \end{vmatrix} = 14.$$

□

is because any potential change of  $B$  is apparent by adding a vector from  $Z(Q)$ .

Choose  $P = A + (-u_2) = B + u_1 \in Q$ . Then

$$\|A - B\|^2 = \|u_1\|^2 + \|u_2\|^2 \geq \|u_2\|^2 = \|A - P\|^2.$$

Hence the minimal distance is obtained for the point  $P$ . Its value is  $\|u_2\|$ .

The general result is obtained in a similar way. For the choice of arbitrary points  $A \in \mathcal{R}$  and  $B \in \mathcal{Q}$  their difference is given as a sum of vectors  $u_1 \in Z(\mathcal{R}) + Z(\mathcal{Q})$  and  $u_2 \in (Z(\mathcal{R}) + Z(\mathcal{Q}))^\perp$ . The component  $u_2$  does not depend on the choice of the points. By adding suitable vectors from the difference spaces of  $\mathcal{R}$  and  $\mathcal{Q}$ , points  $A'$  and  $B'$  are obtained so that the distance between them is  $\|u_2\|$ . □

We consider more elementary problems in affine geometry requiring the concept of distance.

**4.1.14. Examples of standard problems.** (1) To find the distance from the point  $A \in \mathcal{E}_n$  to the subspace  $Q \subset \mathcal{E}_n$ :

A method of solving such a problem is given in proposition 4.1.13.

(2) In  $\mathcal{E}_2$  to construct the straight line  $q$  through a given point  $A$  which forms a given angle with a given line  $p$ :

Recall that we work with angles between vectors in plane geometry already (see e.g. 2.3.22). Find a vector  $u \in \mathbb{R}^2$  lying in the difference space of the line  $p$ . Then choose a vector  $v$  having the prescribed angle with  $u$ . The desired line is given by the point  $A$  and the difference space  $\langle v \rangle$ . The problem has either one or two solutions.

(3) To find a line through a given point, perpendicular to a given line:

The procedure is introduced in the proof of the last but one item of proposition 4.1.13.

(4) In  $\mathcal{E}_3$  to determine the distance between two lines  $p, q$ :

Choose any point from each of the lines,  $A \in p, B \in q$ . The component of the vector  $A - B$  lying in the orthogonal complement  $(Z(p) + Z(q))^\perp$  has length equal to the distance between  $p$  and  $q$ .

(5) In  $\mathcal{E}_3$  to find the axis of two skew lines  $p$  a  $q$ :

By the axis we mean the crossbar which attains the minimal possible distance between the given skew lines in terms of the points of intersection. The procedure can be derived from the proof of proposition 4.1.13 (the last item). Let  $\eta$  be the subspace generated by a single point  $A \in p$  and the sum  $Z(p) + (Z(p) + Z(q))^\perp$ . Provided that the lines  $p$  and  $q$  are not parallel,  $\eta$  is a plane. Then the intersection  $\eta \cap q$  together with the difference space  $(Z(p) + Z(q))^\perp$  gives a parametric description of the desired axis. If the lines are parallel, the problem has an infinite number of solutions.

**4.B.7.** Let the points  $[0, 0, 1]$ ,  $[2, 1, 1]$ ,  $[3, 3, 1]$ ,  $[1, 2, 1]$  define a parallelogram. Determine the point  $X$  lying on the line  $p : [0, 0, 1] + (1, 1, 1)t$  so that the parallelepiped defined by the given parallelogram and a point  $X$  has volume of 1.

**Solution.** Form a determinant which gives the volume of a parallelepiped with  $X$  moving along line  $p$ :

$$\begin{vmatrix} t & t & t \\ 2 & 1 & 0 \\ 1 & 2 & 0 \end{vmatrix}.$$

The volume is  $3t$  which implies  $t = 1/3$ . □

**4.B.8.** Let  $ABCDEFGH$  be a cube (with common notation, i.e. vectors  $E - A$ ,  $F - B$ ,  $G - C$ ,  $H - D$  are orthogonal to the plane defined by vertices  $A, B, C, D$ ) in Euclidean space  $\mathbb{R}^3$ . Compute the angle  $\varphi$  between the vectors  $F - A$  and  $H - A$ .

**Solution.** This problem is solved using the formula for the angle between the vectors. Alternatively notice that the vertices  $A, F, H$  are the vertices of a triangle with all sides of the same length. Hence it is an equilateral triangle. Therefore  $\varphi = \pi/3$ . □

**4.B.9.** Let  $S$  be the midpoint of the edge  $AB$  of the cube  $ABCDEFGH$  (with common labelling). Compute the cosine of the angle between the lines  $ES$  and  $BG$ .

**Solution.** Dilation (homothety) is a mapping which preserves angles. So without loss of generality, the cube edge has length 1. The coordinate system can be placed so that  $A$  is at the origin,  $B = [1, 0, 0]$  and  $E = [0, 0, 1]$ . It follows that then:  $S = [1/2, 0, 0]$ ,  $G = [1, 1, 1]$ ,  $ES = (1/2, 0, -1)$  and  $BG = (0, 1, 1)$ . The desired cosine of the angle  $\varphi$  is then

$$\cos(\varphi) = \left| \frac{(1/2, 0, -1) \cdot (0, 1, 1)}{\|(1/2, 0, -1)\| \|(0, 1, 1)\|} \right| = \frac{\sqrt{2}}{\sqrt{5}}$$

**4.B.10.** Compute the angle between the line  $p$  given by the implicit equations

$$\begin{aligned} x + 3y + z &= 0, \\ -x - y + z &= 0 \end{aligned}$$

and plane the  $\varrho : x + y + 2z + 1 = 0$ .

**Solution.** The normal vector of the plane  $\varrho$  is  $(1, 1, 2)$ . Copy the first equation of the line  $p$ . Sum both of them, to obtain

$$\begin{aligned} x + 3y + z &= 0, \\ 2y + 2z &= 0. \end{aligned}$$

From this system  $y = -z$  and  $x = 2z$ . The vector  $(2, -1, 1)$  is therefore the direction vector of  $p$ . In other words,  $p$  passes through the origin, and

$$p : [0, 0, 0] + t(2, -1, 1), \quad t \in \mathbb{R}.$$

For the angle  $\varphi$  between the vectors  $(1, 1, 2)$ ,  $(2, -1, 1)$ ,

$$\cos \varphi = \frac{2 - 1 + 2}{\sqrt{6} \cdot \sqrt{6}} = \frac{1}{2}.$$

**4.1.15. Angles.** Various geometric notions like angles, orientation, volume etc. in the point spaces  $\mathcal{E}_n$  are defined in terms of suitable notions from Euclidean spaces. The angle between two vectors is defined at the end of the third part of the second chapter, see 2.3.22.

From the Cauchy inequality, it follows that  $0 \leq \frac{|u \cdot v|}{\|u\| \|v\|} \leq 1$ . So it makes sense to define the *angle*  $\varphi(u, v)$  between vectors  $u, v \in V$  in a real vector space with a scalar product given by the equation

$$\cos \varphi(u, v) = \frac{u \cdot v}{\|u\| \|v\|}, \quad 0 \leq \varphi(u, v) \leq 2\pi.$$

This is completely in accordance with the situation in two-dimensional Euclidean space  $\mathbb{R}^2$  and with the philosophy that the notion related to the two vectors is the issue of plane geometry.

In the Euclidean plane, we use also the geometric functions  $\cos$  and  $\sin$  defined by a pure geometric consideration. Therefore, the angle between two vectors in higher-dimensional spaces is measured in the plane which is generated by these two vectors (or it is zero).

In an arbitrary real vector space with a scalar product, it follows that

$$\begin{aligned} \|u - v\|^2 &= \|u\|^2 + \|v\|^2 - 2(u \cdot v) \\ &= \|u\|^2 + \|v\|^2 - 2\|u\| \|v\| \cos \varphi(u, v). \end{aligned}$$

This is the well known *cosine rule* from plane geometry.

Consider an orthonormal basis  $\underline{e}$  of the difference space  $V$  and a vector  $u \in V$ . The square of the size of  $u$  is given by the usual formula

$$\|u\|^2 = \sum_i |u \cdot e_i|^2.$$

By dividing this equation by the number  $\|u\|^2$ ,

$$1 = \sum_i (\cos \varphi(u, e_i))^2,$$

which is known as the *law of direction cosines*  $\cos \varphi(u, e_i)$  of the vector  $u$ .

Now we can derive definitions for angles between general subspaces in a Euclidean vector space from the definitions of angles between vectors. In particular, it must be decided how to deal with cases where the subspaces have a nontrivial intersection. For the angle between two lines, use the smaller of the two possible angles.

In the case of two nonparallel planes in  $\mathbb{R}^3$  we do not say that the angle is zero. They intersect and have one direction in common. Perhaps we take the two perpendicular lines to this common direction in the two planes and measure their angle.

The general cases are treated as follows:

Hence  $\varphi = 60^\circ$ . However, this is the angle between the direction vector of  $p$  and the normal vector  $\rho$ . The desired angle is the complement of this angle, so the solution is  $30^\circ = 90^\circ - 60^\circ$ .  $\square$

**4.B.11.** In the real plane, find a line which passes through the point  $[-3, 0]$ , so that  $60^\circ$  is the angle between this line and the line

$$p : \sqrt{3}x + 3y + 5 = 0.$$

**Solution.** The given line has slope  $-\frac{1}{\sqrt{3}}$ . This is at angle  $-30^\circ$  from the positive  $x$  axis. Thus the required line is either at angle  $-90^\circ$  or angle  $30^\circ$  from the positive  $x$  axis. The former determines the vertical line  $x = -3$ . The latter determines the line with slope  $\frac{1}{\sqrt{3}}$  through  $[-3, 0]$ , hence has equation  $y\sqrt{3} = x + 3$ .  $\square$

**Solution.** (Alternative) Notice that there are two such lines. The general equation of a line in the plane has the form

$$ax + by + c = 0. \quad \text{Choose parameters so that } a^2 + b^2 = 1.$$

We find such numbers  $a, b, c \in \mathbb{R}$ , so that all the conditions are satisfied. Since the line passes through  $[-3, 0]$ ,  $c = 3a$ . The condition of the angle between lines equals  $60^\circ$  then gives

$$\frac{1}{2} = \cos 60^\circ = \frac{|\sqrt{3}a + 3b|}{\sqrt{12}}, \quad \text{tj. } \sqrt{3} = |\sqrt{3}a + 3b|.$$

Performing further operations

$$\pm 1 = a + \sqrt{3}b \quad \text{and exponentiation} \quad 1 = a^2 + 3b^2 + 2\sqrt{3}ab.$$

If we use  $a^2 + b^2 = 1$ , we get

$$0 = 2b^2 + 2\sqrt{3}ab, \quad \text{tj. } 0 = b(b + \sqrt{3}a).$$

Together (remember that  $c = 3a$  and  $a^2 + b^2 = 1$ )

$$a = \pm 1, \quad b = 0, \quad c = \pm 3; \quad a = \pm \frac{1}{2}, \quad b = \mp \frac{\sqrt{3}}{2}, \quad c = \pm \frac{3}{2}$$

We can easily check that lines determined by those coefficients

$$x + 3 = 0, \quad \frac{1}{2}x - \frac{\sqrt{3}}{2}y + \frac{3}{2} = 0$$

satisfy all the conditions.  $\square$

**4.B.12.** Determine the equation of all planes so that the angle between every such plane and the plane  $x + y + z - 1 = 0$  is  $60^\circ$ , and further, that they contain the line  $p : [1, 0, 0] + t(1, 1, 0)$ .  $\circ$

**4.B.13.** Determine the angle between the planes

$$\sigma : [1, 0, 2] + (1, -1, 1)t + (0, 1, -2)s$$

$$\rho : [3, 3, 3] + (1, -2, 0)t + (0, 1, 1)s$$

**Solution.** The line of intersection between the planes has direction vector  $(1, -1, 1)$ . The plane orthogonal to this vector has intersection with the given planes generated by the vectors  $(1, 0, -1)$  and  $(0, 1, 1)$ . The angle between these one-dimensional subspaces is  $60^\circ$ .  $\square$

ANGLES BETWEEN SUBSPACES

**4.1.16. Definition.** Consider finite-dimensional subspaces  $U_1, U_2$  in a Euclidean vector space  $V$  of arbitrary dimension.

The angle between vector subspaces  $U_1, U_2$  is the real number  $\alpha = \varphi(U_1, U_2) \in [0, \frac{\pi}{2}]$  satisfying:

(1) If  $\dim U_1 = \dim U_2 = 1, U_1 = \langle u \rangle, U_2 = \langle v \rangle$ , then

$$\cos \alpha = \frac{|u \cdot v|}{\|u\| \|v\|}.$$

(2) If the dimensions of  $U_1, U_2$  are positive, and if  $U_1 \cap U_2 = \{0\}$ , then the angle is the minimum of all angles between the one-dimensional subspaces

$$\alpha = \min\{\varphi(\langle u \rangle, \langle v \rangle); 0 \neq u \in U_1, 0 \neq v \in U_2\}.$$

Such a minimum always exists.

(3) If  $U_1 \subset U_2$  or  $U_2 \subset U_1$  (in particular if one of them is empty), then  $\alpha = 0$ .

(4) If  $U_1 \cap U_2 \neq \{0\}$  and if  $U_1 \neq U_1 \cap U_2 \neq U_2$ , then

$$\alpha = \varphi(U_1 \cap (U_1 \cap U_2)^\perp, U_2 \cap (U_1 \cap U_2)^\perp).$$

The angle between affine subspaces  $\mathcal{Q}_1, \mathcal{Q}_2$  in a Euclidean point space  $\mathcal{E}_n$  is defined as the angle between their difference spaces  $Z(\mathcal{Q}_1), Z(\mathcal{Q}_2)$ .

Notice that the angle is always well defined. In the last case,

$$(U_1 \cap (U_1 \cap U_2)^\perp) \cap (U_2 \cap (U_1 \cap U_2)^\perp) = \{0\}$$

so we can determine the angle according to item (2). Notice also that in the case  $U_1 \cap U_2 = \{0\}$ , the subspaces  $U_1$  and  $U_2$  are perpendicular in terms of the former definitions if and only if the angle between them is  $\pi/2$ . However, if the intersection is nontrivial, then they cannot be perpendicular in the former sense.

In order to show the validity of the definition, it remains to show that the vectors  $u \in U_1, v \in U_2$  minimizing the expression for the angle always exist. First a special case:

**4.1.17. Lemma.** Let  $v$  be a vector in a Euclidean space  $V$  and  $U \subset V$  an arbitrary subspace. Denote by  $v_1 \in U, v_2 \in U^\perp$  the (uniquely determined) components of the vector  $v$ , i.e.  $v = v_1 + v_2$ . Then the angle  $\varphi$  between the subspace generated by  $v$  and the subspace  $U$  satisfies

$$\cos \varphi(\langle v \rangle, U) = \cos \varphi(\langle v \rangle, \langle v_1 \rangle) = \frac{\|v_1\|}{\|v\|}.$$

**PROOF.** By the Cauchy inequality,

$$\begin{aligned} \frac{|u \cdot v|}{\|u\| \|v\|} &= \frac{|u \cdot (v_1 + v_2)|}{\|u\| \|v\|} = \frac{|u \cdot v_1|}{\|u\| \|v\|} \\ &\leq \frac{\|u\| \|v_1\|}{\|u\| \|v\|} = \frac{\|v_1\|}{\|v\|} = \frac{\|v_1\|^2}{\|v\| \|v_1\|} = \frac{|v_1 \cdot v|}{\|v\| \|v_1\|}. \end{aligned}$$

**4.B.14.** A cube  $ABCD A' B' C' D'$  is given in standard notation. That is,  $ABCD$  and  $A' B' C' D'$  are faces and  $AA', BB'$  are edges. Compute the angle  $\varphi$  between  $AB'$  and  $AD'$ .

**Solution.** It can be assumed that the cube is of side 1 and placed in  $\mathbb{R}^3$  in such a way that the vertices  $A, B, C, D$  have coordinates respectively  $[0, 0, 0], [1, 0, 0], [1, 1, 0], [0, 1, 0]$  and the vertices  $A', B', C', D'$  have coordinates respectively  $[0, 0, 1], [1, 0, 1], [1, 1, 1], [0, 1, 1]$ . Thus  $AB' = B' - A = (1, 0, 1), AD' = D' - A = (0, 1, 1)$ . So

$$\cos(\varphi) = \frac{(1, 0, 1) \cdot (0, 1, 1)}{\|(1, 0, 1)\| \|(0, 1, 1)\|} = \frac{1}{2},$$

hence  $\varphi = 60^\circ$ . □

For further exercises on angles, see .

**4.B.15.** Prove that for every  $n \in \mathbb{N}$  and for all positive  $x_1, x_2, \dots, x_n \in \mathbb{R}$

$$n^2 \leq \left( \frac{1}{x_1} + \frac{1}{x_2} + \dots + \frac{1}{x_n} \right) \cdot (x_1 + x_2 + \dots + x_n).$$

For what arguments does equality hold?

**Solution.** It is sufficient to consider the Cauchy inequality

$$|u \cdot v| \leq \|u\| \|v\|$$

in Euclidean space  $\mathbb{R}^n$  for the vectors

$$u = \left( \frac{1}{\sqrt{x_1}}, \dots, \frac{1}{\sqrt{x_n}} \right), v = (\sqrt{x_1}, \dots, \sqrt{x_n}).$$

We get

$$(1) \quad n \leq \sqrt{\frac{1}{x_1} + \frac{1}{x_2} + \dots + \frac{1}{x_n}} \cdot \sqrt{x_1 + x_2 + \dots + x_n}.$$

We obtain the desired inequality squaring (1). The Cauchy inequality attains equality when vector  $u$  is a multiple of  $v$ , that is, when  $x_1 = x_2 = \dots = x_n$ . □

**4.B.16.** Vectors  $\underline{u} = (u_1, u_2, u_3)$  and  $\underline{v} = (v_1, v_2, v_3)$  are given. Find a third unit vector such that parallelepiped defined by these three vectors has the greatest possible volume.

**Solution.** Denote the desired vector by  $\underline{t} = (t_1, t_2, t_3)$ . By Proposition ?? the volume of the parallelepiped  $\mathcal{P}_3(0; \underline{u}, \underline{v}, \underline{t})$  is the absolute value of determinant

$$\begin{vmatrix} u_1 & v_1 & t_1 \\ u_2 & v_2 & t_2 \\ u_3 & v_3 & t_3 \end{vmatrix} = \begin{vmatrix} t_1 & t_2 & t_3 \\ u_1 & u_2 & u_3 \\ v_1 & v_2 & v_3 \end{vmatrix} = \underline{t} \cdot (\underline{u} \times \underline{v}) \leq \|\underline{t}\| \|\underline{u} \times \underline{v}\| \\ = \|\underline{u} \times \underline{v}\|.$$

The sign of the inequality follows from the Cauchy inequality. This becomes equality if and only if  $\underline{t} = c(\underline{u} \times \underline{v})$ ,  $c \in \mathbb{R}$ . The volume therefore could be at most equal to the area of paralleloid defined by vectors  $\underline{u}, \underline{v}$  (i.e. size of vector  $(\underline{u} \times \underline{v})$ ). Equality holds if and only if

$$t = \pm \frac{(\underline{u} \times \underline{v})}{\|(\underline{u} \times \underline{v})\|}.$$

for all vectors  $u \in U$ . This implies that

$$\cos \varphi(\langle v \rangle, \langle u \rangle) \leq \cos \varphi(\langle v \rangle, \langle v_1 \rangle) = \frac{\|v_1\|}{\|v\|}.$$

Thus the computed vector  $v_1$  represents the largest possible value of the cosine of angles between all choices of vectors in  $U$ . The  $\cos$  function is decreasing on the interval  $[0, \frac{\pi}{2}]$ . Hence the smallest possible angle is obtained in this way, and so the claim is proved. □

**4.1.18. Calculating angles.** The procedure in the previous lemma can be understood as follows. Choose the orthogonal projection of the one-dimensional subspace generated by  $v$  into the subspace  $U$ , and consider the ratio between  $v$  and its image. A similar procedure is used in the higher dimension. The problem is to recognize the directions whose projections give the desired (minimal) angle. This is clear in the previous example if we project the larger space  $U$  into the one-dimensional  $\langle v \rangle$  first, and then orthogonally back to  $U$ . The desired angle corresponds to the direction of the eigenvector of this map. The eigenvalue is the square of the cosine of the angle.

Let  $U_1, U_2$  be two arbitrary subspaces in a Euclidean vector space  $V$ ,  $U_1 \cap U_2 = \{0\}$ . Choose orthonormal bases  $\underline{e}$  and  $\underline{e}'$  of the whole space  $V$  such that  $U_1 = \langle e_1, \dots, e_k \rangle$ ,  $U_2 = \langle e'_1, \dots, e'_l \rangle$ .

Consider the orthogonal projection  $\varphi$  of the space  $V$  on  $U_2$ . Its restriction on  $U_1$  will be denoted by  $\varphi : U_1 \rightarrow U_2$  as before. Similarly, let  $\psi : U_2 \rightarrow U_1$  be the map which has arisen from the orthogonal projection on  $U_1$ . In the bases  $(e_1, \dots, e_k)$  and  $(e'_1, \dots, e'_l)$ , these maps have matrices  $A$  and  $B$ ,

$$\begin{pmatrix} e_1 \cdot e'_1 & \dots & e_k \cdot e'_1 \\ \vdots & & \vdots \\ e_1 \cdot e'_l & \dots & e_k \cdot e'_l \end{pmatrix}, \begin{pmatrix} e'_1 \cdot e_1 & \dots & e'_l \cdot e_1 \\ \vdots & & \vdots \\ e'_1 \cdot e_k & \dots & e'_l \cdot e_k \end{pmatrix},$$

respectively. Since  $e_i \cdot e'_j = e'_j \cdot e_i$  holds for all indices  $i, j$ ,  $B = A^T$ .

The composition of maps  $\psi \circ \varphi : U_1 \rightarrow U_1$  has therefore a symmetric positive semidefinite matrix  $A^T A$ , and  $\psi$  is adjoint to  $\varphi$ . Each such map has only nonnegative real eigenvalues. It has a diagonal matrix with these eigenvalues on the diagonal in a suitable orthonormal basis, see 3.4.7 a 3.4.9.

Now we can derive a general procedure for computing the angle  $\alpha = \varphi(U_1, U_2)$ .

**Theorem.** In the previous notation, let  $\lambda$  be the largest eigenvalue of the matrix  $A^T A$ . Then  $(\cos \alpha)^2 = \lambda$ .

**PROOF.** Let  $u \in U_1$  be the eigenvector of the map  $\psi \circ \varphi$  corresponding to the eigenvalue  $\lambda$ . Consider all eigenvalues  $\lambda_1, \dots, \lambda_k$  (including multiplicities), and let  $\underline{u} = (u_1, \dots, u_n)$  be the corresponding orthonormal basis of  $U_1$  containing the eigenvectors. Assume that  $\lambda = \lambda_1$ , and choose its eigenvector  $u = u_1$ ,  $\|u\| = 1$ . □

**4.B.17.** Find the foot of the line passing through the point  $[0, 0, 7]$  and perpendicular to the plane

$$\rho : [0, 5, 3] + (1, 2, 1)t + (-2, 1, 1)s.$$

**4.B.18.** In Euclidean space  $\mathbb{R}^5$  determine the distance between the planes

$$\begin{aligned} \varrho_1 &: [7, 2, 7, -1, 1] + t_1(1, 0, -1, 0, 0) + s_1(0, 1, 0, 0, -1), \\ \varrho_2 &: [2, 4, 7, -4, 2] + t_2(1, 1, 1, 0, 1) + s_2(0, -2, 0, 0, 3), \end{aligned}$$

where  $t_1, s_1, t_2, s_2 \in \mathbb{R}$ .

**Solution.** First compute the orthogonal complement to sum of vectors defining the planes. Form a matrix with rows as the direction vectors of the planes. Then transform this matrix into normal form.

$$\begin{pmatrix} 1 & 0 & -1 & 0 & 0 \\ 0 & 1 & 0 & 0 & -1 \\ 1 & 1 & 1 & 0 & 1 \\ 0 & -2 & 0 & 0 & 3 \end{pmatrix} \sim \dots \sim \begin{pmatrix} 1 & 0 & -1 & 0 & 0 \\ 0 & 1 & 0 & 0 & -1 \\ 0 & 0 & 1 & 0 & 1 \\ 0 & 0 & 0 & 0 & 1 \end{pmatrix}.$$

So the orthogonal complement is  $\langle(0, 0, 0, 1, 0)\rangle$ . The vector  $(0, 0, 0, 1, 0)$  lies within the orthogonal complement. Transform the matrix into normal form. This shows that the orthogonal complement is one-dimensional. The distance between planes is the length of the perpendicular projection of the vector  $A_1 - A_2$  into the subspace  $\langle(0, 0, 0, 1, 0)\rangle$  for arbitrary points  $A_1 \in \varrho_1, A_2 \in \varrho_2$ . Choose e.g.  $A_1 = [7, 2, 7, -1, 1], A_2 = [2, 4, 7, -4, 2]$ . The orthogonal projection  $A_1 - A_2 = (5, -2, 0, 3, -1)$  to  $\langle(0, 0, 0, 1, 0)\rangle$  is  $(0, 0, 0, 3, 0)$ . The length of  $(0, 0, 0, 3, 0)$  gives the desired distance 3.  $\square$

**4.B.19.** In Euclidean space  $\mathbb{R}^5$  determine the distance of planes

$$\begin{aligned} \sigma_1 &: [0, 1, 2, 0, 0] + p_1(2, 1, 0, 0, 1) + q_1(-2, 0, 1, 1, 0), \\ \sigma_2 &: [3, -1, 7, 7, 3] + p_2(2, 2, 4, 0, 3) + q_2(2, 0, 0, -2, -1), \end{aligned}$$

where  $p_1, q_1, p_2, q_2 \in \mathbb{R}$ .

**Solution.** The sum of the directions  $\sigma_1, \sigma_2$  is generated by the direction vectors. Denote them by

$$\begin{aligned} u_1 &= (2, 1, 0, 0, 1), & u_2 &= (-2, 0, 1, 1, 0), \\ v_1 &= (2, 2, 4, 0, 3), & v_2 &= (2, 0, 0, -2, -1). \end{aligned}$$

Find points  $X_1 \in \sigma_1, X_2 \in \sigma_2$ , that equal the distance between  $\sigma_1$  and  $\sigma_2$ . This requires

$$\begin{aligned} X_1 - X_2 &= [0, 1, 2, 0, 0] - [3, -1, 7, 7, 3] \\ &\quad + p_1u_1 + q_1u_2 - p_2v_1 - q_2v_2 \end{aligned}$$

and

$$\begin{aligned} \langle X_1 - X_2, u_1 \rangle &= 0, & \langle X_1 - X_2, u_2 \rangle &= 0, \\ \langle X_1 - X_2, v_1 \rangle &= 0, & \langle X_1 - X_2, v_2 \rangle &= 0. \end{aligned}$$

We need to show that the angle between an arbitrary  $v \in U_1$  and  $U_2$  is at least as large as the angle between  $u$  and  $U_2$ . Equivalently that the cosine of the corresponding angle cannot be greater. By the previous lemma, it is sufficient to discuss the angle between  $u$  and  $\varphi(u) \in U_2$ . Choose  $v \in U_1, v = a_1u_1 + \dots + a_ku_k, \sum_{i=1}^k a_i^2 = \|v\|^2 = 1$ . Then

$$\begin{aligned} \|\varphi(v)\|^2 &= \varphi(v) \cdot \varphi(v) = (\psi \circ \varphi(v)) \cdot v \\ &\leq \|\psi \circ \varphi(v)\| \|v\| = \|\psi \circ \varphi(v)\|. \end{aligned}$$

Moreover, the previous lemma gives a formula for computing the angle  $\alpha$  between the vector  $v$  and the subspace  $U_2$

$$\cos \alpha = \frac{\|\varphi(v)\|}{\|v\|} = \|\varphi(v)\|.$$

Since  $\lambda_1$  is the largest eigenvalue, and the sum of squares of coordinates  $a_i^2$  is one,

$$\begin{aligned} (\cos \alpha)^2 &= \|\varphi(v)\|^2 \leq \|\psi \circ \varphi(v)\| = \sqrt{\sum_{i=1}^k (\lambda_i a_i)^2} = \\ &= \sqrt{\lambda_1^2 + \sum_{i=1}^k a_i^2 (\lambda_i^2 - \lambda_1^2)} \leq \sqrt{\lambda_1^2}. \end{aligned}$$

If  $v = u$ , we have  $\|\varphi(v)\|^2 = \lambda_1^2 \|v\|^2 = \lambda^2$ , and thus the angle has the minimal value for this vector.  $\square$

**4.1.19. Calculating volume.** An indication of how to calculate volumes in plane geometry is given at the end of the fifth part of the first chapter (see 1.5.11). There the notion of orientation played a fundamental role. We can imagine orientation as the decision whether to look at the plane  $\mathbb{R}^2$  from above or from below. The distinction lies in the order of selecting standard basis vectors  $e_1$  and  $e_2$  on the unit circle. We proceed in the same way in general:

#### ORIENTATION OF A VECTOR SPACE

Two bases  $\underline{u}$  and  $\underline{v}$  of a real vector space  $V$  are said to determine the same *orientation* if the transformation matrix between them has a positive determinant. By the orientation of a vector space  $V$  is meant the equivalence class of bases  $\underline{u}$  with respect to the equivalence defined above, by the sign of the determinant. Equivalent bases in this sense are called compatible with the chosen orientation.

It follows that there exist exactly two orientations on every vector space. From each compatible basis there is a non compatible one by a transformation matrix with a negative determinant.

A vector space with a chosen orientation is called the *oriented vector space*.

The *oriented Euclidean (point) space* is a Euclidean point space whose difference space is oriented. In the sequel we consider the standard Euclidean space  $\mathcal{E}_n$  together with the orientation given by the standard basis of  $\mathbb{R}^n$ .

Hence

$$\begin{aligned} \langle (-3, 2, -5, -7, -3), u_1 \rangle + p_1 \langle u_1, u_1 \rangle + q_1 \langle u_2, u_1 \rangle \\ - p_2 \langle v_1, u_1 \rangle - q_2 \langle v_2, u_1 \rangle &= 0, \\ \langle (-3, 2, -5, -7, -3), u_2 \rangle + p_1 \langle u_1, u_2 \rangle + q_1 \langle u_2, u_2 \rangle \\ - p_2 \langle v_1, u_2 \rangle - q_2 \langle v_2, u_2 \rangle &= 0, \\ \langle (-3, 2, -5, -7, -3), v_1 \rangle + p_1 \langle u_1, v_1 \rangle + q_1 \langle u_2, v_1 \rangle \\ - p_2 \langle v_1, v_1 \rangle - q_2 \langle v_2, v_1 \rangle &= 0, \\ \langle (-3, 2, -5, -7, -3), v_2 \rangle + p_1 \langle u_1, v_2 \rangle + q_1 \langle u_2, v_2 \rangle \\ - p_2 \langle v_1, v_2 \rangle - q_2 \langle v_2, v_2 \rangle &= 0. \end{aligned}$$

By computing the dot products, we obtain the linear equation system

$$\begin{array}{cccccc} 6p_1 & - & 4q_1 & - & 9p_2 & - & 3q_2 & = & 7, \\ -4p_1 & + & 6q_1 & & & + & 6q_2 & = & 6, \\ 9p_1 & & & - & 33p_2 & - & q_2 & = & 31, \\ 3p_1 & - & 6q_1 & - & p_2 & - & 9q_2 & = & -11. \end{array}$$

Solve it by forming a matrix and performing elementary row operations.

$$\left( \begin{array}{cccc|c} 6 & -4 & -9 & -3 & 7 \\ -4 & 6 & 0 & 6 & 6 \\ 9 & 0 & -33 & -1 & 31 \\ 3 & -6 & -1 & -9 & -11 \end{array} \right) \sim \dots \sim \left( \begin{array}{cccc|c} 1 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & -1 \\ 0 & 0 & 1 & 0 & -1 \\ 0 & 0 & 0 & 1 & 2 \end{array} \right).$$

The solution is  $(p_1, q_1, p_2, q_2) = (0, -1, -1, 2)$ . Consequently

$$\begin{aligned} X_1 - X_2 &= (-3, 2, -5, -7, -3) - u_2 + v_1 - 2v_2 \\ &= (-3, 4, -2, -4, 2). \end{aligned}$$

The length of the vector  $(-3, 4, -2, -4, 2)$  equals the distance between the planes  $\sigma_1, \sigma_2$  and is then

$$7 = \sqrt{(-3)^2 + 4^2 + (-2)^2 + (-4)^2 + 2^2}.$$

We solved this problem by a method different to that of the previous problem. We can use both methods in both cases. Try the former method for the case of  $\sigma_1, \sigma_2$ . Find the orthogonal complement of vector subspace generated by  $(2, 1, 0, 0, 1), (-2, 0, 1, 1, 0), (2, 2, 4, 0, 3), (2, 0, 0, -2, -1)$ . We get

$$\left( \begin{array}{ccccc} 2 & 1 & 0 & 0 & 1 \\ -2 & 0 & 1 & 1 & 0 \\ 2 & 2 & 4 & 0 & 3 \\ 2 & 0 & 0 & -2 & -1 \end{array} \right) \sim \dots \sim \left( \begin{array}{ccccc} 1 & 0 & 0 & 0 & 3/2 \\ 0 & 1 & 0 & 0 & -2 \\ 0 & 0 & 1 & 0 & 1 \\ 0 & 0 & 0 & 1 & 2 \end{array} \right),$$

The orthogonal complement is  $\langle (-3/2, 2, -1, -2, 1) \rangle$ , or rather  $\langle (3, -4, 2, 4, -2) \rangle$ . Note that the distance between  $\sigma_1$

Let  $u_1, \dots, u_k$  be arbitrary vectors in the difference space  $\mathbb{R}^n$ ,  $A \in \mathcal{E}_n$  a point. As an example of a convex set, the parallelepiped  $\mathcal{P}_k(A; u_1, \dots, u_k) \subset \mathcal{E}_n$  is given by

$$\mathcal{P}_k(A; u_1, \dots, u_k) = \{A + c_1 u_1 + \dots + c_k u_k; 0 \leq c_i \leq 1\}.$$

If  $u_1, \dots, u_k$  are linearly dependent, the parallelepiped is degenerated and we see the volume

$$\text{Vol } \mathcal{P}_k = 0.$$

If the vectors  $u_1, \dots, u_k$  are linearly independent, we have a  $k$ -dimensional parallelepiped  $\mathcal{P}_k(A; u_1, \dots, u_k) \subset \mathcal{E}_n$ . For given vectors  $u_1, \dots, u_k$  there are also parallelepipeds of lower dimension

$$\mathcal{P}_1(A; u_1), \dots, \mathcal{P}_k(A; u_1, \dots, u_k)$$

in Euclidean subspaces  $A + \langle u_1 \rangle, \dots, A + \langle u_1, \dots, u_k \rangle$  at our disposal. We proceed as in the case of the Gram–Schmidt orthogonalization: Consider the decomposition

$$\begin{aligned} \langle u_1, \dots, u_k \rangle &= \\ &= \langle u_1, \dots, u_{k-1} \rangle \oplus \langle u_1, \dots, u_{k-1} \rangle^\perp \cap \langle u_1, \dots, u_k \rangle. \end{aligned}$$

In this direct sum,  $u_k$  is uniquely expressed as

$$u_k = u'_k + e_k$$

where  $e_k \perp \langle u_1, \dots, u_{k-1} \rangle$ .

The absolute value of the volume of a parallelepiped is defined inductively such that it is the product of the volume of the “base” and the “altitude”:  $|\text{Vol } \mathcal{P}_1(A; u_1)| = \|u_1\|$ ,

$$\begin{aligned} |\text{Vol } \mathcal{P}_k(A; u_1, \dots, u_k)| &= \\ &= \|e_k\| |\text{Vol } \mathcal{P}_{k-1}(A; u_1, \dots, u_{k-1})|. \end{aligned}$$

If  $u_1, \dots, u_n$  is a basis compatible with the orientation of the entire vector space  $V$ , the (oriented) volume of the parallelepiped is defined by

$$\text{Vol } \mathcal{P}_n(A; u_1, \dots, u_n) = |\text{Vol } \mathcal{P}_n(A; u_1, \dots, u_n)|.$$

In the case of a non compatible basis we set

$$\text{Vol } \mathcal{P}_n(A; u_1, \dots, u_n) = -|\text{Vol } \mathcal{P}_n(A; u_1, \dots, u_n)|.$$

**Theorem.** Let  $Q \subset \mathcal{E}_n$  be a Euclidean subspace, and let  $e = (e_1, \dots, e_k)$  be an orthonormal basis of  $Z(Q)$ . For arbitrary vectors  $u_1, \dots, u_k \in Z(Q)$  and  $A \in Q$  the following holds

$$\begin{aligned} (1) \text{ Vol } \mathcal{P}_k(A; u_1, \dots, u_k) &= \begin{vmatrix} u_1 \cdot e_1 & \dots & u_k \cdot e_1 \\ \vdots & & \vdots \\ u_1 \cdot e_k & \dots & u_k \cdot e_k \end{vmatrix} \\ (2) (\text{Vol } \mathcal{P}_k(A; u_1, \dots, u_k))^2 &= \begin{vmatrix} u_1 \cdot u_1 & \dots & u_k \cdot u_1 \\ \vdots & & \vdots \\ u_1 \cdot u_k & \dots & u_k \cdot u_k \end{vmatrix} \end{aligned}$$

PROOF. The matrix

$$A = \begin{pmatrix} u_1 \cdot e_1 & \dots & u_k \cdot e_1 \\ \vdots & & \vdots \\ u_1 \cdot e_k & \dots & u_k \cdot e_k \end{pmatrix}$$

and  $\sigma_2$  equals the size of the orthogonal projection of the vector (the difference of an arbitrary point in  $\sigma_1$  and an arbitrary point in  $\sigma_2$ )

$$u = (3, -2, 5, 7, 3) = [3, -1, 7, 7, 3] - [0, 1, 2, 0, 0]$$

to this orthogonal complement. Denote the orthogonal projection of  $u$  as  $p_u$  and choose  $v = (3, -4, 2, 4, -2)$ . Obviously  $p_u = a \cdot v$  for some  $a \in \mathbb{R}$  and

$$\langle u - p_u, v \rangle = 0, \quad \text{tj.} \quad \langle u, v \rangle - a \langle v, v \rangle = 0.$$

Computing gives  $49 - a \cdot 49 = 0$ . Therefore  $p_u = 1 \cdot v = v$  and the distance between the planes  $\sigma_1$  and  $\sigma_2$  equals

$$\|p_u\| = \sqrt{3^2 + (-4)^2 + 2^2 + 4^2 + (-2)^2} = 7.$$

The method of computing the distance using the orthogonal complement of sum of vector spaces proves to be a "faster way to the solution". It is the same for the planes  $\varrho_1$  and  $\varrho_2$ . The second method however reveals points where the distance can be measured (a pair of points in which the planes are the closest). Find such points in the case of planes  $\varrho_1, \varrho_2$ . Denote

$$u_1 = (1, 0, -1, 0, 0), \quad u_2 = (0, 1, 0, 0, -1),$$

$$v_1 = (1, 1, 1, 0, 1), \quad v_2 = (0, -2, 0, 0, 3).$$

Points  $X_1 \in \varrho_1, X_2 \in \varrho_2$ , which are the "closest" (as commented above), are

$$X_1 = [7, 2, 7, -1, 1] + t_1 u_1 + s_1 u_2,$$

$$X_2 = [2, 4, 7, -4, 2] + t_2 v_1 + s_2 v_2,$$

so

$$X_1 - X_2 = [7, 2, 7, -1, 1] - [2, 4, 7, -4, 2]$$

$$+ t_1 u_1 + s_1 u_2 - t_2 v_1 - s_2 v_2$$

$$= (5, -2, 0, 3, -1)$$

$$+ t_1 u_1 + s_1 u_2 - t_2 v_1 - s_2 v_2.$$

The dot products

$$\langle X_1 - X_2, u_1 \rangle = 0, \quad \langle X_1 - X_2, u_2 \rangle = 0,$$

$$\langle X_1 - X_2, v_1 \rangle = 0, \quad \langle X_1 - X_2, v_2 \rangle = 0$$

then lead to the linear equation system

$$2t_1 = -5,$$

$$2s_1 + 5s_2 = 1,$$

$$-4t_2 - s_2 = -2,$$

$$-5s_1 - t_2 - 13s_2 = -1$$

with the unique solution  $t_1 = -5/2, s_1 = 41/2, t_2 = 5/2, s_2 = -8$ . We obtained

$$X_1 = [7, 2, 7, -1, 1] - \frac{5}{2}u_1 + \frac{41}{2}u_2$$

$$= \left[ \frac{9}{2}, \frac{45}{2}, \frac{19}{2}, -1, -\frac{39}{2} \right],$$

$$X_2 = [2, 4, 7, -4, 2] + \frac{5}{2}v_1 - 8v_2$$

$$= \left[ \frac{9}{2}, \frac{45}{2}, \frac{19}{2}, -4, -\frac{39}{2} \right].$$

The distance between the points  $X_1, X_2$  equals the distance between the planes  $\varrho_1, \varrho_2$  both of which are given by  $\|X_1 - X_2\| = \|(0, 0, 0, 3, 0)\| = 3$ .  $\square$

has the coordinates of the vectors  $u_1, \dots, u_k$  in the chosen basis in columns, and

$$|A|^2 = |A||A| = |A^T||A| = |A^T A|$$

$$= \begin{vmatrix} u_1 \cdot u_1 & \dots & u_k \cdot u_1 \\ \vdots & & \vdots \\ u_1 \cdot u_k & \dots & u_k \cdot u_k \end{vmatrix}.$$

Hence if (1) holds, then also (2) holds.

Directly from the definition, the unoriented volume equals the product

$$|\text{Vol } \mathcal{P}_k(A; u_1, \dots, u_k)| = \|v_1\| \|v_2\| \dots \|v_k\|,$$

where  $v_1 = u_1, v_2 = u_2 + a_1^2 v_1, \dots, v_k = u_k + a_1^k v_1 + \dots + a_{k-1}^k v_{k-1}$  is the result of the Gram-Schmidt orthogonalization. Thus

$$\begin{aligned} (\text{Vol } \mathcal{P}_k(A; u_1, \dots, u_k))^2 &= \begin{vmatrix} v_1 \cdot v_1 & 0 & \dots & 0 \\ \vdots & \ddots & & \\ 0 & 0 & \dots & v_k \cdot v_k \end{vmatrix} \\ &= \begin{vmatrix} v_1 \cdot v_1 & \dots & v_k \cdot v_1 \\ \vdots & & \vdots \\ v_1 \cdot v_k & \dots & v_k \cdot v_k \end{vmatrix}. \end{aligned}$$

Denote by  $B$  the matrix whose columns are formed by the coordinates of vectors  $v_1, \dots, v_k$  in the orthonormal basis  $\underline{e}$ . Since  $v_1, \dots, v_k$  have arisen from  $u_1, \dots, u_k$  as images under a linear transformation with an upper-triangular matrix  $C$  with ones on the diagonal,  $B = CA$  and  $|B| = |C||A| = |A|$ . But then  $|A|^2 = |B|^2 = |A||A|$ , and thus  $\text{Vol } \mathcal{P}_k(A; u_1, \dots, u_k) = \pm|A|$ . The resulting volume is zero if the vectors  $u_1, \dots, u_k$  are linearly dependent. Provided they are independent, the sign of the determinant is positive if and only if the basis  $u_1, \dots, u_k$  defines the same orientation as the basis  $\underline{e}$ .  $\square$

Consider a parallelepiped in a  $k$ -dimensional space, which is spanned by  $k$  vectors. Write down the coordinates (in an orthonormal basis) into the columns of a matrix. Then the volume of the parallelepiped is the determinant of the matrix.

The formula (2) above is called the *Gram determinant*. It is independent of the choice of basis and, therefore it is useful when  $k$  is lower than the dimension of the whole space.

We formulate the following important geometric consequence:

**4.1.20. Corollary.** *For each linear map  $\varphi : V \rightarrow V$  on a Euclidean vector space  $V$ ,  $\det \varphi$  equals the (oriented) volume of the image of the parallelepiped determined by vectors of an orthonormal basis. More generally, the image of the parallelepiped  $\mathcal{P}$ , determined by arbitrary  $\dim V$  vectors, has a volume equal to  $\det \varphi$ -multiple of the former volume.*

**4.B.20.** Find the intersection of the plane passing through the point  $A = [1, 2, 3, 4] \in \mathbb{R}^4$  and orthogonal to the plane

$$\varrho : [1, 0, 1, 0] + (1, 2, -1, -2)s + (1, 0, 0, 1)t, \quad s, t \in \mathbb{R}.$$

**Solution.** Find the plane orthogonal to  $\varrho$ . Its direction is orthogonal to the direction of  $\varrho$ , for vectors  $(a, b, c, d)$  within its direction we get linear equation system

$$\begin{aligned} (a, b, c, d) \cdot (1, 2, -1, -2) &= 0 \quad \equiv \quad a + 2b - c - 2d = 0 \\ (a, b, c, d) \cdot (1, 0, 0, 1) &= 0 \quad \equiv \quad a + d = 0. \end{aligned}$$

The solution is the two-dimensional vector space  $\langle (0, 1, 2, 0), (-1, 0, -3, 1) \rangle$ . The plane  $\tau$  orthogonal to  $\varrho$  passing through  $A$  has parametric equation

$$\tau : [1, 2, 3, 4] + (0, 1, 2, 0)u + (-1, 0, -3, 1)v, \quad u, v \in \mathbb{R}.$$

We can obtain the intersection of the planes from both parametric equations. It is given by the linear equation system

$$\begin{aligned} 1 + s + t &= 1 - v \\ 2s &= 2 + u \\ 1 - s &= 3 + 2u - 3v \\ -2s + t &= 4 + v, \end{aligned}$$

which has the unique solution (it must be so as matrix columns are linearly independent)  $s = -8/19$ ,  $t = 34/19$ ,  $u = -54/19$ ,  $v = -26/19$ . Substitute the parameter values  $s$  and  $t$  into the parametric form of the plane  $\varrho$ , to obtain the intersection  $[45/19, -16/19, 11/19, 18/19]$ . (Needless to say, the same solution is obtained by substituting the values into  $\tau$ ).  $\square$

**4.B.21.** Find a line passing through point  $[1, 2] \in \mathbb{R}^2$  so that the angle between this line and the line

$$p : [0, 1] + t(1, 1)$$

is  $30^\circ$ .

**Solution.** The angle between two lines is the angle between their direction vectors. It is sufficient to find the direction vector  $\underline{v}$  of the line. One way to do so is to rotate the direction vector of  $p$  by  $30^\circ$ . The rotation matrix for the angle  $30^\circ$  is

$$\begin{pmatrix} \cos 30^\circ & -\sin 30^\circ \\ \sin 30^\circ & \cos 30^\circ \end{pmatrix} = \begin{pmatrix} \frac{\sqrt{3}}{2} & -\frac{1}{2} \\ \frac{1}{2} & \frac{\sqrt{3}}{2} \end{pmatrix}.$$

The desired vector  $\underline{v}$  is therefore

$$\underline{v} = \begin{pmatrix} \frac{\sqrt{3}}{2} & -\frac{1}{2} \\ \frac{1}{2} & \frac{\sqrt{3}}{2} \end{pmatrix} \begin{pmatrix} 1 \\ 1 \end{pmatrix} = \begin{pmatrix} \frac{\sqrt{3}}{2} - \frac{1}{2} \\ \frac{\sqrt{3}}{2} + \frac{1}{2} \end{pmatrix}.$$

We could perform the backward rotation as well. The line (one of two possible) has parametric equation

$$[1, 2] + \left( \frac{\sqrt{3}}{2} - \frac{1}{2}, \frac{\sqrt{3}}{2} + \frac{1}{2} \right) t.$$

$\square$

**4.1.21. Outer product and cross product.** The previous considerations are closely related to the tensor product of vectors. We do not go further in this technically more complicated topic now. But we do mention the outer product of  $n = \dim V$  vectors  $u_1, \dots, u_n \in V$ .

Let  $(u_{1j}, \dots, u_{nj})^T$  be coordinate expressions of vectors  $u_j$  in a chosen orthonormal basis  $V$ . Let  $M$  be a matrix with elements  $(u_{ij})$ . Then the determinant  $|M|$  does not depend on the choice of the basis with the same orientation. Its value is called the *outer product* of the vectors  $u_1, \dots, u_n$ , and is denoted by  $[u_1, \dots, u_n]$ . Hence the outer product is the oriented volume of the corresponding parallelepiped, see 4.1.19.

Although the outer product looks like a scalar quantity, the story gets more complicated once we allow for general basis of  $V$ . Then the determinant of the matrix  $M$  built of the coordinates of  $u_i$  changes by the determinants of the transition matrices. Such objects are called *densities* and we shall come back to them in chapter 9.

Several useful properties of the outer product follow directly from the definition

- (1) The map  $(u_1, \dots, u_n) \mapsto [u_1, \dots, u_n]$  is an antisymmetric  $n$ -linear map. It is linear in all arguments, and the interchange of any two arguments causes a change of sign.
- (2) The outer product is zero if and only if the vectors  $u_1, \dots, u_n$  are linearly dependent.
- (3) The vectors  $u_1, \dots, u_n$  form a positive basis if and only if the outer product is positive.

Consider a Euclidean vector space  $V$  of dimension  $n \geq 2$  and vectors  $u_1, \dots, u_{n-1} \in V$ . If these  $n-1$  vectors are substituted into the first  $n-1$  arguments of the  $n$ -linear map defined by the volume determinant as above, then there is one argument left over. This defines a linear form on  $V$ . Since the scalar product is available, each linear form corresponds to exactly one vector. This vector  $v \in V$  is called the *cross product* of the vectors  $u_1, \dots, u_{n-1}$ . For each vector  $w \in V$

$$\langle w, v \rangle = [u_1, \dots, u_{n-1}, w].$$

We denote the cross product by  $v = u_1 \times \dots \times u_{n-1}$ .

If the coordinates of the vectors in an orthonormal basis are  $v = (y_1, \dots, y_n)^T$ ,  $w = (x_1, \dots, x_n)^T$  and  $u_j = (u_{1j}, \dots, u_{nj})^T$ , then the definition can be expressed as

$$y_1 x_1 + \dots + y_n x_n = \begin{vmatrix} u_{11} & \dots & u_{1(n-1)} & x_1 \\ \vdots & & \vdots & \vdots \\ u_{n1} & \dots & u_{n(n-1)} & x_n \end{vmatrix}.$$

Hence the vector  $v$  is determined uniquely. Its coordinates are calculated by the formal expansion of this determinant along the last column. The following properties of the cross product are direct consequences of the definition:

**Theorem.** For the cross product  $v = u_1 \times \dots \times u_{n-1}$

- (1)  $v \in \langle u_1, \dots, u_{n-1} \rangle^\perp$
- (2)  $v$  is nonzero if and only if the vectors  $u_1, \dots, u_{n-1}$  are linearly independent,

**4.B.22.** An octahedron has eight faces consisting of equilateral triangles. Determine  $\cos \alpha$ , where  $\alpha$  is the angle between two adjacent faces of a regular octahedron.

**Solution.** An octahedron is symmetric, therefore it does not matter which two faces are selected. By suitable scaling, the octahedron has edge length 1 and is placed in the standard Cartesian coordinate system  $\mathbb{R}^3$  so that its centroid is at  $[0, 0, 0]$ . Its vertices then are located at the points  $A = [\frac{\sqrt{2}}{2}, 0, 0]$ ,  $B = [0, \frac{\sqrt{2}}{2}, 0]$ ,  $C = [-\frac{\sqrt{2}}{2}, 0, 0]$ ,  $D = [0, -\frac{\sqrt{2}}{2}, 0]$ ,  $E = [0, 0, -\frac{\sqrt{2}}{2}]$  and  $F = [0, 0, \frac{\sqrt{2}}{2}]$ .

We compute the angle between the faces  $CDF$  and  $BCF$ . We need to find vectors orthogonal to their intersection and lying within respective faces, which means orthogonal to  $CF$ . They are altitudes from  $D$  and  $F$  to the edge  $CF$  in the triangles  $CDF$  and  $BCF$  respectively. The altitudes in an equilateral triangle are the same segments as the medians, so they are  $SD$  and  $SB$ , where  $S$  is midpoint of  $CF$ . Because the coordinates of points  $C$  and  $F$  are known,  $S$  has coordinates  $[-\frac{\sqrt{2}}{4}, 0, \frac{\sqrt{2}}{4}]$  and the vectors are  $SD = (\frac{\sqrt{2}}{4}, -\frac{\sqrt{2}}{2}, -\frac{\sqrt{2}}{4})$  and  $SB = (\frac{\sqrt{2}}{4}, \frac{\sqrt{2}}{2}, -\frac{\sqrt{2}}{4})$ . Together

$$\cos \alpha = \frac{(\frac{\sqrt{2}}{4}, -\frac{\sqrt{2}}{2}, -\frac{\sqrt{2}}{4}) \cdot (\frac{\sqrt{2}}{4}, \frac{\sqrt{2}}{2}, -\frac{\sqrt{2}}{4})}{\|(\frac{\sqrt{2}}{4}, -\frac{\sqrt{2}}{2}, -\frac{\sqrt{2}}{4})\| \|(\frac{\sqrt{2}}{4}, \frac{\sqrt{2}}{2}, -\frac{\sqrt{2}}{4})\|}} = -\frac{1}{3}.$$

Therefore  $\alpha \doteq 132^\circ$ . □

**4.B.23.** In Euclidean space  $\mathbb{R}^5$  determine the angle  $\varphi$  between subspaces  $U, V$ , where

- (a)  $U : [3, 5, 1, 7, 2] + t(1, 0, 2, -2, 1), t \in \mathbb{R}$ ,  
 $V : [0, 1, 0, 0, 0] + s(2, 0, -2, 1, -1), s \in \mathbb{R}$ ;
- (b)  $U : [4, 1, 1, 0, 1] + t(2, 0, 0, 2, 1), t \in \mathbb{R}$ ,  
 $V : x_1 + x_2 + x_3 + x_5 = 7$ ;
- (c)  $U : 2x_1 - x_2 + 2x_3 + x_5 = 3$ ,  
 $V : x_1 + 2x_2 + 2x_3 + x_5 = -1$ ;
- (d)  $U : [0, 1, 1, 0, 0] + t(0, 0, 0, 1, -1), t \in \mathbb{R}$ ,  
 $V : [1, 0, 1, 1, 1] + r(1, -1, 2, 1, 0) + s(0, 1, 3, 2, 0)$   
 $+ p(1, 0, 0, 1, 0) + q(1, 3, 1, 0, 0)$ ,  
 $r, s, p, q \in \mathbb{R}$ ;
- (e)  $U : [0, 2, 5, 0, 0] + t(2, 1, 3, 5, 3) + s(0, 3, 1, 4, -2)$   
 $+ r(1, 2, 4, 0, 3), t, s, r \in \mathbb{R}$ ,  
 $V : [0, 0, 0, 0, 0] + p(-1, 1, 1, -5, 0)$   
 $+ q(1, 5, 1, 13, -4), p, q \in \mathbb{R}$ ;
- (f)  $U : [1, 1, 1, 1, 1] + t(1, 0, 1, 1, 1)$   
 $+ s(1, 0, 0, 1, 1), t, s \in \mathbb{R}$ ,  
 $V : [1, 1, 1, 1, 1] + p(1, 1, 1, 1, 1) + q(1, 1, 0, 1, 1)$   
 $+ r(1, 1, 0, 1, 0), p, q, r \in \mathbb{R}$ .

**Solution.** Recall that the angle between affine subspaces is the same as the angle between vector spaces associated to them. Therefore the translation caused by the point addition can be omitted.

Case (a). Since  $U$  and  $V$  are one-dimensional spaces, the angle  $\varphi \in [0, \pi/2]$  is given by formula

$$\cos \varphi = \frac{|(1, 0, 2, -2, 1) \cdot (2, 0, -2, 1, -1)|}{\|(1, 0, 2, -2, 1)\| \|(2, 0, -2, 1, -1)\|} = \frac{5}{\sqrt{10} \cdot \sqrt{10}}.$$

- (3) the length  $\|v\|$  of the cross product equals the absolute value of the volume of parallelepiped  $\mathcal{P}(0; u_1, \dots, u_{n-1})$ ,
- (4)  $(u_1, \dots, u_{n-1}, v)$  is a compatible basis of the oriented Euclidean space  $V$ .

**PROOF.** The first claim follows directly from the defining formula for  $v$ . Substituting an arbitrary vector  $u_j$  for  $w$  gives the scalar product  $v \cdot u_j$  on the left and the determinant with two equal columns on the right.

The rank of the matrix with  $n - 1$  columns  $u_j$  is given by the maximal size of a non-zero minor. The minors which define coordinates of the cross product are of degree  $n - 1$  and thus claim (2) is proved.

If the vectors  $u_1, \dots, u_{n-1}$  are linearly dependent, then (3) also holds. Suppose the vectors are linearly independent. Let  $v$  be their cross product, and choose an orthonormal basis  $(e_1, \dots, e_{n-1})$  of the space  $\langle u_1, \dots, u_{n-1} \rangle$ . It follows from what is proved that there exists a multiple  $(1/\alpha)v, 0 \neq \alpha \in \mathbb{R}$ , such that  $(e_1, \dots, e_k, (1/\alpha)v)$  is an orthonormal basis of  $V$ . The coordinates of the vectors in this basis are

$$u_j = (u_{1j}, \dots, u_{(n-1)j}, 0)^T, \quad v = (0, \dots, 0, \alpha)^T.$$

So the outer product  $[u_1, \dots, u_{n-1}, v]$  equals (see the definition of cross product)

$$[u_1, \dots, u_{n-1}, v] = \begin{vmatrix} u_{11} & \dots & u_{1(n-1)} & 0 \\ \vdots & & \vdots & \vdots \\ u_{(n-1)1} & \dots & u_{(n-1)(n-1)} & 0 \\ 0 & \dots & 0 & \alpha \end{vmatrix} = \langle v, v \rangle = \alpha^2.$$

By expanding the determinant along the last column,

$$\alpha^2 = \alpha \text{Vol } \mathcal{P}(0; u_1, \dots, u_{n-1}),$$

which proves the remaining two claims. □

In technical applications in  $\mathbb{R}^3$ , the cross product is often used. It assigns a vector to any pair of vectors.

## 2. Transformations

This short section backs up a quite wide area of practical considerations displayed in the other column. As usual, we can understand objects well only if we master the mappings preserving the crucial concepts.

Therefore  $\cos \varphi = 1/2$  and  $\varphi = \pi/3$ .

Case (b). The subspace  $U$  has direction vector  $(2, 0, 0, 2, 1)$  and the subspace  $V$  has normal vector  $(1, 1, 1, 0, 1)$ . The angle between them  $\psi = \pi/3$  is derived from the formula

$$\cos \psi = \frac{(2,0,0,2,1) \cdot (1,1,1,0,1)}{\|(2,0,0,2,1)\| \cdot \|(1,1,1,0,1)\|} = \frac{3}{3 \cdot 2}.$$

Notice that  $\varphi = \pi/2 - \psi = \pi/6$ , because  $\varphi$  is complement to  $\psi$ .

Case (c). The hyperplanes  $U$  and  $V$  are defined by normal vectors  $u = (2, -1, 2, 0, 1)$  and  $v = (1, 2, 2, 0, 1)$ . The angle  $\varphi$  equals to angle between the direction vectors  $u$  a  $v$ . Therefore (see (a))

$$\cos \varphi = \frac{|(2,-1,2,0,1) \cdot (1,2,2,0,1)|}{\|(2,-1,2,0,1)\| \cdot \|(1,2,2,0,1)\|} = \frac{1}{2}, \quad \text{tj.} \quad \varphi = \frac{\pi}{3}.$$

Case (d). Denote

$u = (0, 0, 0, 1, -1)$ ,  $v_1 = (1, -1, 2, 1, 0)$ ,  
 $v_2 = (0, 1, 3, 2, 0)$ ,  $v_3 = (1, 0, 0, 1, 0)$ ,  $v_4 = (1, 3, 1, 0, 0)$   
 and denote the orthogonal projection of  $u$  into the vector subspace of  $V$  (subspace generated by  $v_1, v_2, v_3, v_4$ ) by  $p_u$ .

Now

$$p_u = av_1 + bv_2 + cv_3 + dv_4 \quad \text{for some } a, b, c, d \in \mathbb{R}$$

and

$$\begin{aligned} \langle p_u - u, v_1 \rangle &= 0, & \langle p_u - u, v_2 \rangle &= 0, \\ \langle p_u - u, v_3 \rangle &= 0, & \langle p_u - u, v_4 \rangle &= 0. \end{aligned}$$

Substituting for  $p_u$  gives the linear equation system

$$\begin{aligned} 7a + 7b + 2c &= 1, \\ 7a + 14b + 2c + 6d &= 2, \\ 2a + 2b + 2c + d &= 1, \\ 6b + c + 11d &= 0. \end{aligned}$$

The solution is  $(a, b, c, d) = (-8/19, 7/19, 13/19, -5/19)$ .

$$(1) \quad \cos \varphi = \frac{\|p_u\|}{\|u\|}$$

and so

$$\begin{aligned} p_u &= -\frac{8}{19}v_1 + \frac{7}{19}v_2 + \frac{13}{19}v_3 - \frac{5}{19}v_4 = (0, 0, 0, 1, 0), \\ \cos \varphi &= \frac{\|p_u\|}{\|u\|} = \frac{\|(0, 0, 0, 1, 0)\|}{\|(0, 0, 0, 1, -1)\|} = \frac{1}{\sqrt{2}} = \frac{\sqrt{2}}{2}. \end{aligned}$$

Hence  $\varphi = \pi/4$ .

Case (e). Determine the intersection of the vector subspaces associated with the given affine subspaces. The vector  $(x_1, x_2, x_3, x_4, x_5)$  is in the vector subspace of  $U$ , if and only if

$(x_1, x_2, x_3, x_4, x_5) = t(2, 1, 3, 5, 3) + s(0, 3, 1, 4, -2) + r(1, 2, 4, 0, 3)$  for some  $t, s, r \in \mathbb{R}$ . Similarly,  $(x_1, x_2, x_3, x_4, x_5) \in V$  if and only if  $(x_1, x_2, x_3, x_4, x_5) = p(-1, 1, 1, -5, 0) + q(1, 5, 1, 13, -4)$  for some  $p, q \in \mathbb{R}$ . We look for such  $t, s, r, p, q \in \mathbb{R}$ , so that

$$\begin{aligned} t(2, 1, 3, 5, 3) + s(0, 3, 1, 4, -2) + r(1, 2, 4, 0, 3) \\ = p(-1, 1, 1, -5, 0) + q(1, 5, 1, 13, -4). \end{aligned}$$

It is a homogeneous linear equation system. It is solved in matrix form (order of variables is  $t, s, r, p, q$ )

AFFINE MAPS

**4.2.1.** A map  $f : \mathcal{A} \rightarrow \mathcal{B}$  between affine spaces is called an *affine map* if there exists a linear map  $\varphi : Z(\mathcal{A}) \rightarrow Z(\mathcal{B})$  between their difference spaces such that for all  $A \in \mathcal{A}$ ,  $v \in Z(\mathcal{A})$  the following holds:

$$f(A + v) = f(A) + \varphi(v).$$

The maps  $f$  and  $\varphi$  are determined uniquely by this property, and by arbitrarily chosen images of  $(\dim \mathcal{A} + 1)$  points in general position.

For an arbitrary affine combination of points  $t_0A_0 + \dots + t_sA_s \in \mathcal{A}$  we obtain

$$\begin{aligned} f(t_0A_0 + \dots + t_sA_s) &= \\ &= f(A_0 + t_1(A_1 - A_0) + \dots + t_s(A_s - A_0)) \\ &= f(A_0) + t_1\varphi(A_1 - A_0) + \dots + t_s\varphi(A_s - A_0) \\ &= t_0f(A_0) + t_1f(A_1) + \dots + t_sf(A_s). \end{aligned}$$

On the other hand, if a map preserves affine combinations, we may use a specific combination of  $n + 1$  fixed vectors generating the affine frame. After choosing successively the only non-zero coefficients  $t_i = 1$ ,  $i = 1, \dots, s$ , we define the map  $\varphi$  between difference spaces by the relation  $\varphi(A_i - A_0) = f(A_i) - f(A_0)$ . The previous computation can be read in the opposite direction, so we can check the validity and linearity of  $\varphi$ . The assumption that the first and the last rows are equal implies that the second and the third rows are equal. So we have an affine map with the corresponding linear map  $\varphi$  between difference spaces which we described in the chosen affine frame by this procedure. Therefore:

**Theorem.** *Affine maps are exactly those maps which preserve the affine combinations of points.*

It is sufficient to check the invariance of affine combinations for all pairs of points since we can create an arbitrary affine combination from them. The affine combination of  $k + 2$  points  $A_0, \dots, A_{k+1}$  can be expressed as

$$r(t_0A_0 + \dots + t_kA_k) + sA_{k+1},$$

where  $\sum_{i=0}^k t_k = 1$  and  $r + s = 1$ . We choose a point which is an affine combination of  $k + 1$  points only. Then make its combination with the last one. In this way, any finite affine combination can be made step by step from the combination of pairs.

**4.2.2. Ratio of collinear points.** The affine combinations of pairs of points can be also expressed with the help of the *ratio of points* on a straight line. If  $C$  is given by an affine combination of points  $A$  and  $B \neq C$ ,  $C = rA + sB$ , then we say that the number

$$\lambda = (C; A, B) = -\frac{s}{r}$$

is the ratio of the point  $C$  with respect to the given points  $A$  and  $B$ . Since we can express  $C$  as

$$C = A + s(B - A) = B + r(A - B),$$

$$\begin{pmatrix} 2 & 0 & 1 & 1 & -1 \\ 1 & 3 & 2 & -1 & -5 \\ 3 & 1 & 4 & -1 & -1 \\ 5 & 4 & 0 & 5 & -13 \\ 3 & -2 & 3 & 0 & 4 \end{pmatrix} \sim \dots \\ \sim \begin{pmatrix} 1 & 3 & 2 & -1 & -5 \\ 0 & 2 & 1 & -1 & -3 \\ 0 & 0 & 1 & -1 & 1 \\ 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 \end{pmatrix}.$$

The vectors defining  $V$  are linear combination of the vectors of  $U$ . So  $V$  is subset of  $U$ , and hence  $\varphi = 0$ .

Case (f). Find the intersection of  $U$  and  $V$ . Search for numbers  $t, s, p, q, r \in \mathbb{R}$  such that

$$t(1, 0, 1, 1, 1) + s(1, 0, 0, 1, 1) \\ = p(1, 1, 1, 1, 1) + q(1, 1, 0, 1, 1) + r(1, 1, 0, 1, 0).$$

The solution is  $(t, s, p, q, r) = (-a, a, -a, a, 0)$ ,  $a \in \mathbb{R}$ . The intersection  $Z(U) \cap Z(V)$  of vector spaces  $U$  and  $V$  contains the vectors

$$(0, 0, -a, 0, 0) = -a(1, 0, 1, 1, 1) + a(1, 0, 0, 1, 1) \\ = -a(1, 1, 1, 1, 1) + a(1, 1, 0, 1, 1) \\ + 0(1, 1, 0, 1, 0),$$

where  $a \in \mathbb{R}$ .  $Z(U) \cap Z(V)$  is generated by  $(0, 0, 1, 0, 0)$  and its orthogonal complement  $(Z(U) \cap Z(V))^\perp$  is generated by vectors  $(1, 0, 0, 0, 0)$ ,  $(0, 1, 0, 0, 0)$ ,  $(0, 0, 0, 1, 0)$ ,  $(0, 0, 0, 0, 1)$ .

We obtain

$$Z(U) \cap Z(V) \neq \{0\}, \quad Z(U) \cap Z(V) \neq Z(U), \\ Z(U) \cap Z(V) \neq Z(V).$$

The angle  $\varphi$  is defined as the angle between the subspaces  $Z(U) \cap (Z(U) \cap Z(V))^\perp$  and  $Z(V) \cap (Z(U) \cap Z(V))^\perp$ .

It is now established that

$$Z(U) \cap (Z(U) \cap Z(V))^\perp = \langle (1, 0, 0, 1, 1) \rangle, \\ Z(V) \cap (Z(U) \cap Z(V))^\perp = \langle (1, 1, 0, 1, 1), (1, 1, 0, 1, 0) \rangle.$$

It is enough to express  $Z(U)$  as a linear combination of vectors  $(0, 0, 1, 0, 0)$ ,  $(1, 0, 0, 1, 1)$  and  $Z(V)$  by the vectors  $(0, 0, 1, 0, 0)$ ,  $(1, 1, 0, 1, 1)$ ,  $(1, 1, 0, 1, 0)$ . Since the dimension of  $Z(U) \cap (Z(U) \cap Z(V))^\perp$  is 1, we can use the formula (1), where  $u = (1, 0, 0, 1, 1)$  and  $p_u$  is the orthogonal projection of  $u$  into  $Z(V) \cap (Z(U) \cap Z(V))^\perp$ . Then

$$p_u = a(1, 1, 0, 1, 1) + b(1, 1, 0, 1, 0)$$

and

$$\langle p_u - u, (1, 1, 0, 1, 1) \rangle = 0, \quad \langle p_u - u, (1, 1, 0, 1, 0) \rangle = 0,$$

which leads to the linear equation system

$$4a + 3b = 3, \\ 3a + 3b = 2$$

with the unique solution  $a = 1$ ,  $b = -1/3$ . Thus

$$p_u = \left(\frac{2}{3}, \frac{2}{3}, 0, \frac{2}{3}, 1\right).$$

From (1) it follows that

the ratio  $\lambda$  is the ratio of the length of the oriented vectors  $C - A$  and  $C - B$ . In particular,  $\lambda = -1$  if and only if  $C$  is at the centre of the line segment joining  $A$  and  $B$  (i.e.  $r = s = \frac{1}{2}$  in the affine combination).

Hence the characterization of affine maps in terms of affine combinations has the following consequence:

**Corollary.** *Affine maps are exactly those maps for which the ratios are invariant.*

Needless to say that collinearity of points must be preserved in order to talk about the ratios.

**4.2.3. Coordinate expression for maps.** View a general affine map  $f : \mathcal{A} \rightarrow \mathcal{B}$ ,  $f(X) = f(A_0) + \varphi(X - X_0)$ , in coordinates as follows. First express the image  $f(A_0)$  of the origin of the frame  $(A_0, \underline{u})$  on  $\mathcal{A}$  in the frame  $(B_0, \underline{v})$  on  $\mathcal{B}$ . In other words, the vector  $f(A_0) - B_0$  has got coordinates  $y_0$  in the basis  $\underline{v}$ . Everything else is then given by multiplying by the matrix of the map  $\varphi$  in the chosen bases and by adding the outcome. Each affine map therefore has the following form in coordinates:

$$x \mapsto y_0 + Y \cdot x,$$

where  $y_0$  is as above, and  $Y$  is the matrix of the map  $\varphi$ .

Of course, the changes of coordinates are special instances of invertible affine mappings on the standard affine space  $\mathcal{A}_n$ . Similarly to the case of linear mappings, under the choice of two affine coordinate systems  $(A_0, \underline{u})$  and  $(B_0, \underline{v})$  on  $\mathcal{A}$ , the coordinate expression of the identity mapping is the requested rule for the change of coordinates, cf. 4.1.5.

Next, consider the change of the frame

$$x = w + M \cdot x',$$

on the domain by a translation  $w$  and a matrix  $M$ . Further, let

$$y' = z + N \cdot y$$

describe a change of basis on the range space by a translation  $z$  and a matrix  $N$ . Then the coordinate expression  $x \mapsto y_0 + Y \cdot x$  for  $f : \mathcal{A} \rightarrow \mathcal{B}$  is

$$(1) \quad y' = z + N \cdot y = z + N \cdot (y_0 + Y \cdot x) \\ = (z + N \cdot y_0 + N \cdot Y \cdot w) + (N \cdot Y \cdot M) \cdot x'.$$

Hence the affine map in the new bases is given by the translation vector  $z + N \cdot y_0 + N \cdot Y \cdot w$  and matrix  $N \cdot Y \cdot M$ .

#### EUCLIDEAN MAPS

**4.2.4.** The Euclidean maps  $f : \mathcal{E}_1 \rightarrow \mathcal{E}_2$  are affine maps which respects the distances, which happens if and only if the associated linear maps  $\varphi$  are orthogonal.

In particular, the coordinate description of invertible Euclidean maps includes orthogonal matrices  $Y$ . If the dimension of the image is bigger, then we always can complete the image of a chosen orthogonal frame into an orthonormal frame of the co-domain, and then the relevant matrix  $Y$  will contain an orthogonal block, completed by zeros.

$$\cos \varphi = \frac{\| (2/3, 2/3, 0, 2/3, 1) \|}{\| (1, 0, 0, 1, 1) \|} = \frac{\sqrt{7}}{3}. \quad \varphi \doteq 0.49 \ (\approx 28^\circ).$$

□

### C. Geometry of quadratic forms

**4.C.1.** Determine the polar basis of the form  $f : \mathbb{R}^3 \rightarrow \mathbb{R}$ ,  $f(x_1, x_2, x_3) = 3x_1^2 + 2x_1x_2 + x_2^2 + 4x_2x_3 + 6x_3^2$ .

**Solution.** Its matrix is

$$A = \begin{pmatrix} 3 & 1 & 0 \\ 1 & 1 & 2 \\ 0 & 2 & 6 \end{pmatrix}.$$

According to step (1) of the Lagrange algorithm (see Theorem 4.3.1), perform the following operations

$$\begin{aligned} f(x_1, x_2, x_3) &= \frac{1}{3}(3x_1 + x_2)^2 + \frac{2}{3}x_2^2 + 4x_2x_3 + 6x_3^2 \\ &= \frac{1}{3}y_1^2 + \frac{3}{2}\left(\frac{2}{3}y_2 + 2y_3\right)^2 \\ &= \frac{1}{3}z_1^2 + \frac{3}{2}z_2^2. \end{aligned}$$

The form has rank 2 and the matrix changing the basis to the polar basis  $\underline{w}$  is obtained by a combination of following transformations:  $z_3 = y_3 = x_3$ ,  $z_2 = \frac{2}{3}y_2 + 2y_3 = \frac{2}{3}x_2 + 2x_3$  and  $z_1 = y_1 = 3x_1 + x_2$ , so the change of basis matrix is

$$T = \begin{pmatrix} 3 & 1 & 0 \\ 0 & \frac{2}{3} & 2 \\ 0 & 0 & 1 \end{pmatrix}.$$

We computed the polar coordinates, expressed them in standard basis and wrote them as rows of the matrix (the columns of this matrix are vectors of the standard basis in the polar basis). The polar basis vector coordinates are the columns of the matrix  $T^{-1}$ .

$$T^{-1} = \begin{pmatrix} \frac{1}{3} & \frac{-1}{2} & 1 \\ 0 & \frac{3}{2} & -3 \\ 0 & 0 & 1 \end{pmatrix},$$

The polar basis is therefore  $((\frac{1}{3}, 0, 0), (-\frac{1}{2}, \frac{3}{2}, 0), (1, -3, 1))$ . □

**4.C.2.** Determine the polar basis of the form  $f : \mathbb{R}^3 \rightarrow \mathbb{R}^3$ ,  $f(x_1, x_2, x_3) = 2x_1x_3 + x_2^2$ .

**Solution.** The matrix is of the form

$$A = \begin{pmatrix} 0 & 0 & 1 \\ 0 & 1 & 0 \\ 1 & 0 & 0 \end{pmatrix}.$$

Change the order of the variables:  $y_1 = x_2$ ,  $y_2 = x_1$ ,  $y_3 = x_3$ . It is then trivial to apply step (1) of Lagrange algorithm (there are no common terms). However for the next step, case (4) sets in. Introduce the transformation  $z_1 = y_1$ ,  $z_2 = y_2$ ,  $z_3 = y_3 - y_2$ .

$$f(x_1, x_2, x_3) = z_1^2 + 2z_2(z_3 + z_2) = z_1^2 + \frac{1}{2}(2z_2 + z_3)^2 - \frac{1}{2}z_3^2.$$

**Remark.** Notice an amazing fact about transformations on Euclidean spaces keeping the distances invariant, i.e., general mappings  $f : \mathcal{E}_n \rightarrow \mathcal{E}_n$ .

Notice that a point  $C$  is on the segment determined by points  $A$  and  $B$  if and only if  $\|C - B\| + \|C - A\| = \|B - A\|$ . Consequently, any mapping  $f$  preserving distances must map segments to segments, thus also lines to lines. Moreover, if preserving distances, it clearly preserves ratios too, and thus we deal with an affine map. Affine maps preserve distances if and only if they are Euclidean.

In 4.D.1, we can see a purely analytic proof that in principle all such (reasonably “smooth”) maps are affine and thus Euclidean. The advantage of the above synthetic approach is, that even the smoothness of the mapping follows from the assumption.

**4.2.5. Affine and Euclidean properties.** Now we can consider which properties are related to the affine structure and where we really need the scalar product on the difference vector space.

All Euclidean transformations, i.e. bijective affine maps which preserve the distance between points, preserve also all objects we have studied (possibly up to the change of orientation). In particular, they preserve unoriented angles, unoriented volumes, angles between subspaces etc. If we want them to preserve also oriented angles, cross products, and volumes, then we must also assume that the transformations preserve the orientation.

Dealing with a general affine transformation  $T$  on an  $m$ -dimensional Euclidean space, the volumes are multiplied by the determinants of the relevant linear parts of  $T$ .

We ask: *Which concepts are preserved under affine transformations?*

Recall first that an affine transformation on an  $n$ -dimensional space  $\mathcal{A}$  is uniquely defined by mapping  $n + 1$  points in general position, that is, by mapping a one  $n$ -dimensional simplex. In the plane, this means choosing the image of any nondegenerate triangle. Preserved properties are properties related to subspaces and ratios. In particular, incidence properties of the type “a line passing through a point” or “a plane contains a line” etc. are preserved. Moreover, the collinearity of vectors is preserved. For every two collinear vectors, the ratio of their lengths is preserved independently of the scalar product defining the length. Similarly, the ratio of the volumes of two  $n$ -dimensional parallelepipeds is preserved under the transformations, since the determinant of the corresponding matrix changes them by the same multiple.

These affine properties can be used to prove geometric statements. For instance in the plane, to prove the fact that the medians of a triangle intersect in a single point, and in one third of their lengths, it is sufficient to verify this only in the case of an isosceles right-angled triangle or only in the

Together,  $z_1 = y_1 = x_2$ ,  $z_2 = y_2 = x_1$ ,  $z_3 = y_3 - y_2 = x_3 - x_1$ . The matrix  $T$  for change to polar basis is

$$T = \begin{pmatrix} 0 & 1 & 0 \\ 1 & 0 & 0 \\ -1 & 0 & 1 \end{pmatrix} \quad \text{and} \quad T^{-1} = \begin{pmatrix} 0 & 1 & 0 \\ 1 & 0 & 0 \\ 0 & 1 & 1 \end{pmatrix}.$$

The polar basis is therefore  $((0, 1, 0), (1, 0, 1), (0, 1, 1))$ .  $\square$

**4.C.3.** Find the polar basis of the quadratic form  $f : \mathbb{R}^3 \rightarrow \mathbb{R}$ , which in the standard basis is defined as

$$f(x_1, x_2, x_3) = x_1x_2 + x_1x_3.$$

**Solution.** By an application of the Lagrange algorithm:

$$\begin{aligned} f(x_1, x_2, x_3) &= 2x_1x_2 + x_2x_3 \\ \text{substitution } y_2 &= x_2 - x_1, y_1 = x_1, y_3 = x_3 \\ &= 2x_1(x_1 + y_2) + (x_1 + y_2)x_3 \\ &= 2x_1^2 + 2x_1y_2 + x_1x_3 + y_2x_3 \\ &= \frac{1}{2}(2x_1 + y_2 + \frac{1}{2}x_3)^2 - \frac{1}{2}y_2^2 - \frac{1}{8}x_3^2 + y_2x_3 \\ \text{substitution } y_1 &= 2x_1 + y_2 + \frac{1}{2}x_3 \\ &= \frac{1}{2}y_1^2 - \frac{1}{2}y_2^2 - \frac{1}{8}x_3^2 + y_2x_3 \\ &= \frac{1}{2}y_1^2 - 2(\frac{1}{2}y_2 - \frac{1}{2}x_3)^2 + \frac{3}{8}x_3^2 \\ \text{substitution } y_3 &= \frac{1}{2}y_2 - \frac{1}{2}x_3 \\ &= \frac{1}{2}y_1^2 - 2y_3^2 + \frac{3}{8}x_3^2. \end{aligned}$$

With the coordinates  $y_1, y_3, x_3$ , the quadratic form has a diagonal shape, which means that the basis associated with those coordinates is the polar basis of the form. If we want to express the basis, we need to obtain the matrix which changes the basis from polar to standard. By definition of the change of basis matrix, its columns are the polar basis vectors. Either we express the old variables  $(x_1, x_2, x_3)$  by new variables  $(y_1, y_3, x_3)$ , or equivalently we express the new ones by the old ones (which is easier). In the latter case, we need to compute inverse matrix.

$y_1 = 2x_1 + y_2 + \frac{1}{2}x_3 = 2x_1 + (x_2 - x_1) + \frac{1}{2}x_3$  and  $y_3 = \frac{1}{2}y_2 - \frac{1}{2}x_3 = -\frac{1}{2}x_1 + \frac{1}{2}x_3 - \frac{1}{2}x_3$ . The matrix for changing the basis from the polar basis to the standard basis is

$$T = \begin{pmatrix} 2 & 1 & \frac{1}{2} \\ -\frac{1}{2} & \frac{1}{2} & -\frac{1}{2} \\ 0 & 0 & 1 \end{pmatrix}.$$

The inverse matrix is

$$T^{-1} = \begin{pmatrix} \frac{1}{3} & -\frac{2}{3} & -\frac{1}{2} \\ \frac{1}{3} & \frac{4}{3} & \frac{1}{2} \\ 0 & 0 & 1 \end{pmatrix}.$$

Hence one of the polar bases of the given quadratic forms is (see the columns of the matrix),  $\{(1/3, 1/3, 0), (-2/3, 4/3, 0), (-1/2, 1/2, 1)\}$ .  $\square$

case of an equilateral triangle. Then this property holds for all triangles. Think about this argument!

**4.2.6. Transformations of quadrics.** After straight lines (which are mapped to straight lines again by all affine maps), the simplest objects in the analytic geometry of plane are the conic sections. These are given by quadratic equations in Cartesian coordinates. A conic is distinguished as a circle, ellipse, parabola or hyperbola, by examining the coefficients. There are two degenerate cases, namely a pair of lines or a point. We cannot distinguish a circle from an ellipse in affine geometry, but they are different in Euclidean geometry.

In analogy with the equations of conic sections in plane, we may discuss quadratic objects in Euclidean point spaces. These are defined in all orthonormal frames by quadratic equations, and they are known as *quadrics*. Consider a general quadratic equation for the coordinates  $(x_1, \dots, x_n)^T$  of a point  $A \in \mathcal{E}_n$

$$(1) \quad \sum_{i,j=1}^n a_{ij}x_i x_j + \sum_{i=1}^n a_i x_i + a = 0,$$

where it may be assumed by symmetry that  $a_{ij} = a_{ji}$  without loss of generality. This equation can be written as

$$f(u) + g(u) + a = 0$$

for a quadratic form  $f$  (i.e. the restriction of a symmetric bilinear form  $F$  to pairs of equal arguments), a linear form  $g$ , and a scalar  $a \in \mathbb{R}$ . We assume that at least one coefficient  $a_{ij}$  is nonzero. Otherwise the equation is linear and describes a hyperplane.

Notice that the equation (1) keeps the same shape under every affine coordinate transformation, i.e., it splits again into a nontrivial quadratic, linear and constant parts.

Recognizing which of the standard types of quadrics is determined by the given equation is an extremely useful tool (we shall see this later e.g. in multivariate analysis in Chapter 8) and thus we devote the next section to this topic.

Notice that the above observation is true for every fixed order of the multivariate polynomial expressions. In particular, there is the well defined concept of cubics, given by cubic equations and invariant with respect to all affine transformations. Similarly the quartics, quintics, etc.

We shall meet the cubic curves in plain in more details in Chapter 11 because of their fascinating use in cryptography.

### 3. Geometry of quadratic forms and quadrics

We shall start with the affine point of view and proceed to the Euclidean classification later.

**4.3.1. Linear transformations of quadratic forms.** Let us recall the bilinear symmetric forms  $F : \mathbb{R}^n \times \mathbb{R}^n \rightarrow \mathbb{R}$ , cf. 2.3.23, and the corresponding mappings  $f(x) = F(x, x)$  for all  $x \in \mathbb{R}^n$ .

**4.C.4.** Determine the type of conic section defined by

$$3x_1^2 - 3x_1x_2 + x_2 - 1 = 0.$$

**Solution.** Complete the squares:

$$\begin{aligned} 3x_1^2 - 3x_1x_2 + x_2 - 1 &= \frac{1}{3}(3x_1 - \frac{3}{2}x_2)^2 - \frac{3}{4}x_2^2 + x_2 - 1 \\ &= \frac{1}{3}y_1^2 - \frac{4}{3}(\frac{3}{4}x_2 - \frac{1}{2})^2 + \frac{1}{3} - 1 \\ &= \frac{1}{2}y_1^2 - \frac{4}{3}y_2^2 - \frac{2}{3}. \end{aligned}$$

According to the list 4.3.6, the given conic section is a hyperbola.  $\square$

**4.C.5.** By completing the squares, express the quadric

$$-x^2 + 3y^2 + z^2 + 6xy - 4z = 0$$

in such a way that one can determine its type from it.

**Solution.** Complete the square. Deal first with all terms involving an  $x$ . Obtain the equation

$$-(x - 3y)^2 + 9y^2 + 3y^2 + z^2 - 4z = 0.$$

There are no "unwanted" terms containing  $y$ , so repeat the procedure for  $z$ . This gives

$$-(x - 3y)^2 + 12y^2 + (z - 2)^2 - 4 = 0.$$

Conclude that there is a transformation of variables that leads to the equation (we can divide by 4 if desired)

$$-\bar{x}^2 + \bar{y}^2 + \bar{z}^2 - 1 = 0.$$

$\square$

We can tell the type of the conic section without transforming its equation to the form listed in 4.3.6. Every conic section can be expressed as

$$a_{11}x^2 + 2a_{12}xy + a_{22}y^2 + 2a_{13}x + 2a_{23}y + a_{33} = 0.$$

Determinants  $\Delta = \det A = \begin{vmatrix} a_{11} & a_{12} & a_{13} \\ a_{12} & a_{22} & a_{23} \\ a_{13} & a_{32} & a_{33} \end{vmatrix}$  and

$\delta = \begin{vmatrix} a_{11} & a_{12} \\ a_{12} & a_{22} \end{vmatrix}$  are invariants of conic sections which means that they are not changed by Euclidean transformations (rotation and translation). Furthermore, the different types of conic sections have different signs of those determinants.

- $\Delta \neq 0$  for non-degenerate conic sections: ellipse for  $\delta > 0$ , hyperbola for  $\delta < 0$  and parabola for  $\delta = 0$

For a real ellipse (not imaginary), it is necessary that  $(a_{11} + a_{22})\Delta < 0$ .

- $\Delta = 0$  for degenerate conic sections, or pairs of lines.

The signs (or zero-value) of the determinants are really in-

variant to the coordinate transformation. Denote  $X = \begin{pmatrix} x \\ y \\ 1 \end{pmatrix}$

and denote  $A$  as the matrix of the quadratic form. Then the corresponding conic section has equation  $X^TAX = 0$ . The

For an arbitrary basis  $\underline{e}$  on this vector space, the value  $f(x)$  on vector  $x = x_1e_1 + \dots + x_n e_n$  is given by the equation

$$(1) \quad f(x) = F(x, x) = \sum_{i,j} x_i x_j F(e_i, e_j) = x^T \cdot A \cdot x$$

where  $A = (a_{ij})$  is a symmetric matrix with elements  $a_{ij} = F(e_i, e_j)$ . We call such maps  $f$  *quadratic forms*, and the formula (1),  $f(x) = \sum_{i,j} a_{ij}x_i x_j$ , is called the *analytic formula* for the form  $f$ .

In general, by a quadratic form on vector space  $V$  is meant the restriction  $f(u)$  of a symmetric bilinear form  $F(u, v)$  to arguments of the type  $(u, u) \in V \times V$ . Evidently, the whole bilinear form  $F$  can be reconstructed from the values  $f(u)$  (unless we work over scalars  $\mathbb{Z}_2$ ) since

$$f(u + v) = F(u + v, u + v) = f(u) + f(v) + 2F(u, v).$$

This is called the *polarization process*.

Let us come back to the real vector spaces  $\mathbb{R}^n$ . If we change the basis  $\underline{e}$  to a different basis  $e'_1, \dots, e'_n$ , we get different coordinates  $x = S \cdot x'$  for the same vector (here  $S$  is the corresponding transformation matrix), and so

$$f(x) = (S \cdot x')^T \cdot A \cdot (S \cdot x') = (x')^T \cdot (S^T \cdot A \cdot S) \cdot x'.$$

Clearly, if we fix the second argument in the bilinear form  $F$ , we obtain a linear mapping  $V \rightarrow V^*$ , with coordinate description  $x \mapsto F(\cdot, x) = x^T \cdot A$ . Thus, the rank of the matrix  $A$  of the quadratic form  $f$  is the dimension of the image of this mapping and therefore it is independent of the choice of the coordinates. We call it the *rank of the quadratic form*  $f$ .

Our first task is to decide whether two quadratic forms can be transformed one into the other by a linear transformation.

We shall easily see that the matrix  $A$  of each quadratic form may be diagonal for a suitable choice of basis  $\underline{u}$  and this will resolve our task as well. In other words we request  $F(u_i, u_j) = 0$  for  $i \neq j$  for the corresponding symmetric bilinear form  $F$ . Each such basis is called the *polar basis* of the quadratic form  $f$ .

Later we shall see, we could even find a polar orthonormal basis (with respect to any scalar product). Nevertheless, without the use of the scalar product, there is a much simpler algorithm for finding a polar basis among all other bases. At the same time, this algorithm brings relevant information about the affine properties of the quadratic form. The algorithmic procedure in the proof of the next theorem is known as the *Lagrange algorithm*.

**Theorem.** Let  $f : V \rightarrow \mathbb{R}$  be a quadratic form on a real vector space  $V$  of dimension  $n$ . Then there exists a polar basis for  $f$  on  $V$ .

**PROOF.** (1) Let  $A$  be the matrix of  $f$  in basis  $\underline{u} = (u_1, \dots, u_n)$  on  $V$ , and assume  $a_{11} \neq 0$ . Then we may write

$$\begin{aligned} f(x_1, \dots, x_n) &= a_{11}x_1^2 + 2a_{12}x_1x_2 + \dots + a_{22}x_2^2 + \dots \\ &= a_{11}^{-1}(a_{11}x_1 + a_{12}x_2 + \dots + a_{1n}x_n)^2 \\ &\quad + \text{terms not containing } x_1. \end{aligned}$$

standard form is obtained by rotation and translation. This is by a transformation to new coordinates  $x', y'$  satisfying

$$\begin{aligned} x &= x' \cos \alpha - y' \sin \alpha + c_1 \\ y &= x' \sin \alpha + y' \cos \alpha + c_2, \end{aligned}$$

or, in matrix form, for the new coordinates  $X' = \begin{pmatrix} x' \\ y' \\ 1 \end{pmatrix}$ ,

$$(1) \quad X = \begin{pmatrix} x \\ y \\ 1 \end{pmatrix} = \begin{pmatrix} \cos \alpha & -\sin \alpha & c_1 \\ \sin \alpha & \cos \alpha & c_2 \\ 0 & 0 & 1 \end{pmatrix} \begin{pmatrix} x' \\ y' \\ 1 \end{pmatrix} = MX'.$$

Put  $X = MX'$  into the conic section equation to obtain the equation in new coordinates

$$\begin{aligned} X^T A X &= 0 \\ (MX')^T A (MX') &= 0 \\ X'^T M^T A M X' &= 0. \end{aligned}$$

Denote by  $A'$  the matrix of the quadratic form in new coordinates. Then  $A' = M^T A M$ , where matrix

$$M = \begin{pmatrix} \cos \alpha & -\sin \alpha & c_1 \\ \sin \alpha & \cos \alpha & c_2 \\ 0 & 0 & 1 \end{pmatrix} \text{ has unit determinant, so}$$

$$\det A' = \det M^T \det A \det M = \det A = \Delta.$$

Necessarily, the determinant  $A_{33}$ , which is the algebraic complement of  $a_{33}$ , is invariant to the coordination transformation. For rotation only,  $\det A' = \det M^T \det A \det M$ .

In this case the matrix  $M = \begin{pmatrix} \cos \alpha & -\sin \alpha & 0 \\ \sin \alpha & \cos \alpha & 0 \\ 0 & 0 & 1 \end{pmatrix}$

and  $\det A'_{33} = \det A_{33} = \delta$ . For translation only,

$M = \begin{pmatrix} 1 & 0 & c_1 \\ 0 & 1 & c_2 \\ 0 & 0 & 1 \end{pmatrix}$  and this subdeterminant remains unchanged.

**4.C.6.** Determine the type of conic section

$$2x^2 - 2xy + 3y^2 - x + y - 1 = 0.$$

**Solution.** The determinant

$$\Delta = \begin{vmatrix} 2 & -1 & -\frac{1}{2} \\ -1 & 3 & \frac{1}{2} \\ -\frac{1}{2} & \frac{1}{2} & -1 \end{vmatrix} = -\frac{23}{4} \neq 0,$$

hence it is a non-degenerate conic section. Moreover  $\delta = 5 > 0$ , therefore it is an ellipse. Furthermore  $(a_{11} + a_{22})\Delta = (2 + 3) \cdot (-\frac{23}{4}) < 0$ , so it is real ellipse.  $\square$

**4.C.7.** Determine the type of conic section  $x^2 - 4xy - 5y^2 + 2x + 4y + 3 = 0$ .

This suggest to transform the coordinates (i.e., change the basis)

$$x'_1 = a_{11}x_1 + a_{12}x_2 + \dots + a_{1n}x_n, \quad x'_2 = x_2, \dots, \quad x'_n = x_n.$$

This corresponds to the new basis

$$v_1 = a_{11}^{-1}u_1, \quad v_2 = u_2 - a_{11}^{-1}a_{12}u_1, \dots, \quad v_n = u_n - a_{11}^{-1}a_{1n}u_1$$

(As an exercise, compute the transformation matrix.) In the new basis the corresponding symmetric bilinear form satisfies  $F(v_i, v_i) = 0$  for all  $i > 1$  (compute it!). Thus  $f$  has the analytic form  $a_{11}^{-1}x_1'^2 + h$  in the new coordinates, where  $h$  is a quadratic form independent of the variable  $x_1$ .

It is often easier to choose  $v_1 = u_1$  in the new basis. Then  $f = f_1 + h$ , where  $f_1$  depends only on  $x'_1$ , while  $x'_1$  does not appear in  $h$ , but  $F(v_1, v_1) = a_{11}$ .

(2) Assume that after step (1),  $h$  is a matrix of rank less than  $n$  with a nonzero coefficient of  $x_2'^2$ . Then the same procedure can be repeated to obtain the expression  $f = f_1 + f_2 + h$ , where  $h$  contains only the variables with index greater than two. Proceed in this way until a diagonal form is obtained after  $n - 1$  steps, or in (say) the  $i$ -th step, the element  $a_{ii}$  is zero.

(3) If the last possibility occurs, and there exists some other element  $a_{jj} \neq 0$  with  $j > i$ , then it suffices to exchange the  $i$ -th and the  $j$ -th vector of the basis. Then continue according the previous procedure.

(4) Assume that the situation is  $a_{jj} = 0$  for all  $j \geq i$ . If there is no element  $a_{jk} \neq 0$  with  $j \geq i, k \geq i$ , then we are finished, since then the matrix is diagonal. If  $a_{jk} \neq 0$ , then we use the transformation  $v_j = u_j + u_k$  and we keep the other vectors of basis unchanged (i.e.  $x'_k = x_k - x_j$ , the other remain without change). Then  $h(v_j, v_j) = h(u_j, u_j) + h(u_k, u_k) + 2h(u_k, u_j) = 2a_{jk} \neq 0$  and we can continue as for case (1).  $\square$

**4.3.2. Affine classification of quadratic forms.**

The vectors in the basis obtained from the Lagrange algorithm can be rescaled by scalars such that the coefficients of the squares of variables are only the scalars 1, -1 and 0. Moreover, the following *law of inertia* says that the number of one's and minus one's does not depend on the choices in the course of the algorithm. These numbers are called the *signature of a quadratic form*. As before, there is a complete description of quadratic forms in the sense that two such forms may be transformed each one into the other by a linear transformation if and only if they have the same signature.

**Theorem.** For each nonzero quadratic form of rank  $r$  on a real vector space  $V$  there exists a natural number  $p$ , and  $r$  independent linear forms  $\varphi_1, \dots, \varphi_r \in V^*$  such that  $0 \leq p \leq r$  and  $f(u)$  becomes

$$(\varphi_1(u))^2 + \dots + (\varphi_p(u))^2 - (\varphi_{p+1}(u))^2 - \dots - (\varphi_r(u))^2.$$

Otherwise put, there exists a polar basis, in which  $f$  has an analytic formula

$$f(x_1, \dots, x_n) = x_1^2 + \dots + x_p^2 - x_{p+1}^2 - \dots - x_r^2.$$

**Solution.** The determinant  $\Delta = \begin{vmatrix} 1 & -2 & 1 \\ -2 & -5 & 2 \\ 1 & 2 & 3 \end{vmatrix} = -34 \neq 0$ ,

furthermore  $\delta = \begin{vmatrix} 1 & -2 \\ -2 & -5 \end{vmatrix} = -9 < 0$ , it is therefore a hyperbola.  $\square$

**4.C.8.** Determine the equation and type of conic section passing through the points

$$[-2, -4], [8, -4], [0, -2], [0, -6], [6, -2].$$

**Solution.** Input the coordinates of the points into the general conic section equation

$$a_{11}x^2 + a_{22}y^2 + 2a_{12}xy + a_1x + a_2y + a = 0$$

There follows the linear equation system

$$\begin{aligned} 4a_{11} + 16a_{22} + 16a_{12} - 2a_1 - 4a_2 + a &= 0, \\ 64a_{11} + 16a_{22} - 64a_{12} + 8a_1 - 4a_2 + a &= 0, \\ 4a_{22} - 2a_2 + a &= 0, \\ 36a_{22} - 6a_2 + a &= 0, \\ 36a_{11} + 4a_{22} - 24a_{12} + 6a_1 - 2a_2 + a &= 0. \end{aligned}$$

In matrix form we perform operations

$$\begin{aligned} &\begin{pmatrix} 4 & 16 & 16 & -2 & -4 & 1 \\ 64 & 16 & -64 & 8 & -4 & 1 \\ 0 & 4 & 0 & 0 & -2 & 1 \\ 0 & 36 & 0 & 0 & -6 & 1 \\ 36 & 4 & -24 & 6 & -2 & 1 \end{pmatrix} \sim \dots \\ &\sim \begin{pmatrix} 4 & 16 & 16 & -2 & -4 & 1 \\ 0 & 4 & 0 & 0 & -2 & 1 \\ 0 & 0 & 64 & -8 & 12 & -9 \\ 0 & 0 & 0 & 24 & -36 & 27 \\ 0 & 0 & 0 & 0 & 3 & -2 \end{pmatrix} \sim \dots \\ &\sim \begin{pmatrix} 48 & 0 & 0 & 0 & 0 & -1 \\ 0 & 12 & 0 & 0 & 0 & -1 \\ 0 & 0 & 64 & 0 & 0 & 0 \\ 0 & 0 & 0 & 24 & 0 & 3 \\ 0 & 0 & 0 & 0 & 3 & -2 \end{pmatrix}. \end{aligned}$$

Then

$$a_{11} = 1, \quad a_{22} = 4, \quad a_{12} = 0, \quad a_1 = -6, \quad a_2 = 32.$$

The conic section has equation

$$x^2 + 4y^2 - 6x + 32y + 48 = 0.$$

Complete the terms  $x^2 - 6x$ ,  $4y^2 + 32y$  to squares. The result is

$$(x - 3)^2 + 4(y + 4)^2 - 25 = 0,$$

or rather

$$\frac{(x - 3)^2}{5^2} + \frac{(y + 4)^2}{\left(\frac{5}{2}\right)^2} - 1 = 0.$$

The conic section is an ellipse with centre at  $[3, -4]$ .  $\square$

The number  $p$  of positive diagonal coefficients in the matrix of the given quadratic form (and thus the number  $r - p$  of negative coefficients) does not depend on the choice of polar basis.

Two symmetric matrices  $A, B$  of dimension  $n$  are matrices of the same quadratic form in different bases if and only if they have the same rank and the same number of positive coefficients in the polar basis.

**PROOF.** By completing the squares,  $f(x_1, \dots, x_n) = \lambda_1 x_1^2 + \dots + \lambda_r x_r^2$ ,  $\lambda_i \neq 0$ , in a basis on  $V$ . Assume moreover that the first  $p$  coefficients  $\lambda_i$  are positive. Then the transformation  $y_1 = \sqrt{\lambda_1}x_1, \dots, y_p = \sqrt{\lambda_p}x_p, y_{p+1} = \sqrt{-\lambda_{p+1}}x_{p+1}, \dots, y_r = \sqrt{-\lambda_r}x_r, y_{r+1} = x_{r+1}, \dots, y_n = x_n$  yields the desired formula. The forms  $\varphi_i$  are exactly the forms from the dual basis in  $V^*$  to the obtained polar basis.

It remains to prove that  $p$  does not depend on the procedure. Assume that there is a formula for the same form  $f$  in the polar bases  $\underline{u}, \underline{v}$ , i.e.

$$\begin{aligned} f(x_1, \dots, x_n) &= x_1^2 + \dots + x_p^2 - x_{p+1}^2 - \dots - x_r^2 \\ f(y_1, \dots, y_n) &= y_1^2 + \dots + y_q^2 - y_{q+1}^2 - \dots - y_r^2. \end{aligned}$$

Denote the subspace generated by the first  $p$  vectors of the first basis by  $P = \langle u_1, \dots, u_p \rangle$ , and similarly  $Q = \langle v_{q+1}, \dots, v_r \rangle$ . Then for each  $0 \neq u \in P$ ,  $f(u) > 0$  while for  $0 \neq v \in Q$ ,  $f(v) \leq 0$ . Hence necessarily  $P \cap Q = \{0\}$ , and therefore  $\dim P + \dim Q \leq n$ . Hence  $p + (r - q) \leq r$ , so that  $p \leq q$ . By interchanging the subspaces,  $q \leq p$ , and so  $p = q$ .

Thus  $p$  is independent of the choice of the polar basis. Consequently for two matrices with the same rank and the same number of positive coefficients in the diagonal form of the corresponding quadratic form, the analytic formulas are the same.  $\square$

While discussing symmetric maps we talked about definite and semidefinite maps. The same discussion has an obvious meaning also for symmetric bilinear forms and quadratic forms.

#### TYPES OF QUADRATIC FORMS

A quadratic form  $f$  on a real vector space  $V$  is called

- (1) *positive definite* if  $f(u) > 0$  for all vectors  $u \neq 0$ ,
- (2) *positive semidefinite* if  $f(u) \geq 0$  for all vectors  $u \in V$ ,
- (3) *negative definite* if  $f(u) < 0$  for all vectors  $u \neq 0$ ,
- (4) *negative semidefinite* if  $f(u) \leq 0$  for all vectors  $u \in V$ ,
- (5) *indefinite* if  $f(u) > 0$  and  $f(v) < 0$  for two vectors  $u, v \in V$ .

The same names are used for symmetric matrices corresponding to quadratic forms. By the signature of a symmetric matrix is meant the signature of the corresponding quadratic form.

**4.C.9. Other characteristics and concepts of conic sections.** The axis of a conic section is a line of reflection symmetry for the conic section. From the canonical form of a conic section in polar basis (4.3.6) it can be shown that an ellipse and a hyperbola both have two axes ( $x = 0$  and  $y = 0$ ). A parabola has one axis ( $x = 0$ ). The intersection of a conic section and its axis is called a *conic section vertex*.

The numbers  $a, b$  from the canonical form of a conic section (which express the distance between vertices and the origin) are called the *length of semi-axes*. In the case of an ellipse and hyperbola, the axes intersect at the origin. This is a point of central symmetry for the conic section, called the *centre of the conic section*.

For practical problems involving conic sections, it is often easiest to describe them in parametric form. Often, this avoids contending with messy square roots.

Every point  $P$  on the parabola  $y^2 = 4ax$ ,  $a > 0$ , can be described by  $P = (x, y) = (at^2, 2at)$ , for real  $t$ . The standard parametric form for the parabola is the pair of equations

$$x = at^2 \quad y = 2at,$$

(Note that the roles of  $x$  and  $y$  are interchanged, so that the axis of symmetry is the line  $y = 0$ .) The tangent line at  $(at^2, 2at)$  has slope  $\frac{1}{t}$  and equation  $t(y - 2at) = (x - at^2)$ . The point  $F = (a, 0)$  on the axis is called the focus of the parabola, and the line  $x = -a$  is called the directrix. Each point on the parabola is equidistant from the focus and the directrix. This property can be used to define a parabola.

Every point  $P$  on the ellipse  $\frac{x^2}{a^2} + \frac{y^2}{b^2} = 1$  can be described by  $P = (x, y) = (a \cos \theta, b \sin \theta)$ , where  $0 < b \leq a$ . The standard parametric form for the ellipse is the pair of equations

$$x = a \cos \theta, \quad y = b \sin \theta.$$

The tangent line at  $P$  has slope  $-\frac{b \cos \theta}{a \sin \theta}$  and consequently has equation  $(a \cos \theta)(y - b \sin \theta) = -b \cos \theta(x - a \cos \theta)$ . The positive number  $e$ , defined by  $b^2 = a^2(1 - e^2)$  is called the eccentricity of the ellipse. If  $e = 0$ , the ellipse becomes a circle or radius  $a = b$ . Otherwise  $0 < e < 1$ . The two points  $F_1 = (ae, 0)$  and  $F_2 = (-ae, 0)$  are the foci of the ellipse, and the lines  $x = \pm a/e$  are the directrices.

Every point  $P$  on the hyperbola  $\frac{x^2}{a^2} - \frac{y^2}{b^2} = 1$ ,  $0 < a, 0 < b$ , can be described by  $P = (x, y) = (a \cosh \theta, b \sinh \theta)$ . The standard parametric form for the hyperbola is the pair of equations

$$x = a \cosh \theta, \quad y = b \sinh \theta.$$

The tangent line at  $P$  has slope  $\frac{b \cosh \theta}{a \sinh \theta}$  and consequently has equation  $(a \cosh \theta)(y - b \sinh \theta) = b \cosh \theta(x - a \cosh \theta)$ . The positive number  $e$ , defined by  $b^2 = a^2(e^2 - 1)$  is called the eccentricity of the hyperbola. Necessarily,  $e > 1$ . The two points  $F_1 = (ae, 0)$  and  $F_2 = (-ae, 0)$  are the foci of the ellipse, and the lines  $x = \pm a/e$  are the directrices. A hyperbola has two asymptotes. In standard form, the equations are  $y = \pm(b/a)x$ .

**4.3.3. Theorem.** A symmetric real matrix  $A$  is positive definite if and only if all its leading principal minors are positive.

A symmetric real matrix  $A$  is negative definite if and only if  $(-1)^i |A_i| > 0$  for all leading principal submatrices  $A_i$ .

**PROOF.** The claim about negative definite forms follows immediately from the first part of the theorem. Just observe that  $A$  is positive definite if and only if  $-A$  is negative definite.

Suppose that the form  $f$  is positive definite. Then  $A = P^T E P = P^T P$  for a suitable regular matrix  $P$ . Hence  $|A| = |P|^2 > 0$ . Let  $\underline{u}$  be a chosen basis in which the form  $f$  has matrix  $A$ . The restrictions of  $f$  to the subspaces  $V_k = \langle u_1, \dots, u_k \rangle$  are positive definite forms  $f_k$  again, and the corresponding matrices in the bases  $u_1, \dots, u_k$  are the leading principal submatrices  $A_k$ . Thus  $|A_k| > 0$ , too.

In order to prove the other implication, analyse in detail the form of the transformations used in completing the square in the Lagrange algorithm. The transformation used in the first step always has an upper triangular matrix  $T$ . By rescaling, see the proof of Theorem 4.3.1, the matrix may have ones on the diagonal:

$$T = \begin{pmatrix} 1 & -\frac{a_{12}}{a_{11}} & \dots & -\frac{a_{n2}}{a_{11}} \\ 0 & 1 & \dots & 0 \\ \vdots & & \ddots & \vdots \end{pmatrix}.$$

Such a matrix of the transformation from basis  $\underline{u}$  to basis  $\underline{v}$  has several useful properties. In particular, its leading principal submatrices  $T_k$  formed by the first  $k$  rows and columns are the transformation matrices of a subspace  $P_k = \langle u_1, \dots, u_k \rangle$  from basis  $(u_1, \dots, u_k)$  to basis  $(v_1, \dots, v_k)$ . The leading principal submatrices  $A_k$  of the matrix  $A$  of the form  $f$  are matrices of restrictions of the form  $f$  to  $P_k$ . Therefore, the matrices  $A_k$  and  $A'_k$  of restrictions to  $P_k$  in basis  $\underline{u}$  and  $\underline{v}$  respectively satisfy  $A_k = T_k^T A'_k T_k$ , where  $T$  is the transformation matrix from  $\underline{u}$  to  $\underline{v}$ . The inverse matrix to an upper triangular matrix with one's on the diagonal is again an upper triangular matrix with one's on the diagonal. Hence we may similarly express  $A'$  in terms of  $A$ . Thus the determinants of the matrices  $A_k$  and  $A'_k$  are equal by Cauchy formula. We may conclude:

**Claim.** Let  $f$  be a quadratic form on  $V$ ,  $\dim V = n$ . Let  $\underline{u}$  be a basis of  $V$  such that the items (3) and (4) from the Lagrange algorithm while finding the polar basis are not needed. Then the analytic formula

$$f(x_1, \dots, x_n) = \lambda_1 x_1^2 + \lambda_2 x_2^2 + \dots + \lambda_r x_r^2$$

is obtained where  $r$  is the rank of the form  $f$ ,  $\lambda_1, \dots, \lambda_r \neq 0$  and for the leading principal submatrices of the (former) matrix  $A$  of quadratic form  $f$ ,  $|A_k| = \lambda_1 \lambda_2 \dots \lambda_k$ ,  $k \leq r$ .

**4.C.10. Existence of foci.** For an ellipse with lengths of semi-axes  $a > b$ , show that the sum of the distances from any point on the ellipse to the two foci is constant, namely  $2a$ .

**Solution.** If  $P = (a \cos \theta, b \sin \theta)$  and  $F_1 = (ae, 0)$ , then

$$\begin{aligned} |PF_1|^2 &= (a \cos \theta - ae)^2 + b^2 \sin^2 \theta \\ &= a^2 \cos^2 \theta - 2a^2 e \cos \theta + a^2 e^2 + a^2(1 - e^2) \sin^2 \theta \\ &= a^2[-2e \cos \theta + e^2 - e^2(1 - \cos^2 \theta)] \\ &= a^2(1 - e \cos \theta)^2. \end{aligned}$$

So  $|PF_1| = a(1 - e \cos \theta)$ . Similarly  $|PF_2| = a(1 + e \cos \theta)$ . Hence  $|PF_1| + |PF_2| = 2a$ .  $\square$

**Solution.** (Alternative). Consider the points  $X = [x, y]$ , which satisfy the property  $|F_1X| + |F_2X| = 2a$ . Coordinate-wise, this implies the equation

$$\sqrt{(x + ae)^2 + y^2} + \sqrt{(x - ae)^2 + y^2} = 2a$$

Rewrite this as

$$\sqrt{(x + ae)^2 + y^2} = 2a - \sqrt{(x - ae)^2 + y^2}$$

Square, simplify and square again to get

$$(1 - e^2)x^2 + y^2 = a^2(1 - e^2).$$

Substitute  $b^2 = a^2(1 - e^2)$  and divide by  $b^2$  to obtain

$$\frac{x^2}{a^2} + \frac{y^2}{b^2} = 1.$$

which is the ellipse in standard form.  $\square$

**Remark.**

Similarly, the *hyperbola foci* are the points  $F_1, F_2$ , which satisfy  $||F_2X| - |F_1X|| = 2a$  for an arbitrary  $X$  on the hyperbola. You can check this in same the way as above for the ellipse, with  $F_1 = [ae, 0], F_2 = [-ae, 0], ae = \sqrt{a^2 + b^2}$ .

*Parabola focus* If the parabola has equation  $x^2 = 2py$ , the focus is the point  $F$  with coordinates  $F = [0, \frac{p}{2}]$ . It is characterized by the fact that the distance between this point and an arbitrary  $X$  on parabola is equal to the distance between  $X$  and line  $y = -\frac{p}{2}$ .

**4.C.11.** Find the foci of the ellipse  $x^2 + 2y^2 = 2$ .

**Solution.** From the equation that semi-axes lengths are  $a = \sqrt{2}$  and  $b = 1$ . Compute (see 4.C.10):  $ae = \sqrt{a^2 - b^2} = 1$  The foci coordinates are at  $[-1, 0]$  and  $[1, 0]$ .  $\square$

**4.C.12.** Prove that the product of the distances between the foci of an ellipse and any tangent line is constant. Find the value of the constant.

**Solution.** Every point  $T$  on the ellipse has coordinates  $T = (x, y)$  where  $x = a \cos \theta, y = b \sin \theta$  for some  $\theta$ . The tangent line to the ellipse at  $T$  has equation

$$\begin{aligned} y - b \sin \theta &= -\frac{b \cos \theta}{a \sin \theta}(x - a \cos \theta). \\ a(\sin \theta)(y - b \sin \theta) &= -b(\cos \theta)(x - a \cos \theta). \end{aligned}$$

After each step in this procedure, the resulting matrix contains zeros under the diagonal in the already processed columns. At the same time, all the principal minors remain the same.

Consequently if the leading principal minors are nonzero, then the next diagonal term in  $A$  is nonzero and we do not need other steps than completing the squares. Moreover,  $\lambda_i = |A_i|/|A_{i-1}|$ . This proves the following:

**Corollary (Jacobi theorem).** Let  $f$  be a quadratic form of rank  $r$  on a vector space  $V$  with matrix  $A$  for the basis  $\underline{u}$ . Steps other than completing the square are not required if and only if the leading principal submatrices of  $A$  satisfy  $|A_1| \neq 0, \dots, |A_r| \neq 0$ . Then there exists a polar basis in which  $f$  has the analytic formula

$$f(x_1, \dots, x_n) = |A_1|x_1^2 + \frac{|A_2|}{|A_1|}x_2^2 + \dots + \frac{|A_r|}{|A_{r-1}|}x_r^2.$$

Hence if all leading principal minors are positive, then  $f$  is positive definite by the Jacobi theorem and the Sylvester criterion is proved.  $\square$

**4.3.4. Euclidean classification of quadratic forms.** We come back to the discussion of equation 4.2.6(1) in the Euclidean context.

Begin with its quadratic part, i.e. bilinear symmetric form  $F : V \times V \rightarrow \mathbb{R}$ .

Assume now that the real vector space is equipped with a scalar product and choose an orthogonal basis. Then the matrix of the bilinear form  $F$ , which is the same as the matrix of  $f$ , transforms under a change of coordinates in such a way that for orthogonal changes it coincides with the transformation of a matrix of a linear map (i.e., then  $S^{-1} = S^T$ ). This result can be interpreted as the following observation:

**Proposition.** Let  $V$  be a real vector space with a scalar product. Then formula

$$\varphi \mapsto F, \quad F(u, u) = \langle \varphi(u), u \rangle$$

defines a bijection between symmetric linear maps and quadratic forms on  $V$ .

**PROOF.** Each bilinear form with a fixed second argument becomes a linear form  $F(\cdot, u)$ . In the presence of a scalar product, it is given by the formula  $F(v, u) = v \cdot w$  for a suitable vector  $w$ . Put  $\varphi(u) = w$ . Directly from the coordinate expression 4.3.1(1) displayed above,  $\varphi$  is the linear map with symmetric matrix  $A$ . Hence it is selfadjoint.

On the other hand, each symmetric map  $\varphi$  defines a symmetric bilinear form  $F$  by formula  $F(u, v) = \langle \varphi(u), v \rangle = \langle u, \varphi(v) \rangle$ , and thus is also a quadratic form.  $\square$

It is immediate that for each quadratic form  $f$  there exists an orthonormal basis in which  $f$  has a diagonal matrix. The values on the diagonal are the eigenvalues of the matrix and they are determined uniquely up to their order.

The rank of  $f$  equals the dimension of the image of the corresponding map  $\varphi$ .

This meets the  $x$ -axis at the point  $(a/\cos\theta, 0)$ . The distance from the focus  $F_1$  to the tangent line is  $D_1 = [a/\cos\theta - ae]\sin\varphi$  where  $\tan\varphi = \pm \frac{b\cos\theta}{a\sin\theta}$ . Eliminate  $\varphi$  to get

$$\begin{aligned} D_1^2 &= a^2(1 - e\cos\theta)^2 \left[ \frac{b^2}{a^2\sin^2\theta + b^2\cos^2\theta} \right] \\ &= (1 - e\cos\theta)^2 \left[ \frac{b^2}{\sin^2\theta + (1 - e^2)\cos^2\theta} \right] \\ &= (1 - e\cos\theta)^2 \left[ \frac{b^2}{1 - e^2\cos^2\theta} \right] \\ &= b^2(1 - e\cos\theta) \left[ \frac{1}{1 + e\cos\theta} \right] \end{aligned}$$

Since  $D_2$  is the same as  $D_1$  with  $e$  replaced by  $-e$ , it follows that  $D_1D_2 = b^2$ .  $\square$

**Solution.** (Alternative). Consider the polar basis. The ellipse matrix has diagonal shape  $\text{diag}(\frac{1}{a^2}, \frac{1}{b^2}, -1)$  and the tangent equation at  $X=[x_0, y_0]$  is  $\frac{x_0}{a^2}x + \frac{y_0}{b^2}y = 1$ . The distance between  $F_1, F_2 = [\mp ae, 0]$  and this line equals

$$\frac{1 \pm ae \frac{x_0}{a^2}}{\sqrt{\frac{x_0^2}{a^4} + \frac{y_0^2}{b^4}}}$$

Its product is

$$\frac{1 - e^2 \frac{x_0^2}{a^4}}{\frac{x_0^2}{a^4} + \frac{y_0^2}{b^4}}$$

If we substitute  $a^2e^2 = a^2 - b^2$  and  $\frac{y_0^2}{b^2} = 1 - \frac{x_0^2}{a^2}$  (the point  $X$  is lying on the ellipse), we find that the previous term equals  $b^2$ .  $\square$

**4.C.13. Projective approach to conic section.** Projective space gives an ability to approach the conic section from a new perspective (compare with 4.4.11). We can understand conic sections in  $\mathcal{E}_2$  defined by the quadratic form

$$f(x, y) = a_{11}x^2 + 2a_{12}xy + a_{22}y^2 + 2a_{13}x + 2a_{23}y + a_{33}$$

**4.3.5. Classification of quadrics.** We return to the equation 4.2.6(1). The above results enable us to rewrite this equation in suitable orthonormal frame of the difference space as

$$\sum_{i=1}^n \lambda_i x_i^2 + \sum_{i=1}^n b_i x_i + b = 0.$$

Hence we may assume that the quadric is given in this form.

In the next step, we “complete the square” for the coordinates  $x_i$  with  $\lambda_i \neq 0$ , which “absorbs” the squares together with the linear terms in the same variable. So only linear terms are left corresponding to variables for which the coefficient of the quadratic term is zero. We have

$$\sum_{i=1}^n \lambda_i (x_i - p_i)^2 + \sum_j b_j x_j + c = 0.$$

where the summation over  $j$  is only for  $j$  satisfying  $\lambda_j = 0$ .

This corresponds to a translation of the origin about the vector with coordinates  $p_i$ . To such a choice of basis of the difference space the desired diagonal form is in the quadratic part. In the identification of quadratic forms with linear maps derived above, this means that  $\varphi$  is diagonal on the orthogonal complement of its kernel. If there are also some linear terms left, the orthonormal basis of the difference space can be adjusted for the kernel of  $\varphi$  so that the corresponding linear form is a multiple of the first term of the dual basis. Hence the final formula reads

$$\sum_{i=1}^k \lambda_i y_i^2 + by_{k+1} + c = 0,$$

where  $k$  is the rank of matrix of quadratic form  $f$ . If  $b \neq 0$ , it can be arranged that the constant  $c$  in the equation is zero by a further change of the origin.

Hence the linear term may (but does not have to) appear only in the case that the rank of  $f$  is less than  $n$ , while  $c \in \mathbb{R}$  may be nonzero only if  $b = 0$ . The resulting equations are called the *canonical analytic formulas* for quadrics.

**4.3.6. The case of  $\mathcal{E}_2$ .** As an example of the previous procedure, we discuss the simplest case of a non-trivial dimension, namely dimension two. The original equation has the form

$$a_{11}x^2 + a_{22}y^2 + 2a_{12}xy + a_1x + a_2y + a = 0.$$

By a suitable choice of a basis of the difference space, and the subsequent completion of the square, it is written in the form (using the same notation  $x, y$  for the new coordinates):

$$a_{11}x^2 + a_{22}y^2 + a_1x + a_2y + a = 0$$

where  $a_i$  is nonzero only in the case that  $a_{ii}$  is zero. By the last step of the general procedure, exactly one of the following equations is involved (notice the equations of quadrics are determined up to a multiple):

$0 = x^2/a^2 + y^2/b^2 + 1$	empty set
$0 = x^2/a^2 + y^2/b^2 - 1$	ellipse
$0 = x^2/a^2 - y^2/b^2 - 1$	hyperbola
$0 = x^2/a^2 - 2py$	parabola
$0 = x^2/a^2 + y^2/b^2$	point
$0 = x^2/a^2 - y^2/b^2$	2 concurrent lines
$0 = x^2 - a^2$	2 parallel lines
$0 = x^2$	2 identical lines
$0 = x^2 + a^2$	empty set

as a set of points in projective plane  $\mathcal{P}^2$  with homogenous coordinates  $(x : y : z)$ , which are the zero points of the homogenous quadratic form

$$f(x, y, z) = a_{11}x^2 + 2a_{12}xy + a_{22}y^2 + 2a_{13}xz + 2a_{23}yz + a_{33}z^2.$$

Or rather  $f(v) = v^T Av$ , where  $v$  is a column vector with coordinates  $(x, y, z)$  and matrix  $A$  is symmetric matrix  $(a_{ij})$ . By theorem 4.3.2, there exists a basis in which this quadratic form has one of the following equations

$$f(x, y, z) = x^2 + y^2 + z^2, \quad f(x, y, z) = x^2 + y^2 - z^2.$$

In the former case there is only one solution of  $f(x, y, z) = 0$  and therefore the original form does not represent a real conic section. The second quadratic form represents a cone in  $\mathbb{R}^3$ . We obtain the corresponding conic section by moving back to inhomogeneous coordinates. That means intersecting the cone with the plane which has the equation  $z = 1$  in the original basis. Immediately we obtain the conic section classification from 4.29., which corresponds to the intersecting cone in  $\mathbb{R}^3$  with different planes. Non-degenerate sections are depicted. Degenerate sections are those which pass through the vertex of the cone.

We define the following useful terms for a conic section in projective plane :

Points  $P, Q \in \mathcal{P}^2$  corresponding to one-dimensional subspaces  $\langle p \rangle, \langle q \rangle$  (generated by vectors  $p, q \in \mathbb{R}^3$ ) are called *polar conjugated* with respect to conic section  $f$ , if  $F(p, q) = 0$ , or rather  $p^T Aq = 0$ .

Point  $P = \langle p \rangle$  is called *singular point* of conic section  $f$ , when it is polar conjugated with respect to  $f$  with all points of the plane, so  $F(p, x) = 0 \quad \forall x \in \mathcal{P}^2$ . In other words,  $Ap = 0$ . Hence the matrix  $A$  of the conic section does not have maximal rank and therefore defines a degenerate conic section. Non-degenerate conic sections do not contain singular points.

The set of all points  $X = \langle x \rangle$  are called polar conjugated with  $P = \langle p \rangle$  polar of the point  $P$  with respect to the conic section  $f$ . It is therefore the set of points for which  $F(p, x) = p^T Ax = 0$ . Because the polar is given by a linear combination of coordinates, it is always (in the non-singular case) a line. The following explains the geometric interpretation of polar.

**4.C.14. Polar characterization.** Consider a non-degenerate conic section  $f$ . The polar of a point  $P \in f$  with respect to  $f$  is the tangent to  $f$  with the touch point  $P$ . The polar of

The origin of the Cartesian coordinates is the *center* of the studied conic. The new orthonormal basis of the difference space gives the direction of *semiaxes*. The final coefficients  $a, b$  then give the lengths of the semiaxes in the non-degenerate directions.

#### 4. Projective geometry

In many elementary texts on analytic geometry, the authors finish with the affine and Euclidean objects described above. The affine and Euclidean geometries are sufficient for many practical problems, but not for all problems.

For instance in processing an image from a camera, angles are not preserved and parallel lines may (but do not have to) intersect.

Moreover, it is often difficult to distinguish very small angles from zero angles, and thus it would be convenient to have tools which do not need such distinguishing.

The basic idea of projective geometry is to extend affine spaces by points at infinity. This permits an easy way to deal with linear objects such as points, lines, planes, projections, etc.

**4.4.1. Projective extension of affine plane.** We begin with the simplest interesting case, namely geometry in a plane. If we imagine the points in the plane  $\mathcal{A}_2$  as the plane  $z = 1$  in  $\mathbb{R}^3$ , then each point  $P$  in the affine plane is represented by a vector  $u = (x, y, 1) \in \mathbb{R}^3$ . So it is represented also by a one-dimensional subspace  $\langle u \rangle \subset \mathbb{R}^3$ . On the other hand, almost every one-dimensional subspace in  $\mathbb{R}^3$  intersects the plane in exactly one point  $P$ . The vectors of such a subspace are given by coordinates  $(x, y, z)$  uniquely up to a common scalar multiple. Only the subspaces corresponding to vectors  $(x, y, 0)$  do not intersect the plane.

#### PROJECTIVE PLANE

**Definition.** The projective plane  $\mathcal{P}_2$  is the set of all one-dimensional subspaces in  $\mathbb{R}^3$ . The homogeneous coordinates of a point  $P = (x : y : z)$  in the projective plane are triples of real numbers given up to a common scalar multiple, at least one of which must be nonzero. A straight line in the projective plane is defined as a set of one-dimensional subspaces (i.e. points in  $\mathcal{P}_2$ ) which generate a two-dimensional subspace (i.e. a plane) in  $\mathbb{R}^3$ .

the point  $P \notin f$  is the line defined by the touch points of the tangents to  $f$  passing through  $P$ .

**Solution.** First consider  $P \in f$ . Suppose that the polar of  $P$ , defined by  $F(p, x) = 0$ , intersects  $f$  in  $Q = \langle q \rangle \neq P$ . Then  $F(p, q) = 0$  and  $f(q) = F(q, q) = 0$ . For an arbitrary point  $X = \langle x \rangle$  lying on  $P$  and  $Q$ ,  $x = \alpha p + \beta q$  for some  $\alpha, \beta \in \mathbb{R}$ . Because of the bilinearity and symmetry of  $F$ ,

$$f(x) = F(x, x) = \alpha^2 F(p, p) + 2\alpha\beta F(p, q) + \beta^2 F(q, q) = 0.$$

So every point  $X$  of the line lies on the conic section  $f$ . However, when the conic section contains a line, it has to be degenerate, which is a contradiction.

The claim for  $P \notin f$  follows from the corollary of the symmetry of the bilinear form  $F$ . When the  $Q$  lies on the polar of  $P$ , then  $P$  lies on the polar of  $Q$ .

□

Using polar conjugates we can find the axes and the centre of the conic sections without using the Lagrange algorithm.

Consider the conic section matrix as a block matrix

$$A = \begin{pmatrix} \bar{A} & a \\ a^T & \alpha \end{pmatrix},$$

where  $\bar{A} = (a_{ij})$  for  $i, j = 1, 2$ ,  $a$  is vector  $(a_{13}, a_{23})$  and  $\alpha = a_{33}$ . This means that the conic section is defined by the equation

$$u^T \bar{A} u + 2a^T u + \alpha = 0$$

for a vector  $u = (x, y)$ . Now we show that

**4.C.15.** The axes of a conic section are the polars of the points at infinity determined by the eigenvectors of the matrix  $\bar{A}$ .

**Solution.** Because of the symmetry of  $\bar{A}$  in the basis of its eigenvectors, it has a diagonal shape  $D = \begin{pmatrix} \lambda & 0 \\ 0 & \mu \end{pmatrix}$ , where  $\lambda, \mu \in \mathbb{R}$  and this basis is orthogonal. Denote by  $U$  the matrix changing basis to a basis of eigenvectors (columns), then the conic section matrix is

$$\begin{pmatrix} U^T & 0 \\ 0 & 1 \end{pmatrix} \begin{pmatrix} \bar{A} & a \\ a^T & \alpha \end{pmatrix} \begin{pmatrix} U & 0 \\ 0 & 1 \end{pmatrix} = \begin{pmatrix} D & U^T a \\ a^T U & \alpha \end{pmatrix}$$

For a concrete example, consider two parallel lines in the affine plane  $\mathbb{R}^2$

$$L_1 : y - x - 1 = 0, \quad L_2 : y - x + 1 = 0.$$

If the points of lines  $L_1$  and  $L_2$  are finite points in projective space  $\mathcal{P}_2$ , then their homogeneous coordinates  $(x : y : z)$  satisfy equations

$$L_1 : y - x - z = 0, \quad L_2 : y - x + z = 0.$$

the intersection  $L_1 \cap L_2$  is the point  $(1 : 1 : 0) \in \mathcal{P}_2$  in this context. It is the point at infinity corresponding to the common direction vector of the lines.

**4.4.2. Affine coordinates in the projective plane.** If we begin with the projective plane and if we want to see the affine plane as its “finite” part, then instead of the plane  $z = 1$  we may take another plane  $\sigma$  in  $\mathbb{R}^3$  which does not pass through the origin  $0 \in \mathbb{R}^3$ . Then the finite points are those one-dimensional subspaces which have a nonempty intersection with the plane  $\sigma$ .

Consider the two parallel lines from the previous paragraph. Let us choose the plane  $y = 1$  to obtain two lines in the affine plane

$$L'_1 : 1 - x - z = 0, \quad L'_2 : 1 - x + z = 0$$

The “infinite” points of the former affine plane are given by  $z = 0$ . The lines  $L'_1$  and  $L'_2$  intersect at the “finite” point  $(x, z) = (1, 0)$ . This corresponds to the geometric concept that two parallel lines  $L_1, L_2$  in the affine plane meet at infinity, at the point  $(1 : 1 : 0)$ , but this point becomes finite in different finite affine plane.

**4.4.3. Projective spaces.** We shall not go for an axiomatic definition of projective spaces here. We generalize the procedure in the affine plane for each finite dimension instead.

By choosing an arbitrary affine hyperplane  $\mathcal{A}_n$  in the vector space  $\mathbb{R}^{n+1}$  which does not pass through origin, we may identify the points  $P \in \mathcal{A}_n$  with one-dimensional subspaces generated by these points. The remaining one-dimensional subspaces determine a hyperplane parallel to  $\mathcal{A}_n$ . They are called *infinite points* in the projective extension  $\mathcal{P}_n$  of the affine plane  $\mathcal{A}_n$ .

The set of infinite points in  $\mathcal{P}_n$  is always a projective space of dimension one less. An affine straight line has only one infinite point in its projective extension (both ends of the line “intersect” at infinity and thus the projective line looks like a circle). The projective plane has a projective line of infinite points, the three-dimensional projective space has a projective plane of infinite points etc.

More generally, we can define the *projectivization of a vector space*. For an arbitrary vector space  $V$  of dimension  $n + 1$ , we define

$$\mathcal{P}(V) = \{P \subset V; P \subset V, \dim V = 1\}.$$

So in this basis there is the canonical form defined by vector  $U^T a$  (up to a translation). Specifically, denote the eigenvectors by  $v_\lambda, v_\mu$ , and then

$$\lambda(x + \frac{a^T v_\lambda}{\lambda})^2 + \mu(y + \frac{a^T v_\mu}{\mu})^2 = \frac{(a^T v_\lambda)^2}{\lambda} + \frac{(a^T v_\mu)^2}{\mu} - \alpha.$$

This means that the eigenvectors are the direction vectors of the conic section axes (main directions). The axes equations in this basis are  $x = -\frac{a^T v_\lambda}{\lambda}$  and  $y = -\frac{a^T v_\mu}{\mu}$ . The axes coordinates  $u_\lambda$  and  $u_\mu$  in the standard basis satisfy  $v_\lambda^T u_\lambda = -\frac{a^T v_\lambda}{\lambda}$  and  $v_\mu^T u_\mu = -\frac{a^T v_\mu}{\mu}$ , because  $v_\lambda^T(\lambda u_\lambda + a) = 0$  and  $v_\mu^T(\mu u_\mu + a) = 0$ . These equations are equivalent to the equations  $v_\lambda^T(\bar{A}u_\lambda + a) = 0$  and  $v_\mu^T(\bar{A}u_\mu + a) = 0$  which are the polar equations of the points defined by the vectors  $v_\lambda$  a  $v_\mu$ .  $\square$

**4.C.16. Remark.** A corollary of the previous claim is that the centre of the conic section is polar conjugated with all points at infinity. The coordinates of the centre  $s$  then satisfy the equation  $\bar{A}s + a = 0$ .

If  $\det(A) \neq 0$ , then the equation  $\bar{A}s + a = 0$  for centre coordinates has exactly one solution if  $\delta = \det(\bar{A}) \neq 0$ , and no solutions if  $\delta = 0$ . That means that, regarding non-degenerate conic sections, the ellipse and the hyperbola have exactly one centre. The parabola has no centre. (its centre is point at infinity).

**4.C.17.** Prove that the angle between the tangent to the parabola (with arbitrary touch point) and the parabola axis is the same as the angle between the tangent and the line connecting the focus and the point of tangency

**Solution.** The polar (i.e. tangent) of a point  $X=[x_0, y_0]$  to a parabola defined by the canonical equation in the polar basis is a line satisfying

$$(x_0, y_0, 1) \begin{pmatrix} 1 & 0 & 0 \\ 0 & 0 & -p \\ 0 & -p & 0 \end{pmatrix} \begin{pmatrix} x \\ y \\ 1 \end{pmatrix} = x_0x - py - py_0 = 0$$

The cosine of the angle between the tangent and the axis of the parabola ( $x = 0$ ) is given by the dot product of the corresponding unit direction vectors. The unit direction vector of the tangent is  $\frac{1}{\sqrt{p^2+x_0^2}}(p, x_0)$  and therefore

$$\frac{1}{\sqrt{p^2+x_0^2}}(p, x_0) \cdot (0, 1) = \frac{x_0}{\sqrt{p^2+x_0^2}}$$

Now we show that this is the same as the cosine of the angle between the tangent and line connecting the focus  $F=[0, \frac{p}{2}]$ , and the touch point  $X$ . The unit direction vector of the connecting line is

$$\frac{1}{\sqrt{x_0^2 + (y_0 - \frac{p}{2})^2}}(x_0, y_0 - \frac{p}{2}).$$

For the cosine of the angle,

$$\frac{1}{\sqrt{p^2+x_0^2}} \frac{1}{\sqrt{x_0^2 + (y_0 - \frac{p}{2})^2}}(x_0y_0 + \frac{px_0}{2})$$

By choosing a basis  $\underline{u}$  in  $V$  we obtain *homogeneous coordinates* on  $\mathcal{P}(V)$ . For a  $P \in \mathcal{P}(V)$  we use the nonzero vector  $u \in V$  and the coordinates of this vector in a basis  $\underline{u}$ . The points of the projective space  $\mathcal{P}(V)$  are called *geometric points*. Their generators in  $V$  are called *arithmetic representatives*.

In the chosen homogeneous coordinates, we fix one of them to be one. Thus we exclude all points of the projective space  $\mathcal{P}(V)$  which have this coordinate equal to zero. We have an embedding of  $n$ -dimensional affine space  $\mathcal{A}_n \subset \mathcal{P}(V)$ . This is precisely the construction used in the example on the projective plane.

**4.4.4. Perspective projection.** Our basic “projective” concepts are now (projective) points, lines, planes, etc., together with their incidencies (i.e. point in a line, line in a plane, etc.). Thus the morphisms of the projective geometry must respect these.

The best known example is given by perspective projections  $\mathbb{R}^3 \rightarrow \mathbb{R}^2$ . Imagine that an observer sitting in the origin observes “one half of the world”, that is, the points  $(X, Y, Z) \in \mathbb{R}^3$  with  $Z > 0$ . The observer sees the image “projected” on the screen given by plane  $Z = f > 0$ .

picture missing!

Thus a point  $(X, Y, Z)$  in the “real world” projects to a point  $(x, y)$  on the screen as follows:

$$x = -f \frac{X}{Z}, \quad y = -f \frac{Y}{Z}.$$

This is a nonlinear formula. The accuracy of calculations are problematic when  $Z$  is small.

By extending this transformation to a map between projective spaces, we have  $(X : Y : Z : W) \mapsto (x : y : z) = (-fX : -fY : Z)$ , which is well defined for all  $Z > 0$ . That is, a map described by a simple linear formula

$$\begin{pmatrix} x \\ y \\ z \end{pmatrix} = \begin{pmatrix} f & 0 & 0 & 0 \\ 0 & f & 0 & 0 \\ 0 & 0 & 1 & 0 \end{pmatrix} \cdot \begin{pmatrix} X \\ Y \\ Z \\ W \end{pmatrix}$$

This simple expression defines the perspective projection for finite points in the open half-space in  $\mathbb{R}^3 \subset \mathcal{P}_3$  which we

Substitute  $y_0 = \frac{x_0^2}{2p}$  to obtain  $\frac{x_0}{\sqrt{p^2+x_0^2}}$ .

This example shows that lightrays striking parallel with axis of parabolic mirror are reflecting to the focus and, vice versa, light rays going through focus reflect in direction parallel with axis of parabola. This is the principle of many devices such as parabolic reflectors.  $\square$

**Solution.** (Alternative) At the point  $P = (at^2, 2at)$  on the parabola, the tangent line has slope  $(1/t)$  and the focus is at  $(a, 0)$ . So the line joining  $P$  to the focus  $F$  has slope  $\frac{2at-0}{at^2-a} = \frac{2t}{t^2-1}$ . If  $\theta$  is the angle between the tangent line and the  $x$ -axis, then  $\tan \theta = 1/t$ , so

$$\tan 2\theta = \frac{2 \tan \theta}{1 - \tan^2 \theta} = \frac{2/t}{(1 - 1/t^2)} = \frac{2t}{t^2 - 1}$$

By subtraction, the angle between the tangent line and the line joining  $P$  to the focus is  $\theta$ .

Note that the tangent line meets the  $x$ -axis at  $Q$  where  $Q = (-at^2, 0)$ . The result follows from showing that  $|FP| = |FQ|$ , and hence the triangle  $QFP$  is isosceles.  $\square$

You can find many more examples on quadrics on 4.D.1

substitute as points with  $W = 1$ . In this way we eliminate problems with points whose image runs to infinity. Indeed, if the  $Z$ -coordinate of a real point is close to zero, then the value of the third homogeneous coordinate of the image is close to zero, i.e. it corresponds to a point close to infinity.

**4.4.5. Affine and projective transformations.** Each in-

jective linear map  $\varphi : V_1 \rightarrow V_2$  between vector spaces maps one-dimensional subspaces to one-dimensional subspaces. Therefore, we have a map on projectivizations  $T : \mathcal{P}(V_1) \rightarrow \mathcal{P}(V_2)$ . We shall call such maps *projective maps* or *homographies*. A slightly more general concept posits the property that a map  $C : \mathcal{P}(V_1) \rightarrow \mathcal{P}(V_2)$  is bijective and maps projective lines to projective lines. They are called *collineations*. Of course, every invertible homography is a collineation.<sup>1</sup>

Otherwise put, the projective map is a map between projective spaces such that in each system of homogeneous coordinates on the domain and image, it is given by the multiplication by a matrix. More generally if the auxiliary linear map is not injective, then we need to define the projective map only outside of its kernel, that is, on points whose homogeneous coordinates do not map to zero. This is, what we saw in the previous paragraph when discussing the perspective projections.

In general, each collineation does not have to be a homography. For example, if we work with complex vector spaces, then we may use the field homomorphism  $z \mapsto \bar{z}$ , i.e. the conjugation, to define the map  $F : (z_0 : \cdots : z_n) \mapsto (\bar{z}_0 : \cdots : \bar{z}_n)$  in any fixed homogeneous coordinates. Clearly this is bijective and since the colinearity is computed by subdeterminants (and the determinants are equivariant with respect to each field homomorphism) the colinearity is preserved. Thus,  $F$  is a collineation which does not come from a linear automorphism of the vector space  $\mathbb{C}^{n+1}$ . Fortunately, there is the so called *fundamental theorem of projective geometry* saying that in dimensions at least two, each collineation is composed of a homography and an collineation coming from a field homomorphism in the above way. Of course, in dimension one, every bijection is a collineation and this concept does not make much sense there.

Notice, there are no nontrivial field homomorphisms on the real scalars  $\mathbb{R}$  and thus the two concepts coincide for our real projective spaces in dimensions at least two.

Since injective maps  $V \rightarrow V$  of a vector space to itself are invertible, all projective maps of projective space  $\mathcal{P}_n$  to itself are invertible. They are also called *regular collineations* or *projective transformations*. In homogeneous coordinates, they correspond to invertible matrices of dimension  $n + 1$ . Two such matrices define the same projective transformation if and only if one is a (nonzero) multiple of the other.

<sup>1</sup>Since projective geometry is an old and rich mathematical discipline with very abstract current versions, there is a lot of terminology and different names for similar or same objects involved.

If we choose the first coordinate as the one whose vanishing defines infinite points, then the transformations preserving infinite points are given by matrices whose first row vanishes up to its first element. If we wish to switch to affine coordinates of finite points, (i.e the first coordinate is fixed at one), the first element in the first row also equals one. Hence the matrices of collineations preserving finite points of the affine space have the form:

$$\begin{pmatrix} 1 & 0 & \cdots & 0 \\ b_1 & a_{11} & \cdots & a_{1n} \\ \vdots & & \ddots & \\ b_n & a_{n1} & \cdots & a_{nn} \end{pmatrix}$$

where  $b = (b_1, \dots, b_n)^T \in \mathbb{R}^n$  and  $A = (a_{ij})$  is an invertible matrix of dimension  $n$ . The action of such a matrix on the vector  $(1, x_1, \dots, x_n)$  is exactly a general affine transformation, where  $b$  is the translation and  $A$  is its linear part. Thus the affine maps are exactly those collineations which preserve the hyperplane of points at infinity.

**4.4.6. Determining collineations.** In order to define an affine map, it is necessary and sufficient to define an image of the affine frame. In the above description of affine transformations as special cases of projective maps, this corresponds to a suitable choice of an image of a suitable arithmetic basis of the vector space  $V$ .

In general it is not true that the image of an arithmetic basis of  $V$  determines the collineation uniquely. The basic problem is illustrated by a simple example of affine plane.

Choose four points  $A, B, C, D$  in the plane such that no three of them lie on a line. Then choose their images in the collineation as follows:

Choose arbitrarily their four images  $A', B', C', D'$  with the same property, and choose their homogeneous coordinates  $u, v, w, z, u', v', w', z'$  in  $\mathbb{R}^3$ . The vectors  $z$  and  $z'$  can be written as linear combinations

$$z = c_1u + c_2v + c_3w, \quad z' = c'_1u' + c'_2v' + c'_3w',$$

where all six coefficients must be nonzero, otherwise there exist three points not in general position.

Now choose new arithmetic representatives  $\tilde{u} = c_1u$ ,  $\tilde{v} = c_2v$  and  $\tilde{w} = c_3w$  of points  $A, B$  and  $C$  respectively. Similarly  $\tilde{u}' = c_1u'$ ,  $\tilde{v}' = c_2v'$  and  $\tilde{w}' = c_3w'$  for points  $A', B'$  and  $C'$ . This choice defines an unique linear map  $\varphi$  which maps successively

$$\varphi(\tilde{u}) = \tilde{u}', \quad \varphi(\tilde{v}) = \tilde{v}', \quad \varphi(\tilde{w}) = \tilde{w}'.$$

But then,

$$\varphi(z) = \varphi(\tilde{u} + \tilde{v} + \tilde{w}) = \tilde{u}' + \tilde{v}' + \tilde{w}' = z',$$

and so the constructed collineation maps the points which we have chosen in advance. The linear map  $\varphi$  is given uniquely by the construction, thus the collineation is given uniquely by this choice.

The argument holds also in the case when some of the chosen points are infinite (i.e. one or two). The same phenomenon can be explained even more easily by the regular collineation of a projective line. These are defined by pairwise different images of three pairwise different points.

The procedure works in an arbitrary dimension  $n$ . Then we say that  $n + 2$  points are in *general position* if no  $n + 1$  of them lie in the same hyperplane. We also call these points linearly independent, forming a *geometric basis* of projective space.

**Theorem.** *A regular collineation on  $n$ -dimensional projective space is uniquely determined by linearly independent images of  $n + 2$  linearly independent points.*

**PROOF.** The proof is exactly the same as in dimension two. We recommend writing it in detail as an exercise.  $\square$

**4.4.7. Cross-ratio.** Recall that affine maps preserve ratios of lengths of line segments on each line. Technically, we defined this ratio as for three points  $A, B$  and  $C \neq B, C = rA + sB$  as  $\lambda = (C; A, B) = -\frac{s}{r}$ .

For central projection the ratios are not preserved. Moreover, even the relative position of points on a line is not necessarily preserved. On the contrary we may determine uniquely a projective transformation by choosing arbitrarily images of three pairwise different points on a projective line. However, one can show relatively easily that the ratio of such ratios for two distinct points  $C$  is preserved:

Consider four distinct points  $A, B, C, D$  in projective space with arithmetic coordinates  $x, y, w, z$  respectively which lie on a projective line. Since these four vectors lie in the subspace generated by  $\langle x, y \rangle$ , we may write  $w$  and  $z$  as linear combinations

$$w = t_1x + s_1y, \quad z = t_2x + s_2y.$$

Define the *cross-ratio of four points*  $(A, B, C, D)$  as

$$\rho = \frac{s_1 t_2}{t_1 s_2}.$$

The definition is valid, since although the vectors  $x$  and  $y$  are determined up to a scalar multiple, these freedom is cancelled out in the definition.

Each projective transformation preserves cross-ratios: Indeed, if the transformation is given in arithmetic coordinates by a matrix  $A$ , we have images  $A \cdot w = t_1 A \cdot x + s_1 A \cdot y$ , and similarly for  $Az$ . Therefore the four images have the same cross-ratio.

We discuss the characterization of projective transformations. These are exactly those maps which preserve cross-ratios. But this is not a very practical characterization, since it contains implicitly the claim that these maps map projective lines to projective lines.

We shall not go into details here, but one can prove a much stronger statement. A map of arbitrarily small open area in affine space  $\mathbb{R}^n$  (e.g. a ball without boundary) into

the same affine space which maps lines to lines is actually a restriction of a uniquely determined globally defined collineation of the projective extension  $\mathcal{P}\mathbb{R}^{n+1}$  of the former affine space  $\mathbb{R}^n$ . As we heard above, all collineations of real projective space of finite dimensions at least two are projective transformations in our sense and thus these transformations also preserve cross-ratios.

**4.4.8. Duality.** Projective hyperplanes in an  $n$ -dimensional projective space  $\mathcal{P}(V)$  are defined as the projectivizations of  $n$ -dimensional vector subspaces in the vector space  $V$ . Hence in homogeneous coordinates, they are defined as kernels of linear forms  $\alpha \in V^*$  which in turn are determined up to a scalar multiple.

Thus in a chosen arithmetic basis, a projective hyperplane is given by a row vector  $\alpha = (\alpha_0, \dots, \alpha_n)$ . But the forms  $\alpha$  are given uniquely up to a scalar multiple. Therefore, each hyperplane in  $V$  is identified with exactly one geometric point in the projectivization of the dual space  $\mathcal{P}(V^*)$ . We call such a space the *dual projective space*, and we talk about a duality between points and hyperplanes.

On forms, the linear map defining a given collineation acts by the multiplication of row vectors from the right by the same matrix

$$\alpha = (\alpha_0, \dots, \alpha_n) \mapsto \alpha \cdot A.$$

Viewing the coordinates  $\alpha_i$  as columns, this corresponds to the action of the dual map with the matrix  $A^T$ . But the dual map maps forms in the opposite direction, from the “target space” to the “initial one”. Therefore the inverse map for the collineation of  $f$  is required in order to study the effect of regular collineations on points and their dual hyperplanes. The inverse is given by the matrix  $A^{-1}$ . Hence the matrix for the action of the corresponding collineation on forms is  $(A^T)^{-1}$ . Since the inverse matrix equals the algebraically adjoint matrix  $A_{\text{alg}}^*$ , up to the multiplication by the inverse of determinant, (see equation (1) on page 106) we can work directly with the projective transformation of the space  $\mathcal{P}(V^*)$  given by the matrix  $(A_{\text{alg}}^*)^T$  (or without transposing if we multiply row vectors from the right).

The projective point  $X$  belongs to the hyperplane  $\alpha$  if the arithmetic coordinates satisfy  $\alpha \cdot x = 0$ . It still holds after acting with an arbitrary collineation, since

$$(\alpha \cdot A^{-1}) \cdot (A \cdot x) = \alpha \cdot x = 0.$$

**4.4.9. Fixed points, centers and axes.** Consider a regular collineation  $f$  given in an arithmetic basis of projective space  $\mathcal{P}(V)$  by a matrix  $A$ .

By the *fixed point* of the collineation  $f$ , we mean a point  $P$  which is mapped to itself. That is,  $f(P) = P$ . By the *fixed hyperplane* of collineation  $f$  is meant a hyperplane  $\alpha$  which is mapped to itself. That is,  $f(\alpha) \subset \alpha$ .

Hence the arithmetic representatives of fixed points are exactly the eigenvectors of the matrix  $A$ .

In the geometry of the plane, we meet many types of collineations: reflection through a point, reflection across a line, translation, homothety etc. Perhaps we remember also some types of projections, e.g. the projection of a plane in  $\mathbb{R}^3$  to another from a center  $S \in \mathbb{R}^3$ .

Note also that there appear fixed lines next to fixed points in all cases of such affine maps. For example, the reflection through a point preserves also all lines passing through this point. In the case of a translation the infinite points behave similarly.

Now we discuss this phenomenon in an arbitrary dimension. First, we define a classical notion related to the incidence of points and hyperplanes.

A set of hyperplanes passing through a point  $P \in \mathcal{P}(V)$  is a set of all hyperplanes which contain the point  $P$ . For each point  $P$  the corresponding set of hyperplanes itself is a hyperplane in the dual space  $\mathcal{P}(V^*)$ . It is given by one homogeneous linear equation in arithmetic coordinates.

For a collineation  $f : \mathcal{P}(V) \rightarrow \mathcal{P}(V)$ , a point  $S \in \mathcal{P}(V)$ , is called the *center of collineation*  $f$ , if all hyperplanes in the set determined by  $S$  are fixed hyperplanes. A hyperplane  $\alpha$  is called the *axis of collineation*  $f$  if all its points are fixed points.

It follows that the axis of a collineation is the center of the dual collineation, while the set of hyperplanes defining the center of collineation is the axis of the dual collineation.

Since the matrices of a collineation on the former and the dual space differ only by the transposition, their eigenvalues coincide (the eigenvectors are column vectors, respectively row vectors corresponding to the same eigenvalues). For example in the projective plane (and for the same reason in each real projective space of even dimension) each collineation has at least one fixed point, since the characteristic polynomials of corresponding linear maps are of odd degree. Hence they have at least one real root.

Instead of discussing a general theory, we illustrate its usefulness in several results for projective planes.

**Proposition.** *A projective transformation of the projective plane other than the identity has either exactly one center and exactly one axis, or it has neither a center nor an axis.*

**PROOF.** Consider a collineation  $f$  on  $\mathcal{P}\mathbb{R}^3$  and assume that it has two distinct centers  $A$  and  $B$ . Denote by  $\ell$  the line given by these two centers, and choose a point  $X$  in the projective plane outside of  $\ell$ . If  $p$  and  $q$  are the lines passing through pairs of points  $(A, X)$  respectively  $(B, X)$ , then  $f(p) = p$  and  $f(q) = q$ . In particular,  $X$  is fixed. But then all points of the plane outside of  $\ell$  are fixed. Hence each line different from  $\ell$  has all points out of  $\ell$  fixed and thus also its intersection with  $\ell$  is fixed. It follows that  $f$  is the identity mapping. So it is proved that every projective transformation other than the identity has at most one center. The same argument for the dual projective plane proves that there is at most one axis.

If  $f$  has a center  $A$ , then all lines passing through  $A$  are fixed. They correspond therefore to a two-dimensional subspace of a row eigenvectors of the matrix corresponding to the transformation  $f$ . Therefore, there exists a two-dimensional subspace of column eigenvectors for the same eigenvalue. This represents exactly the line of fixed points, hence it represents the axis. The same consideration in the reversed order proves the opposite statement – if a projective transformation of plane has an axis, then it has also a center.  $\square$

picture missing!

For practical problems it is useful to work with complex projective extensions also in the case of a real plane. Then the geometric behaviour can be easily read off the potential existence of real or imaginary centers and axes.

**4.4.10. Pappus Theorem.** The following result known as Pappus theorem is a classic result of projective geometry.

**Proposition.** *Let two triples of distinct consecutive collinear points  $\{A, B, C\}$  and  $\{A', B', C'\}$  lie on two lines that meet at the point  $T$ , which is closest to  $A$  and  $A'$ , respectively. Define points  $Q, R$  and  $S$  as*

$$Q = [AB'] \cap [BA'], \quad R = [AC'] \cap [CA'], \quad S = [BC'] \cap [CB'].$$

*Then  $\{Q, R, S\}$  are also collinear.*

picture missing!

PROOF. Without loss of generality, consider the plane, passing through  $\{T, A, B, C, A', B', C'\}$  as a 2-dimensional plane in  $\mathcal{P}^2$  defined by  $z = 1$  in the homogeneous coordinates  $(x : y : z)$ .

The points  $\{T, A, B, C, A', B', C'\}$  may be considered as objects in  $\mathcal{P}^2$ , representing lines through the origin in  $\mathbb{R}^3$  with directional vectors  $\{t, a, b, c, a', b', c'\}$ , respectively. These can be chosen up to a real non-zero factor. The condition  $\{z = 1\}$  uniquely identifies those points in  $\mathbb{R}^3$  regardless of the choice of  $\{t, a, b, c, a', b', c'\}$ . Since  $\{T, A, B, C\}$  are collinear points, (they lie in the same 2-dimensional linear subspace of  $\mathbb{R}^3$ ), we may assume that this plane is generated by  $t$  and  $a$ . Choose

$$b = t + a, \quad c = \lambda t + a,$$

and analogously, for  $\{T, A', B', C'\}$

$$b' = t + a', \quad c' = \lambda' t + a'$$

for some real constants  $\lambda$  and  $\lambda'$ . It is only necessary to show that the vectors  $q, r, s$ , representing  $Q, R, S$  in  $\mathcal{P}^2$  generate a 2-dimensional subspace in  $\mathbb{R}^3$ .

Since

$$(t + a) + a' = a + (t + a'),$$

$q = t + a + a'$  represents  $Q$ . Since

$$\lambda\lambda't + \lambda'a + \lambda a' = \lambda(\lambda't + a') + \lambda'a = \lambda'(\lambda t + a) + \lambda a',$$

$r = \lambda\lambda't + \lambda'a + \lambda a'$  represents  $R$ . Finally,

$$\begin{aligned} s &= q - r = t + a + a' - \lambda\lambda't - \lambda'a - \lambda a' \\ &= (1 - \lambda')(t + a) + (1 - \lambda)(\lambda't + a') \\ &= (1 - \lambda)(t + a') + (1 - \lambda')(\lambda t + a) \end{aligned}$$

represents the point  $S$ . Thus, the points  $\{Q, R, S\}$  lie in the 2-dimensional subspace generated by vectors  $q$  and  $r$ . Since  $Q, R, S$  also belong to the plane  $\{z = 1\}$ , these points are collinear.  $\square$

#### 4.4.11. Projective classification of quadrics.

To end this section, we return to conics and quadrics. A quadric  $Q$  in  $n$ -dimensional affine space  $\mathbb{R}^n$  is defined by a general quadratic equation 4.2.6(1) on the page 342. By viewing the affine space  $\mathbb{R}^n$  as affine coordinates in projective space  $\mathcal{P}\mathbb{R}^{n+1}$  we may wish to describe the set  $Q$  by homogeneous coordinates in projective space. The formula in these coordinates should contain only the terms of second order since only a homogeneous formula is independent of the choice of the multiple of homogeneous coordinates  $(x_0, x_1, \dots, x_n)$  of a point. Hence we search for a homogeneous formula whose restriction to affine coordinates, (that is, substitution  $x_0 = 1$ ), gives the original formula 4.2.6(1).

But this is especially easy. Simply add the right number of  $x_0$  to all terms – nothing to the quadratic terms, one to the linear terms and  $x_0^2$  to the constant term in the original affine equation for  $Q$ . We obtain a well defined quadratic form  $f = \sum_{i,j=0}^n a_{ij}x_i x_j$  on the vector space  $\mathbb{R}^{n+1}$  whose zero set defines correctly the *projective quadric*  $\bar{Q}$ .

The intersection of a “cone”  $\bar{Q} \subset \mathbb{R}^{n+1}$  of the zero set of this form with the affine plane  $x_0 = 1$  is the original quadric  $Q$  whose points are called the proper points of the quadric. The other points  $\bar{Q} \setminus Q$  in the projective extension are the infinite points.

The classification of real or complex projective quadrics, up to projective transformations, is a problem already considered. It is all about finding the canonical polar basis, see paragraph 4.3.2. From this classification, given by the signature of the form in the real case and by the rank only in the complex case, we can deduce also the classification of the affine quadrics. We show the essential part of the procedure in the case of conics in the affine and the projective plane.

The projective classification gives the following possibilities, described by homogeneous coordinates  $(x : y : z)$  in the projective plane  $\mathcal{P}\mathbb{R}^3$ :

- imaginary regular conic given by  $x^2 + y^2 + z^2 = 0$
- real regular conic given by  $x^2 + y^2 - z^2 = 0$
- pair of imaginary lines given by  $x^2 + y^2 = 0$
- pair of real lines given by  $x^2 - y^2 = 0$
- one double line  $x^2 = 0$ .

We consider this classification as real, that is, the classification of quadratic forms is given not only by its rank but also by its signature. Nevertheless, the points of a quadric are considered also in the complex extension. In this way we should understand the stated names. For example the imaginary conic does not have any real points.

**4.4.12. Affine classification of quadrics.** For an affine classification we must restrict the projective transformations to those which preserve the projective subspace of infinite points. This can be seen also by the converse procedure — for a fixed projective type of conic  $Q$ , that is, its cone  $\tilde{Q} \subset \mathbb{R}^3$ , we choose different affine planes  $\alpha \subset \mathbb{R}^3$  which do not pass through the origin. We observe the changes to the set of points  $\tilde{Q} \cap \alpha$ , which are proper points of  $Q$  in affine coordinates, as realized by the plane  $\alpha$ .

Hence in the case of a regular conic there is a real cone  $\tilde{Q}$  given by the equation  $z^2 = x^2 + y^2$ . As planes  $\alpha$  we may for instance choose the tangent planes to the unit sphere. If we begin with the plane  $z = 1$ , the intersection consists only of finite points forming a unit circle  $Q$ . By a gradual change of the slope of  $\alpha$  we obtain a more and more stretched ellipse until we get such a slope that  $\alpha$  is parallel with one of lines of the cone. At that moment there appears one (double) infinite point of the conic whose finite points still form one connected component, and so we have a parabola. Continuing to change the slope gives rise to two infinite points. The set of finite points is no longer connected, and so we obtain the last regular quadric in the affine classification, a hyperbola.

We can take advice from the introduced method which enables us to continue the classification in higher dimensions. In particular, we notice that the intersection of the conic with the projective line of infinite points is always a quadric in dimension one less. It is either the empty set or a double point

or two points as types of quadrics on a projective line. Next we found an affine transformation transforming one of possible realizations of a fixed projective type to another one, only if the corresponding quadrics in the subspace of infinite points were projectively equivalent. In this way, it is possible to continue the classification of quadrics in dimension three and above.

**D. Further exercise on this chapter**

**4.D.1.** [TO BE MOVED TO AN APPROPRIATE SPOT IN CHAPTER 8 OR 9] Show that all twice differentiable mappings  $F : \mathbb{R}^n \rightarrow \mathbb{R}^n$  which preserve distances are affine mappings, and thus Euclidean (also the so called rigid motions).

**Solution.** Suppose  $F : \mathbb{R}^n \rightarrow \mathbb{R}^n$  keeps distances, i.e.,  $\|F(x + tv) - F(x)\| = \|tv\|$ , where  $t \in \mathbb{R}$ ,  $v \in \mathbb{R}^n$ . Then the Taylor expansion says

$$t\|v\| = \|F(x+tv) - F(x)\| = \|DF(x)(tv) + \frac{1}{2}D^2F(x+s_tv)(tv, tv)\| = t\|DF(x)(v) + \frac{t}{2}D^2F(x+s_tv)(v, v)\|,$$

where  $0 \leq s_t \leq t$ . Now, the limit for  $t \rightarrow 0$  leads to  $\|v\| = \|DF(x)(v)\|$ , i.e., the expected fact that the differential of  $F$  must be an orthogonal linear map. Consequently, writing  $F_{x_i}$  for the partial derivatives, its columns are orthogonal:

$$(1) \quad F_{x_i} \cdot F_{x_j} = \delta_{ij}.$$

In particular,  $F$  is invertible on a neighborhood of  $x$  and we may look at  $G(y) = DF(x)^{-1} \circ F(y)$  instead of  $F$ . Now, the differential of  $G$  is the identity matrix at the point  $x$  and  $G$  keeps distances again. Thus, differentiating the equation (1) for  $G$  we arrive at

$$G_{x_i x_k}(x) \cdot G_{x_j}(x) + G_{x_i}(x) \cdot G_{x_j x_k}(x) = 0$$

and taking into account  $G_{x_i}^j(x) = \delta_i^j$ , the latter equation reduces to  $\alpha_{jik} = -\alpha_{ijk}$ , where we write  $\alpha_{ijk} = G_{x_j x_k}^i(x)$  for the second partial derivatives of the relevant component function. Clearly, we also know  $\alpha_{ijk} = \alpha_{ikj}$  since the second derivatives are commutative. Thus,

$$\alpha_{ijk} = -\alpha_{jik} = -\alpha_{jki} = \alpha_{kji} = \alpha_{kij} = -\alpha_{ikj} = -\alpha_{ij k}$$

and thus all the quantities  $\alpha_{ijk}$  have to vanish. This means all the second partial derivatives of  $G$  in the point  $x$  vanish and by the definition, this also implies that all the second order partial derivatives of  $F(y) = DF(x) \circ G(y)$  in the point  $x$  vanish (write down the formulae explicitly in case of any doubts!). The point  $x$  was arbitrary and thus we have verified that  $F$  is affine by the Taylor expansion. □

**4.D.2.** Find a parametric equation for the intersection of the following planes in  $\mathbb{R}^3$ :

$$\sigma : 2x + 3y - z + 1 = 0 \quad \text{a} \quad \rho : x - 2y + 5 = 0.$$

**4.D.3.** Find a common perpendicular for the skew lines

$$p : [1, 1, 1] + t(2, 1, 0), \quad q : [2, 2, 0] + t(1, 1, 1).$$

**4.D.4.** Jarda is standing in  $[-1, 1, 0]$  and has a stick of length 4. Can he simultaneously touch the lines  $p$  and  $q$ , where

$$\begin{aligned} p & : [0, -1, 0] + t(1, 2, 1), \\ q & : [3, 4, 8] + s(2, 1, 3)? \end{aligned}$$

(The stick must pass through  $[-1, 1, 0]$ .)

**4.D.5.** A cube  $ABCDEFGH$  is given. The point  $T$  lies on the edge  $BF$ , with  $|BT| = \frac{1}{4}|BF|$ . Compute the cosine of the angle between  $ATC$  and  $BDE$ . □

**4.D.6.** A cube  $ABCDEFGH$  is given. The point  $T$  lies on the edge  $AE$ , with  $|AT| = \frac{1}{4}|AE|$ .  $S$  is the midpoint of  $AD$ . Compute the cosine of the angle between  $BDT$  and  $SCH$ . □

**4.D.7.** A cube  $ABCDEFGH$  is given. The point  $T$  lies on the edge  $BF$ ,  $|BT| = \frac{1}{3}|BF|$ . Compute the cosine of the angle between  $ATC$  and  $BDE$ . □

**4.D.8.** What are the lengths of semi-axes, when the sum of their lengths equals the distance between foci both equal 1.

**Solution.** It is given that  $a + b = 1$  and  $2ae = 1$ . Also  $b^2 = a^2(1 - e^2)$ . Eliminating  $e$  gives  $b^2 = a^2 - (1/4)$ . So  $1/4 = a^2 - b^2 = (a - b)(a + b) = a - b$ . So  $a = 5/8$  and  $b = 3/8$ . □

**Solution.** (Alternative.) Solve the system

$$\begin{aligned} a + b & = 1 \\ 2e & = 2\sqrt{a^2 - b^2} = 1 \end{aligned}$$

and find solution  $a = \frac{5}{8}$ ,  $b = \frac{3}{8}$ . □

**4.D.9.** For what slopes  $k$  are the lines passing through  $[-4, 2]$  secant and tangent lines of the ellipse defined by

$$\frac{x^2}{9} + \frac{y^2}{4} = 1$$

**Solution.** The direction vector of the line is  $(1, k)$  and its parametric equations then are  $x = -4 + t$ ,  $y = 2 + kt$ . The intersection with the ellipse satisfies

$$\frac{(-4 + t)^2}{9} + \frac{(2 + kt)^2}{4} = 1$$

This quadratic equation has discriminant equal to

$$D = -\frac{k}{9}(7k + 16).$$

This implies that for  $k \in (-\frac{16}{7}, 0)$  there are two solutions, and the line is a secant. For  $k = -\frac{16}{7}$  and  $k = 0$  there is only one solution and the line is a tangent to the ellipse.  $\square$

**4.D.10.** Find all lines tangent to the ellipse  $3x^2 + 7y^2 = 30$ , so that the distance from the centre of the ellipse to the tangent is 3.

**Solution.** All lines at distance 3 from the origin are tangents to the circle centre at  $[0, 0]$  and radius 3. They all have an equation  $x \cos \theta + y \sin \theta = 3$  for some  $\theta$ . This line meets the standard ellipse  $x^2/a^2 + y^2/b^2 = 1$  where

$$\frac{x^2}{a^2} + \frac{(3 - x \cos \theta)^2}{b^2 \sin^2 \theta} = 1$$

or

$$x^2(a^2 \cos^2 \theta + b^2 \sin^2 \theta) - 6a^2 x \cos \theta - a^2(b^2 \sin^2 \theta - 9) = 0$$

It is a tangent line if the above equation has a double root for  $x$ . Thus it is required that

$$36a^4 \cos^2 \theta = 4(a^2 \cos^2 \theta + b^2 \sin^2 \theta)(9 - b^2 \sin^2 \theta).$$

This simplifies to requiring that

$$a^2 \cos^2 \theta + b^2 \sin^2 \theta = 9.$$

This implies

$$\cos^2 \theta = \frac{(9 - b^2)}{(a^2 - b^2)}$$

$$\sin^2 \theta = \frac{(a^2 - 9)}{(a^2 - b^2)}$$

For the given problem  $a^2 = 10$  and  $b^2 = 30/7$ . The solution is  $x\sqrt{33} + y\sqrt{7} = 3\sqrt{40}$ .  $\square$

**Solution.** (Alternative.) The tangent line is  $(y - b \sin \theta) = -\frac{b \cos \theta}{a \sin \theta}(x - a \cos \theta)$  with  $a^2 = 10$  and  $b^2 = 30/7$ . The distance to the origin, 3, implies  $3 = (a/\cos \theta) \sin \varphi$  where

$$\tan \varphi = \frac{b \cos \theta}{a \sin \theta} \quad 3 \cos \theta = a \sin \varphi \quad \text{where} \quad a \sin \theta \tan \varphi = b \cos \theta \quad 3 \sin \theta = b \cos \varphi$$

$$9/a^2 \cos^2 \theta + 9/b^2 \sin^2 \theta = 1. \quad 9 \cos^2 \theta + 21 \sin^2 \theta = 10. \quad 12 \sin^2 \theta = 1$$

$$(y - \sqrt{35/2}) = -(x - \sqrt{55}/\sqrt{6})[\sqrt{33/7}] \quad \square$$

**Solution.** (Alternative.) The centre of the ellipse is at the origin. The distance  $d$  between the line  $ax + by + c = 0$  and the origin is  $d = \frac{|c|}{\sqrt{a^2 + b^2}}$ . The tangent then satisfies  $a^2 + b^2 = \frac{c^2}{9}$ . The equation of the tangent passing through the point  $[x_T, y_T]$  is  $3xx_T + 7yy_T - 30 = 0$ . For coordinates of the point of tangency,

$$\begin{aligned} (3x_T)^2 + (7y_T)^2 &= 100 \\ 3x_T^2 + 7y_T^2 &= 30 \end{aligned}$$

Its solution is  $x_T = \pm\sqrt{\frac{55}{6}}$ ,  $y_T = \pm\sqrt{\frac{5}{14}}$ . Considering the symmetry of ellipse, there are four solutions

$$\pm 3\sqrt{\frac{55}{6}}x \pm 7\sqrt{\frac{5}{14}}y - 30 = 0. \quad \square$$

**4.D.11.** A hyperbola  $x^2 - y^2 = 2$  is given. Find an equation of a hyperbola having the same foci and passing through point  $[-2, 3]$ .

**Solution.** The given hyperbola has  $a^2 = b^2 = 2$ , so  $a^2e^2 = a^2 + b^2 = 4$ , and the foci are at  $(\pm ae, 0) = (\pm 2, 0)$ . So the desired hyperbola has equation

$$\sqrt{(x-2)^2 + y^2} - \sqrt{(x+2)^2 + y^2} = k,$$

for some constant  $k$ . Since the hyperbola passes through  $[-2, 3]$ ,  $k = 2$ . Squaring gives

$$\sqrt{(x-2)^2 + y^2} = [\sqrt{(x+2)^2 + y^2} + 2],$$

$$(x-2)^2 + y^2 = (x+2)^2 + y^2 + 4\sqrt{(x+2)^2 + y^2} + 4$$

$(-2x-1)^2 = (x+2)^2 + y^2$  or  $3x^2 = y^2 + 3$  which is the required hyperbola. □

**Solution.** (Alternative.) The equation of the desired hyperbola is  $\frac{x^2}{a^2} - \frac{y^2}{b^2} = 1$ , with its eccentricity  $e$  satisfying  $a^2e^2 = a^2 + b^2 = 4$ , since the foci are at  $(\pm ae, 0) = (\pm 2, 0)$ . The point  $[-2, 3]$  lies on the hyperbola, so  $\frac{4}{a^2} - \frac{9}{b^2} = 1$ . It follows that  $a^2 = 1$ ,  $b^2 = 3$ . The desired hyperbola is  $x^2 - \frac{y^2}{3} = 1$ . □

**4.D.12.** Determine the equations of the tangent lines to the hyperbola  $4x^2 - 9y^2 = 1$ , which are perpendicular to line  $x - 2y + 7 = 0$ .

**Solution.** All lines perpendicular to the given line have an equation  $2x + y + c = 0$  for some  $c$ . So the line has an intersection with a double root with the given hyperbola. So the equation  $4x^2 - 9(-2x - c)^2 = 1$  has a double root. Hence  $(36c)^2 - 4 \cdot 32 \cdot (9c^2 + 1) = 0$ , and  $c = \pm \frac{2\sqrt{2}}{3}$ . □

**4.D.13.** Determine the tangent to the ellipse  $\frac{x^2}{16} + \frac{y^2}{9} = 1$  which is parallel with line  $x + y - 7 = 0$ .

**Solution.** The lines parallel with the given line intersect this line in a point at infinity  $(1 : -1 : 0)$ . Construct tangents to given ellipse passing through this point. The point of tangency  $T = (t_1 : t_2 : t_3)$  lies on its polar and therefore satisfies  $\frac{t_1}{16} - \frac{t_2}{9} = 0$ , so  $t_2 = \frac{9}{16}t_1$ . Substituting into the ellipse equation, we get  $t_1 = \pm \frac{16}{5}$ . The touching points of the desired tangents are  $[\frac{16}{5}, \frac{9}{5}]$  and  $[-\frac{16}{5}, -\frac{9}{5}]$ . The tangents are polars of those points. They have equations  $x + y = 5$  and  $x + y = -5$ . □

**Solution.** (Alternative.) The given line has slope  $-1$ . The tangent line at  $(4 \cos \theta, 3 \sin \theta)$  has slope  $-\frac{3 \cos \theta}{4 \sin \theta}$ , so it is required that  $\tan \theta = \frac{3}{4}$ . The tangent line has equation  $(y - 3 \sin \theta) = (-1)(x - 4 \cos \theta)$  where either  $\sin \theta = 3/5$  and  $\cos \theta = 4/5$  or  $\sin \theta = -3/5$  and  $\cos \theta = -4/5$ . The two solutions are  $x + y = \pm 5$ . □

**4.D.14.** Determine the points at infinity and the asymptotes of the conic section

$$2x^2 + 4xy + 2y^2 - y + 1 = 0$$

**Solution.** The equation for the points at infinity of  $2x^2 + 4xy + 2y^2 = 0$  or rather  $2(x + y)^2 = 0$  has a solution  $x = -y$ . The only point at infinity therefore is  $(1 : -1 : 0)$ , so the conic section is a parabola. The asymptote is a polar of this point, specifically the line at infinity  $z = 0$ . □

**4.D.15.** Prove that the product of the distances between an arbitrary point on a hyperbola and both of its asymptotes is constant. Find its value.

**Solution.** Denote the point lying on the hyperbola by  $P$ . The asymptote equation of the hyperbola in canonical form is  $bx \pm ay = 0$ . Their normals are  $(b, \pm a)$  and from here we determine the projections  $P_1, P_2$  of point  $P$  to asymptotes. For the distance between point  $P$  and asymptotes we get  $|PP_{1,2}| = \frac{|aq \pm bp|}{\sqrt{a^2 + b^2}}$ . The product is therefore equal to  $\frac{a^2q^2 - b^2p^2}{a^2 + b^2} = \frac{a^2b^2}{a^2 + b^2}$ , because  $P$  lies on hyperbola. □

**4.D.16.** Compute the angle between the asymptotes of the hyperbola  $3x^2 - y^2 = 3$ .

**Solution.** For the cosine of the angle between the asymptotes of the hyperbola in canonical form,  $\cos \alpha = \frac{b^2 - a^2}{b^2 + a^2}$ . In this case the angle is 60 degrees. □

**4.D.17.** Locate the centers of the conic sections

- (a)  $9x^2 + 6xy - 2y - 2 = 0$   
 (b)  $x^2 + 2xy + y^2 + 2x + y + 2 = 0$   
 (c)  $x^2 - 4xy + 4y^2 + 2x - 4y - 3 = 0$   
 (d)  $\frac{(x-\alpha)^2}{a^2} + \frac{(y-\beta)^2}{b^2} = 1$

**Solution.** (a) The system  $\bar{A}s + a = 0$  for computing centers is

$$\begin{aligned} 9s_1 + 3s_2 &= 0 \\ 3s_1 - 2 &= 0 \end{aligned}$$

Solve it to obtain the center at  $[\frac{2}{3}, -2]$ .

(b) In this case,

$$\begin{aligned} s_1 + s_2 + 1 &= 0 \\ s_1 + s_2 + \frac{1}{2} &= 0. \end{aligned}$$

Therefore there is no proper center (the conic section is a parabola). Moving to homogeneous coordinates we can obtain the center at infinity  $(1 : -1 : 0)$ .

(c) The coordinates of the center in this case satisfy

$$\begin{aligned} s_1 - 2s_2 + 1 &= 0 \\ -2s_1 + 4s_2 - 2 &= 0. \end{aligned}$$

The solution is the line of centers. This is so because the conic section is degenerate: it is a pair of parallel lines.

(d) The center is at  $(\alpha, \beta)$ . The coordinates of the center therefore give the translation of the coordinate system to the frame in which the ellipse has its basic form. □

**4.D.18.** Find the equations of the axes of the conic section  $6xy + 8y^2 + 4y + 2x - 13 = 0$ .

**Solution.** The major and minor axes of the conic section are in the direction of the eigenvectors of matrix  $\begin{pmatrix} 0 & 3 \\ 3 & 8 \end{pmatrix}$ . The characteristic equation has the form  $\lambda^2 - 8\lambda - 9 = 0$ . The eigenvalues are therefore  $\lambda_1 = -1, \lambda_2 = 9$ . The corresponding eigenvectors are then  $(3, -1)$  and  $(1, -3)$ . The axes are the polars of points at infinity defined by those directions. For  $(3, -1)$ , the axis equation is  $-3x + y + 1 = 0$ . For  $(1, -3)$  it is  $-9x - 21y - 5 = 0$ . □

**4.D.19.** Determine the equations of the axes of the conic section  $4x^2 + 4xy + y^2 + 2x + 6y + 5 = 0$ .

**Solution.** The eigenvalues of the matrix  $\begin{pmatrix} 4 & 2 \\ 2 & 1 \end{pmatrix}$  are  $\lambda_1 = 0, \lambda_2 = 5$  and the corresponding eigenvectors are  $(-1, 2)$  and  $(2, 1)$ . There is one axis  $2x + y + 1 = 0$ , and the conic section is a parabola. □

**4.D.20.** The equation

$$x^2 + 3xy - y^2 + x + y + 1 = 0.$$

defines a conic section. Determine its center, axes, asymptotes and foci.

**4.D.21.** Find the equation of the tangent at  $P=[1, 1]$  to the conic section

$$4x^2 + 5y^2 - 8xy + 2y - 3 = 0$$

**Solution.** By projecting, this is a conic section defined by the quadratic form  $(x, y, z)A(x, y, z)^T$  with matrix

$$A = \begin{pmatrix} 4 & -4 & 0 \\ -4 & 5 & 1 \\ 0 & 1 & -3 \end{pmatrix}$$

Using the previous theorem, the tangent is a polar of P, which has homogenous coordinates  $(1 : 1 : 1)$ . It is given by equation  $(1, 1, 1)A(x, y, z)^T = 0$ , which in this case gives

$$2y - 2z = 0$$

Moving back to inhomogeneous coordinates, the tangent line equation is  $y = 1$ .

□

**4.D.22.** Find the coordinates of the intersection of the  $y$  axis and the conic section defined by

$$5x^2 + 2xy + y^2 - 8x = 0$$

**Solution.** The  $y$  axis, is the line  $x = 0$ . It is the polar of the point P with homogeneous coordinates  $\langle p \rangle = (p_1 : p_2 : p_3)$ . That means that the equation  $x = 0$  is equivalent to the polar equation  $F(p, v) = p^T Av = 0$ , where  $v = (x, y, z)^T$ . This is satisfied when  $Ap = (\alpha, 0, 0)^T$  for some  $\alpha \in \mathbb{R}$ . This condition gives the conic section matrix

$$A = \begin{pmatrix} 5 & 1 & -4 \\ 1 & 1 & 0 \\ -4 & 0 & 0 \end{pmatrix}$$

equation system

$$\begin{aligned} 5p_1 + p_2 - 4p_3 &= \alpha j \\ p_1 + p_2 &= 0 \\ -4p_1 &= 0 \end{aligned}$$

We can find the coordinates of P by the inverse matrix,  $p = A^{-1}(\alpha, 0, 0)^T$ , or solve the system directly by backward substitution. In this case we can easily obtain solution  $p = (0, 0, -\frac{1}{4}\alpha)$ . So the  $y$  axis touches the conic section at the origin.

□

**4.D.23.** Find a touch point of the line  $x = 2$  with the conic section from the previous exercise.

**Solution.** The line has equation  $x - 2z = 0$  in its projective extension and therefore we get the condition  $Ap = (\alpha, 0, -2\alpha)$  for the touch point P, which gives

$$\begin{aligned} 5p_1 + p_2 - 4p_3 &= \alpha \\ p_1 + p_2 &= 0 \\ -4p_1 &= -2\alpha \end{aligned}$$

Its solution is  $p = (\frac{1}{2}\alpha, -\frac{1}{2}\alpha, \frac{1}{4}\alpha)$ . These homogeneous coordinates are equivalent to  $(2, -2, 1)$  and hence the touch point has coordinates  $[2, -2]$ .

□

**4.D.24.** Find equations of the tangents passing through  $P = [3, 4]$  to the conic defined by

$$2x^2 - 4xy + y^2 - 2x + 6y - 3 = 0.$$

**Solution.** Suppose that the point of tangency  $T$  has homogeneous coordinates given by a multiple of the vector  $t = (t_1, t_2, t_3)$ . The condition that  $T$  lies on the conic section is  $t^T At = 0$ , which gives

$$2t_1^2 - 4t_1t_2 + t_2^2 - 2t_1t_3 + 6t_2t_3 - 3t_3^2 = 0$$

The condition that P lies on the polar of T is  $p^T At = 0$ , where  $p = (3, 4, 1)$  are the homogeneous coordinates of point P. In this case, the equation gives

$$(3, 4, 1) \begin{pmatrix} 2 & -2 & -1 \\ -2 & 1 & 3 \\ -1 & 3 & -3 \end{pmatrix} \begin{pmatrix} t_1 \\ t_2 \\ t_3 \end{pmatrix} = -3t_1 + t_2 + 6t_3 = 0$$

Now we can substitute  $t_2 = 3t_1 - 6t_3$  to the previous quadratic equation. Then

$$-t_1^2 + 4t_1t_3 - 3t_3^2 = 0$$

Because the equation is not satisfied for  $t_3 = 0$ , we move to inhomogeneous coordinates  $(\frac{t_1}{t_3}, \frac{t_2}{t_3}, 1)$ , for which we get

$$-\left(\frac{t_1}{t_3}\right)^2 + 4\left(\frac{t_1}{t_3}\right) - 3 = 0 \quad \text{a} \quad \frac{t_2}{t_3} = 3\left(\frac{t_1}{t_3}\right) - 6,$$

tj.  $\frac{t_1}{t_3} = 1$  a  $\frac{t_2}{t_3} = -3$ , nebo  $\frac{t_1}{t_3} = 3$  a  $\frac{t_2}{t_3} = 3$ . So the touch points have homogeneous coordinates  $(1 : -3 : 1)$  and  $(3 : 3 : 1)$ . The tangent equations are the polars of those points  $7x - 2y - 13 = 0$  and  $x = -3$ .

□

**4.D.25.** Find an equation of the tangent passing through the origin to the circle

$$x^2 + y^2 - 10x - 4y + 25 = 0$$

**Solution.** The touch point  $(t_1 : t_2 : t_3)$  satisfies

$$(0, 0, 1) \begin{pmatrix} 1 & 0 & -5 \\ 0 & 1 & -2 \\ -5 & -2 & 25 \end{pmatrix} \begin{pmatrix} t_1 \\ t_2 \\ t_3 \end{pmatrix} = -5t_1 - 2t_2 + 25 = 0$$

From here we eliminate  $t_2$  and substitute into circle equation, which  $(t_1 : t_2 : t_3)$  has to be satisfied as well. We obtain the quadratic equation  $29t_1^2 - 250t_1 + 525 = 0$ , with solutions  $t_1 = 5$  and  $t_1 = \frac{105}{29}$ . We compute the coordinate  $t_2$  and get touch points  $[5, 0]$  and  $[\frac{105}{29}, \frac{100}{29}]$ . The tangents are polars of those points with equations  $y = 0$  and  $20x - 21y = 0$ .  $\square$

**4.D.26.** Find tangents equations to circle  $x^2 + y^2 = 5$  which are parallel with  $2x + y + 2 = 0$ .

**Solution.** In the projective extension, these tangents intersect at the point at infinity satisfying  $2x + y + z = 0$ , so in point with homogeneous coordinates  $(1 : -2 : 0)$ . They are tangents from this point to the circle. We can use the same method as in previous exercise. The conic section matrix is diagonal with the diagonal  $(1, 1, -5)$  and therefore the touch point  $(t_1 : t_2 : t_3)$  of the tangents satisfies  $t_1 - 2t_2 = 0$ . Substitute into the circle equation to get  $5t_2^2 = 5$ . Since  $t_2 = \pm 1$ , the touch points are  $[2, 1]$  and  $[-2, -1]$ .  $\square$

**Solution.** Alternative. The point  $P = \sqrt{5}(\cos \theta, \sin \theta)$  lies on the circle for all  $\theta$ . The tangent line at  $P$  is  $x \cos \theta + y \sin \theta = \sqrt{5}$ . This has slope  $-(\cos \theta)/(\sin \theta)$  which is  $-2$  provided  $\tan \theta = 1/2$ . It follows that  $P$  is at either  $[2, 1]$  or  $[-2, -1]$ .  $\square$

A tangent line touching the conic section at infinity is called an *asymptote*. The number of asymptotes of a conic section equals the number of intersections between the conic section and the line at infinity. So the ellipse has no real asymptotes, the parabola has one (which is however a line at infinity) and the hyperbola has two.

**4.D.27.** Find the points at infinity and the asymptotes of the conic section defined by

$$4x^2 - 8xy + 3y^2 - 2y - 5 = 0$$

**Solution.** First, rewrite the conic section in homogeneous coordinates.

$$4x^2 - 8xy + 3y^2 - 2yz - 5z^2 = 0$$

the homogeneous coordinates  $(x : y : 0)$  satisfying this equation, which means

$$4x^2 - 8xy + 3y^2 = 0.$$

It follows that either:  $\frac{x}{y} = -\frac{1}{2}$  or  $\frac{x}{y} = -\frac{3}{2}$ . The conic section is therefore a hyperbola with points at infinity  $P = (-1 : 2 : 0)$  and  $Q = (-3 : 2 : 0)$ .

$$(-1, 2, 0) \begin{pmatrix} 4 & -4 & 0 \\ -4 & 3 & -1 \\ 0 & -1 & -5 \end{pmatrix} \begin{pmatrix} x \\ y \\ 1 \end{pmatrix} = -12x + 10y - 2 = 0$$

and

$$(-3, 2, 0) \begin{pmatrix} 4 & -4 & 0 \\ -4 & 3 & -1 \\ 0 & -1 & -5 \end{pmatrix} \begin{pmatrix} x \\ y \\ 1 \end{pmatrix} = -20x + 18y - 2 = 0$$

$\square$

There are further exercises on conic sections on the page 361.

**4.D.28. Harmonic cross-ratio.** If the cross-ratio of four points lying on the line equals  $-1$ , we talk about a *harmonic quadruple*. Let  $ABCD$  be a quadrilateral. Denote by  $K$  the intersection of the lines  $AB$  and  $CD$ , by  $M$  the intersection of the lines  $AD$  and  $BC$ . Further let  $L, N$  be the intersection of  $KM$  and  $AC, BD$  respectively. Show that the points  $K, L, M, N$  are a harmonic quadruple.  $\circ$

**Exercise solution**

## Establishing the ZOO

which functions do we need for our models?  
– a thorough menagerie

### A. Polynomial interpolation

Our first “route” in the zoo of functions is devoted to a beautiful topic, concerning the elementary notion of polynomials. Usually, given a polynomial one wants to find its roots, and in the first chapter we learned to evaluate polynomials via the Horner’s scheme. Of course, evaluation is an essential part of any root-finding method and we know that the fundamental theorem of algebra classifies all roots of a polynomial over  $\mathbb{C}$  (see also the paragraph 12.2.8).

Below we adopt a slightly different approach, and focus on applications related to the notion of polynomial interpolation of real or complex functions. Roughly speaking this means that we will use polynomials of certain degree to approximate such functions. This includes the so called “Lagrange interpolation”, but we will also explain how the theory of derivatives involves, in terms of “Hermite’s interpolation problem” and “cubic splines”. We mention that in this part the use of elementary functions is stressed, although they are systematically analyzed later in this chapter.

**5.A.1. Using Sage for plotting graphs.** Computer algebra programs, as Mathematica, Matlab, Maple, Sage, and other, all include simple syntaxes available for drawing the graph  $G_f = \{(x, f(x)) : x \in I\}$  of a real polynomial  $f(x) = a_n x^n + \dots + a_1 x + a_0$  of some fixed degree  $n \in \mathbb{N}$ , or

In this chapter, we start using tools allowing us to model dependencies which are neither linear, nor discrete. Such models are often needed when dealing with time dependent systems. We try to describe them not only at discrete moments of time, but “continuously”. Sometimes this is advantageous, for instance in physical models of classical mechanics and engineering. It might also be appropriate and computationally effective to employ an approximation of discrete models in economics, chemistry, or biology. In particular such ideas may be appropriate in relation to stochastic models, as we shall see in Chapter 10.

The key concept is that of a function, also called a “signal” in practical applications. The larger the class of functions used, the more difficult is the development of effective tools. On the other hand, if there are only a few simple types of functions available, it may be that some real situations cannot be modelled at all.

The objective of the following two chapters is thus to introduce explicitly the most elementary functions of real variables. It is also to describe implicitly many more functions, and to build the standard tools to use them. This is the differential and integral calculus of one variable. While the focus has been mainly on the part of mathematics called *algebra*, the emphasis will now be on *mathematical analysis*. The link between the two is provided by a “geometric approach”. If possible, this means building concepts and intuition independently of any choice of coordinates. Often this leads to a discrete (finite) description of the objects of interest. This is immediate when working with polynomials now.

### 1. Polynomial interpolation

In the previous chapters, we often worked with sequences of real or complex numbers, i.e. with scalar functions  $\mathbb{N} \rightarrow \mathbb{K}$  or  $\mathbb{Z} \rightarrow \mathbb{K}$ , where  $\mathbb{K}$  is a given set of numbers. We also worked with sequences of vectors over real or complex numbers.

Recall the discussion from paragraph 1.1.6, about dealing with scalar functions. This discussion is adequate to work with functions  $\mathbb{R} \rightarrow \mathbb{R}$  (*real-valued functions of one real variable*), or  $\mathbb{R} \rightarrow \mathbb{C}$  (*complex-valued functions of one real variable*), or sometimes more generally the *vector-valued functions of one real variable*  $\mathbb{R} \rightarrow V$ . The results can usually be

more general of some real function  $f : I \rightarrow \mathbb{R}$ , where  $I$  is a suitable interval in the real line. Next we will use Sage, and its command `plot(f(x), x, a, b)`, a situation that we encountered already in Chapter 1.

It worths to mention that Sage computes the plot of a given function  $f$  by evaluating the function at a large number of random points lying in the chosen interval  $[a, b]$ . Since in general Sage tries to plot the whole graph of  $f$ , it is often useful to restrict the “ $y$ -range” between certain values (“compatible” with the range of  $y = f(x)$ , say  $c \leq y = f(x) \leq d$ ).<sup>1</sup> This can be done by including inside the command `plot` the options `ymin = c` and `ymax = d`, respectively. The restriction of the  $y$ -range is also useful for treating further specialities, as for example for the graphs of functions with (vertical) asymptotes and other situations. We will discuss such details later.

**5.A.2. Low degree polynomials.** Describe geometrically real polynomials of degree zero, one, two, and three, respectively. Use Sage to plot the corresponding graphs for the most “fancy cases” (i.e., the non-linear cases).

**Solution.** Let us discuss the cases of degree  $n = 2, 3$  only (whose graphs are more interesting than straight lines, being the graphs for the cases  $n = 0, 1$ ). So, recall that a second degree polynomial has the form  $f(x) = a_2x^2 + a_1x + a_0 = ax^2 + bx + c$ , with  $a_2 = a \neq 0$ , and  $x \in \mathbb{R}$ . Its graph is a parabola, symmetric with respect to the vertical line  $x = -\frac{b}{2a}$  and oriented upwards or downwards, depending on the sign of  $a$ . Below we present the graph of the parabola  $f(x) = 4x^2 - 2x - 3$ , constructed in Sage. This indicates also its axis of symmetry and its vertex  $V = [-\frac{b}{2a}, f(-\frac{b}{2a})] = [1/4, -13/4]$ .

Recall from 1.G.5 that a method to sketch the graph of  $f(x) = a_0 + a_1x + a_2x^2$  is based on the substitution method and in particular relies on a combination of the commands `plot` and `subs`. This allows to substitute certain values of the parameters  $a_0, a_1, a_2$  and quickly sketch the corresponding  $C_f$  (this can be applied to plot the graph of any polynomial).

```
a=SR.var("a", 3); P=a[0]+a[1]*x+a[2]*x^2
q=plot(P.subs(a[0]==-3,a[1]==-2,a[2]==4),
x,-6,6); q.show()
```

As a side remark related to the use of `ymin` and `ymax` mentioned in 5.A.1, observe that one may include them also in

<sup>1</sup>This is extremely useful when for example we need to sketch the graph of a rational function.

extended to cases concerning vector values over the considered scalars, rather than just real and complex numbers.

We begin with some easily computable functions.

**5.1.1. Polynomials.** We can add and multiply scalars.

These operations satisfy a number of properties which we listed in the paragraphs 1.1.1 and 1.1.5. If we admit any finite number of these operations, leaving one of the variables as an unknown and fixing the other scalars, we obtain the polynomial functions. We consider the scalars  $\mathbb{K} = \mathbb{R}, \mathbb{C}$ , or  $\mathbb{Q}$ .

POLYNOMIALS

A polynomial over a ring of scalars  $\mathbb{K}$  is a mapping  $f : \mathbb{K} \rightarrow \mathbb{K}$  given by the expression

$$f(x) = a_nx^n + a_{n-1}x^{n-1} + \dots + a_1x + a_0,$$

where  $a_i, i = 0, \dots, n$ , are fixed scalars. Multiplication is indicated by juxtaposition of symbols, and “+” denotes addition. If  $a_n \neq 0$ , the polynomial  $f$  is said to have degree  $n$ . The degree of the zero polynomial is undefined. The scalars  $a_i$  are called the *coefficients of the polynomial*  $f$ .

The polynomials of degree zero are exactly the non-zero constant mappings. In algebra, polynomials are more often defined as formal expressions of the aforementioned form of  $f(x)$ , i. e. a polynomial is defined to be a sequence  $a_0, a_1, \dots$  of coefficients such that only finitely many of them are non-zero. However, we will show shortly that these approaches are equivalent for our choices of scalars.

It is easy to verify that the polynomials over a given ring of scalars form a ring. Multiplication and addition of polynomials are given by the operations in the original ring  $\mathbb{K}$  by the values of the polynomials. Hence,

$$(f \cdot g)(x) = f(x) \cdot g(x), \quad (f + g)(x) = f(x) + g(x),$$

where the operations on the left-hand side are interpreted in the ring of polynomials whereas the operations on the right-hand side are of the ring of scalars (see the second part of Chapter 12 for detailed algebraic treatment).

**5.1.2. Division of polynomials.** As already mentioned, the scalar fields used are  $\mathbb{Q}, \mathbb{R}$ , or  $\mathbb{C}$ . In all of these fields, the following holds:

EUCLIDEAN DIVISION OF POLYNOMIALS

**Proposition.** For any two polynomials  $f$  of degree  $n$  and  $g$  of degree  $m$ , there is exactly one pair of polynomials  $q, r$  such that  $f = q \cdot g + r$ , where either  $r = 0$ , or the degree of  $r$  is less than  $m$ .

**PROOF.** This is a special simple case of the much more general algebraic result in 12.3.6. Write  $f(x) = a_nx^n + a_{n-1}x^{n-1} + \dots + a_1x + a_0$  for the polynomial of degree  $n$ , and  $g(x) = b_mx^m + b_{m-1}x^{m-1} + \dots + b_1x + b_0$ , with  $a_n \neq 0$  and  $b_m \neq 0$ .

the command `show` ending the previous block, to restrict the values of  $f$ . For  $n = 3$ , the graph of a general cubic polynomial  $f(x) = a_3x^3 + a_2x^2 + a_1x + a_0$ , with  $a_3 \neq 0$  is a curve running from  $-\infty$  to  $\infty$ , if  $a_3 > 0$ , or the opposite way from  $\infty$  to  $-\infty$  if  $a_3 < 0$ . A cubic polynomial can be continuously either increasing or decreasing, or it can have two bumps. Observe also that such a polynomial always meets the  $x$ -axis, providing a real root either once or three times (see also 1.A.6 in Chapter 1). Later in Section C we will discuss conditions distinguishing these cases.  $\square$

*Functions as trigonometric, exponential or logarithmic, have an elementary role in our zoo of functions, hence we will meet them very often. It will be also useful to know how to treat and evaluate them in Sage, a goal that we quickly figure out for the trigonometric one via our next task.*

**5.A.3. Trigonometric functions via Sage.** Use Sage to obtain the exact values of all the elementary trigonometric functions at the points  $0, \pi/6, \pi/4, \pi/3, \pi/2, 2\pi/3, \pi, 3\pi/2$ , and  $2\pi$ , in case they are defined there.

**Solution.** All the trigonometric functions are built into Sage. We type `sin`, `cos` and `tan` for  $\sin$ ,  $\cos$  and  $\tan = \frac{\sin}{\cos}$ , respectively. Similarly we type `cot`, `sec` and `csc` for the cotangent, secant, and cosecant function. To save your time, we recall that these are the functions defined by  $\cot(x) = \frac{\cos(x)}{\sin(x)} = \frac{1}{\tan(x)}$ ,  $\sec(x) = \frac{1}{\cos(x)}$  and  $\csc(x) = \frac{1}{\sin(x)}$ , respectively.

To obtain the required values in an exact way, you may type `sin(pi/6)`, `cos(3*pi/2)`, and so on.<sup>2</sup> When a function is not defined at a certain point, Sage returns `Infinity`. This is the case for the commands `cot(0)` and `sec(pi/2)`, for example. In this way one may recover the following table:

	sin	cos	tan	cot	sec	csc
0	0	1	0	—	1	—
$\pi/6$	$1/2$	$\sqrt{3}/2$	$\sqrt{3}/3$	$\sqrt{3}$	$2\sqrt{3}/3$	2
$\pi/4$	$\sqrt{2}/2$	$\sqrt{2}/2$	1	1	$\sqrt{2}$	$\sqrt{2}$
$\pi/3$	$\sqrt{3}/2$	$1/2$	$\sqrt{3}$	$\sqrt{3}/3$	2	$2\sqrt{3}/3$
$\pi/2$	1	0	—	0	—	1
$2\pi/3$	$\sqrt{3}/2$	$-1/2$	$-\sqrt{3}$	$-\sqrt{3}/3$	-2	$2\sqrt{3}/3$
$\pi$	0	-1	0	—	-1	—
$3\pi/2$	-1	0	—	0	—	-1
$2\pi$	0	1	0	—	1	—

Notice the inverse trigonometric functions are also built into Sage. Hence we type `arcsin`, `arccos`, `arctan`, `arccot`, `arcsec` and `arccsc` for the inverse of  $\sin$ ,  $\cos$ ,  $\tan$ ,  $\cot$ ,  $\sec$  and  $\csc$ , respectively. You may use Sage to evaluate these functions, or to obtain their graph. For some of them, we will do this later in this chapter.  $\square$

*Let us now focus on polynomial interpolation. Recall by 5.1.3 that given some distinct nodes  $x_0, x_1, \dots, x_n$  there is precisely a polynomial  $P(x)$  of degree not greater than  $n$ ,*

<sup>2</sup>In case you need a decimal approximation, type `N(sin(pi/6))`, etc. An alternative can be the command `n(sin(pi/6))`, though we should be careful not having introduced in the same cell “ $n$ ” as a symbolic variable.

Consider uniqueness. Suppose there are polynomials  $q, q', r$ , and  $r'$ , such that

$$f = q \cdot g + r = q' \cdot g + r'.$$

Then subtraction gives  $0 = (q - q') \cdot g + (r - r')$ .

If  $q = q'$ , then also  $r = r'$ . If  $q \neq q'$ , then the term of highest degree in  $(q - q') \cdot g$  cannot be replicated in  $r - r'$ . This leads to a contradiction. This proves uniqueness.

It remains to prove that  $f$  can always be expressed in the desired form. If  $m > n$ , then  $f = 0 \cdot g + f$  satisfies the requirements. So suppose that  $n \geq m$ . The result is proved by induction on the degree of  $f$ .

If  $f$  is of degree zero, then the statement is trivial. Suppose the statement holds for all polynomials  $f$  of degree less than  $n > 0$ . Put

$$h(x) = f(x) - \frac{a_n}{b_m} x^{n-m} g(x).$$

If  $h(x)$  is the zero polynomial, then  $f$  is of the desired form. Otherwise  $h(x)$  is a polynomial of degree less than that of  $f$  and so  $h$  be written in the desired form as  $h(x) = q \cdot g + r$ . But then

$$f(x) = h(x) + \frac{a_n}{b_m} x^{n-m} g(x) = (q + \frac{a_n}{b_m} x^{n-m})g(x) + r$$

and the proof is complete.  $\square$

If  $f(b)$  equals zero for some element  $b \in \mathbb{K}$ , then the equality  $f(x) = q(x)(x-b) + r$  yields  $0 = f(b) = q(b) \cdot 0 + r$ , and so the constant remainder is  $r = 0$ . Consequently  $f(x) = (x-b)q(x)$ . The value  $b$  is called a *root of the polynomial*  $f$ . The degree of  $q$  is then  $n - 1$ . If  $q$  also has a root, we can continue and in no more than  $n$  steps we arrive at a constant polynomial. It follows that the number of roots of any non-zero polynomial over the field  $\mathbb{K}$  is at most the degree of the polynomial. Hence the following observation:

**Corollary.** *If the field of scalars  $\mathbb{K}$  is infinite, then the polynomials  $f$  and  $g$  are equal as mappings if and only if they are equal as sequences of coefficients.*

**PROOF.** Suppose that  $f = g$ , i.e.  $f - g = 0$ , as a mapping. Then the polynomial  $(f - g)(x)$  has infinitely many roots, which is possible only if it is the zero polynomial.  $\square$

Notice that of course, this statement does not hold for finite fields. A simple counter-example is the polynomial  $x^2 + x$  over  $\mathbb{Z}_2$  which represents a constant zero mapping.

**5.1.3. Interpolation polynomial.** It is often desirable to use an easily computable expression for a function which is given by its values at some given points  $x_0, \dots, x_n$ . Mostly this would be an approximation of an unknown function represented by the finite values only. We look for such polynomials.

If the values were all zeros, we can immediately find a polynomial of degree  $n + 1$ , namely

$$f(x) = (x - x_0)(x - x_1) \dots (x - x_n).$$

which takes a prescribed value  $y_i$  at  $x_i$ , for all  $i = 0, 1, \dots, n$ . This is given by  $P(x) = y_0 \cdot \ell_0(x) + \dots + y_n \cdot \ell_n(x)$ , with

$$\ell_i(x) := \frac{(x - x_0) \cdots (x - x_{i-1})(x - x_{i+1}) \cdots (x - x_n)}{(x_i - x_0) \cdots (x_i - x_{i-1})(x_i - x_{i+1}) \cdots (x_i - x_n)}$$

for any  $i = 0, 1, \dots, n$ . Observe that  $\ell_i(x_i) = 1$  for all  $i = 0, 1, \dots, n$ , while  $\ell_i(x_j) = 0$  for all  $i \neq j$ .

The polynomial  $P(x)$  is known as the Lagrange interpolation polynomial, while  $\ell_i$  are referred to as the elementary Lagrange polynomials, see 5.1.4 for details. Notice if we have  $y_i = f(x_i)$  for some function  $f$ , then  $P(x)$  is referred to as the Lagrange interpolation polynomial for  $f$ . Let us now illustrate the situation by examples.

**5.A.4. Lagrange interpolation.** Consider the nodes  $x_0 = 0$ ,  $x_1 = 1$ ,  $x_2 = 4$  and the values  $y_0 = 1$ ,  $y_1 = 2$ ,  $y_2 = 4$ . Write down the corresponding Lagrange interpolation polynomial  $P(x)$ , and sketch its graph, together with the graphs of  $\ell_0, \ell_1, \ell_2$ .

**Solution.** According to 5.1.4 the Lagrange interpolation polynomial will be at most of degree two. We compute  $\ell_0(x) = \frac{(x-1)(x-4)}{4}$ ,  $\ell_1(x) = -\frac{x(x-4)}{3}$  and  $\ell_2(x) = \frac{x(x-1)}{12}$ , and hence  $P(x) = -\frac{1}{12}x^2 + \frac{13}{12}x + 1$ . For an implementation of the Lagrange interpolation, Sage provides an inbuilt method based on the command `lagrange.polynomial`. For example, in our case we can give the block

```
nodes=[(0, 1), (1, 2), (4, 4)]
R=PolynomialRing(QQ, "x")
P=R.lagrange_polynomial(nodes); show(P)
```

Check yourself that this cell prints out the explicit expression of the polynomial  $P(x)$ . Notice also that you can use the `bool` command to confirm Sage's output. This can be done by adding in the cell posed above the following syntax:

```
l0(x)=(x-1)*(x-4)/4; l1(x)=-x*(x-4)/3
l2(x)=x*(x-1)/12
eq=P(x)-l0(x)-2*l1(x)-4*l2(x)==0; eq
bool(eq)
```

As for the required graphs, we present them below (check yourself that the reproduction of this figure in Sage is really enjoyable).

This is zero at these points and only at them. However, there are other polynomials which are zero at the given points. For instance the zero polynomial, which turns out to be the only such polynomial in the vector space of polynomials of degree at most  $n$ . The general situation is analogous:

INTERPOLATION POLYNOMIALS

Let  $\mathbb{K}$  be an infinite field of scalars. An interpolation polynomial  $f$  for the set of (pairwise distinct) points  $x_0, \dots, x_n \in \mathbb{K}$  and given values  $y_0, \dots, y_n \in \mathbb{K}$  is either the zero polynomial, or a polynomial of degree at most  $n$  such that  $f(x_i) = y_i$  for all  $i = 0, 1, \dots, n$ .

**Theorem.** For every set of  $n + 1$  (pairwise distinct) points  $x_0, \dots, x_n \in \mathbb{K}$  and given values  $y_0, \dots, y_n \in \mathbb{K}$ , there is exactly one interpolation polynomial  $f$ .

**PROOF.** If  $f$  and  $g$  are interpolation polynomials with the same defining values, then their difference is a polynomial of degree  $n$  which has at least  $n + 1$  roots, and thus  $f - g = 0$ . This proves uniqueness.

It remains to prove the existence. Label the coefficients of the polynomial  $f$  of degree  $n$ :

$$f = a_n x^n + \dots + a_1 x + a_0.$$

Substituting the desired values leads to a system of  $n + 1$  equations for the same number of unknown coefficients  $a_i$

$$\begin{aligned} a_0 + x_0 a_1 + \dots + (x_0)^n a_n &= y_0 \\ &\vdots \\ a_0 + x_n a_1 + \dots + (x_n)^n a_n &= y_n. \end{aligned}$$

The existence of a solution of this system is easily shown by constructing the polynomial by using the Lagrange polynomials for the given points  $x_0, \dots, x_n$ , introduced in the next paragraph.

However, the proof can be concluded by using only basic knowledge from linear algebra. This system of linear equations has a unique solution if the determinant of its matrix is a non-zero scalar (see 2.3.5 and 2.2.11). The determinant is the *Vandermonde determinant*, which was discussed in the exercise 2.E.21 on page 151.

Since it is verified that for zero right-hand sides, there is exactly one solution, we know that this determinant must be non-zero. □

**5.A.5.** Find a polynomial  $P$  satisfying the following conditions:  $P(2) = 1, P(3) = 0, P(4) = -1, P(5) = 6$ .

**Solution.** Initially one may want to use Sage to plot the given points in  $\mathbb{R}^2$ . We can do this by the cell

```
list_plot({2: 1, 3: 0, 4: -1, 5: 6}, size=30,
         figsize=4, color="black")
```

Now, we can solve the task by two different ways. Four points are given, so we know that there is exactly one polynomial of degree at most three, satisfying the given conditions. Hence we can assume that  $P(x) = a_3x^3 + a_2x^2 + a_1x_1 + a_0$ , for some  $a_0, \dots, a_3 \in \mathbb{R}$ , and in such terms it is easy to see that the system  $\{P(2) = 1, P(3) = 0, P(4) = -1, P(5) = 6\}$  consists of the equations  $a_0 + 2a_1 + 4a_2 + 8a_3 = 1, a_0 + 3a_1 + 9a_2 + 27a_3 = 0, a_0 + 4a_1 + 16a_2 + 64a_3 = -1$ , and  $a_0 + 5a_1 + 25a_2 + 125a_3 = 6$ . Applying the Sage cell

```
var("a0, a1, a2, a3")
eq1=a0+2*a1+4*a2+8*a3-1; eq2=a0+3*a1+9*a2+27*a3
eq3=a0+4*a1+16*a2+64*a3-1
eq4=a0+5*a1+25*a2+125*a3-6
solve([eq1==0, eq2==0, eq3==0, eq4==0], a0, a1, a2, a3)
```

we obtain a unique solution given by

```
[a0 == -29, a1 == (101/3), a2 == -12, a3 == (4/3)]
```

An alternative, more “solid” way to treat this system via Sage is here:

```
a=SR.var("a", 4)
P(x)=a[0]+a[1]*x+a[2]*x^2+a[3]*x^3
solve([P(2)-1==0, P(3)==0, P(4)+1==0, P(5)-6==0], a[0], a[1], a[2], a[3])
```

To summarize, the polynomial  $P$  has the form  $\frac{4}{3}x^3 - 12x^2 + \frac{101}{3}x - 29$ .

Let us now verify this answer by the method described before, based on the Lagrange polynomial:

$$\begin{aligned}
 P(x) &= 1 \cdot \frac{(x-3)(x-4)(x-5)}{(2-3)(2-4)(2-5)} + 0 \cdot (\dots) \\
 &\quad + (-1) \cdot \frac{(x-2)(x-3)(x-5)}{(4-2)(4-3)(4-5)} \\
 &\quad + 6 \cdot \frac{(x-2)(x-3)(x-4)}{(5-2)(5-3)(5-4)} \\
 &= \frac{4}{3}x^3 - 12x^2 + \frac{101}{3}x - 29.
 \end{aligned}$$

Of course, such a computation can be done faster in Sage via the `lagrange.polynomial` command, as in 5.A.4, and we leave to the reader this verification. Below we present the graph of  $P(x)$  together with the given nodes.

Since polynomials are equal as mappings if and only if they are equal as sequences of coefficients, the theorem is proved.  $\square$

**5.1.4. Applications of interpolation.** At first sight, it may seem that real or rational polynomials, that is, polynomial functions  $\mathbb{R} \rightarrow \mathbb{R}$  or  $\mathbb{Q} \rightarrow \mathbb{Q}$ , form a very useful class of functions of one variable. We can arrange for them to attain any set of given values. Moreover, they are easily expressible, so their value at any point can be calculated without difficulties.

However, there are a number of problems when trying to use them in practice.

The first of the problems is to find quickly the polynomial which will interpolate the given data. Solving the aforementioned system of linear equations generally requires time proportional to the cube of the number of given points  $x_i$ . This is unacceptable for large data. We will demonstrate how to overcome this on one popular type of polynomials related to fixed points  $x_0, \dots, x_n$ :

LAGRANGE<sup>1</sup> INTERPOLATION POLYNOMIALS

The *Lagrange interpolation polynomial* is expressed in terms of the *elementary Lagrange polynomials*  $\ell_i$  of degree  $n$  with the properties

$$\ell_i(x_j) = \begin{cases} 1 & i = j \\ 0 & i \neq j \end{cases}.$$

These polynomials must (up to a constant factor) equal the expressions  $(x-x_0) \dots (x-x_{i-1})(x-x_{i+1}) \dots (x-x_n)$ . So

$$\ell_i(x) = \frac{\prod_{j \neq i} (x-x_j)}{\prod_{j \neq i} (x_i-x_j)}.$$

The desired Lagrange interpolation polynomial is then given by

$$f(x) = y_0\ell_0(x) + y_1\ell_1(x) + \dots + y_n\ell_n(x).$$

Notice that the elementary Lagrange polynomials can be quite easily expressed by means of the derivatives, see the exercise ??.

The usage of Lagrange polynomials is especially efficient when working with different values  $y_i$  for the same set of values  $x_i$ . For in this case, the elementary polynomials  $\ell_i$  are already prepared.

One of the disadvantages of this expression is a large sensitivity to inaccuracies in a computation when the differences of the given values  $x_i$  are small. This is because division by these differences is required.

Another disadvantage (common to all ways of expressing the unique interpolation polynomial) is poor stability of the values of real or rational polynomials outside of the interval containing all its roots.

<sup>1</sup>Joseph-Louis Lagrange (1736-1813) was a famous Italian mathematician and astronomer, who contributed in particular to celestial mechanics. His famous *Mécanique analytique* appeared in 1788. His name appears often even in this elementary textbook.

$\square$

**5.A.6.** Find the Lagrange interpolation polynomial for the function  $f(x) = \frac{1}{4+x^2}$  by dividing the closed interval  $[-1, 1] \subset \mathbb{R}$  into  $n$  equal parts, for  $n = 20$ . Use Sage to present a figure including the graph of  $f$  and that of the interpolation polynomial, along with the interpolated points.

**Solution.** The procedure of dividing  $[-1, 1]$  to  $n$  equal parts gives rise to  $n + 1$  points of the form

$$-1 + \frac{2k}{n}, \quad k = 0, 1, \dots, n.$$

For instance for  $n = 1$  we get the points  $-1, 1$ , for  $n = 2$  we get the points  $-1, 0, 1$ , for  $n = 3$  we get the points  $-1, -1/3, 1/3, 1$ , etc. We can now use Sage and the command `.lagrange_polynomial()`, as follows:

```
f(x)=1/(4+x**2)
fig=plot(f(x), (x, -1, 1), figsize=4, color="black")
show(fig)
R=PolynomialRing(QQ, "x"); n=20
points=[(-1+k*(2/n), f(-1+k*2/n)) for k
        in [0, 1, .., n]]
P(x)=R.lagrange_polynomial(points)
fig+=plot(P(x), (x, -1, 1), color="purple")
fig+=list_plot(points, size=20, figsize=4,
               color="blue"); fig
```

This block includes commands appropriate to produce the plots of  $f$  and of  $P$ , along with the interpolated points. This allows us to illustrate the interpolation, as in the figure below. Notice to obtain the explicit form of  $P(x)$  one should type `show(P(x))`, which we do not present to save some space (type alone in your editor the given code to read  $P(x)$ ).

**5.A.7.** Repeat the task in 5.A.6 by replacing  $f$  with the function  $g(x) = (x/(1 + 8x^2))$ . Next present the graphs of  $g(x)$  and of the Lagrange interpolation polynomial along with the given points, via a programming package of your desire. ○

**5.A.8.** Find a polynomial  $P$  of degree two or less, taking the values  $y_0 = 1, y_1 = -3, y_2 = 4$  at the points  $x_0 = -1, x_1 = 1, x_2 = 2$ , respectively. ○

**5.A.9.** Find a polynomial  $P$  of third degree satisfying  $P(0) = 1, P(1) = 0, P(2) = 1$ , and  $P(3) = 10$ . ○

**5.A.10.** Find a polynomial  $P$  satisfying:

- (i)  $P(1 + i) = i, P(2) = 1, P(3) = -i$ ,
- (ii)  $P(1) = i, P(-1) = -i, P(i) = -1$ .

Soon we will develop tools for an exact description of the functions' behaviour. But even without such tools, it is clear that, according to the sign of the coefficient of the term with highest degree, the value of the polynomial will rapidly approach plus or minus infinity as  $x$  increases (or decreases).

However, the above mentioned sign is even not stable under small changes of the defining values  $y_i$ . This is illustrated by the following two diagrams, displaying eleven values of the function  $\sin(x)$  with two different small changes of values. The interpolated function  $\sin(x)$  is the dotted line, the circles are the gently moved values  $y_i$  and the uniquely determined interpolation polynomial is the solid line. While the approximation is quite good inside the interval covering the eleven points, it is very poor at the margins.

There is a rich theory about the interpolation polynomials. If interested, consult the special literature.

**5.1.5. Remark.** Numerical instability caused by the closeness of (some of) the points  $x_i$  is clearly seen in the system of equations from the proof of the Theorem 5.1.3. When solving a system of linear equations, instability is closely related to the size of the determinant of the corresponding matrix. This is the Vandermonde determinant  $V$  in our case.

□ **Lemma.** For any sequence of pairwise distinct scalars  $x_0, \dots, x_n \in \mathbb{K}$ ,

$$V(x_0, \dots, x_n) = \prod_{i>k=0}^n (x_i - x_k).$$

**PROOF.** The proof is by induction on the number of the points  $x_i$ . The result is true for  $n = 1$ . (The problem is completely uninteresting for  $n = 0$ ). Suppose that the result is true for  $n - 1$ , i.e.

$$V(x_0, \dots, x_{n-1}) = \prod_{i>k=0}^{n-1} (x_i - x_k).$$

Consider the values  $x_0, \dots, x_{n-1}$  to be fixed, and vary the value of  $x_n$ . Expand the determinant by the last row (see

**Solution.** A straightforward computation reveals the expression  $P(z) = (-\frac{3}{5} - \frac{4}{5}i)z^2 + (2 + 3i)z - \frac{3}{5} - \frac{14}{5}i$ . We can compute this directly via Sage, as in 5.A.5, although we have to change the field into  $\mathbb{C}$ :

```
R = PolynomialRing(CC, "z")
R.lagrange_polynomial([(1+I, I), (2, 1), (3, -I)])
Sage returns the answer as follows:
(-0.6000000000000000 - 0.8000000000000000*I)*z^2
+ (2.0000000000000000 + 3.0000000000000000*I)*z
- 0.6000000000000000 - 2.8000000000000000*I
```

In the second case, the solution is easier. This is because the conditions are satisfied of the rotation by angle  $\pi/2$  in the complex plane. This means that the polynomial must be of the form  $f(z) = iz$ .  $\square$

*Assuming a bit of experience on elementary functions, we now proceed with tasks highlighting the interplay between elementary functions and polynomial interpolation. Later, in Chapter 7, we will study the so called Chebyshev polynomials, which may enrich this relationship.*

**5.A.11.** Based on Lagrange interpolation, present an approximate polynomial formula of the sine function, using the known values of  $\sin(x)$  at the points  $0, \frac{\pi}{6}, \frac{\pi}{4}, \frac{\pi}{3}, \frac{\pi}{2}$ . Next present the graphs of the interpolation polynomial and of  $\sin(x)$  for  $x \in [0, \pi]$ , including in your figure the given nodes.

**Solution.** According to the statement we have the table

$x$	0	$\pi/6$	$\pi/4$	$\pi/3$	$\pi/2$
$\sin(x)$	0	1/2	$\sqrt{2}/2$	$\sqrt{3}/2$	1

To solve our task we can use this table and apply the same technique in Sage, as above. This can be done by the block

```
nodes=[(0, 0), (pi/6, 1/2), (pi/4, sqrt(2)/2),
(pi/3, sqrt(3)/2), (pi/2, 1)]
R=PolynomialRing(RR, "x")
P=R.lagrange_polynomial(nodes); show(P)
```

Sage's answer says that the interpolation polynomial  $P(x)$  is approximately given by  $0.0288x^4 - 0.2043x^3 + 0.0214x^2 + 0.9956x$ .

Now, in order to produce the required graphs together with the given points, one may proceed with the code

```
nodes=[(0, 0), (pi/6, 1/2), (pi/4, sqrt(2)/2),
(pi/3, sqrt(3)/2), (pi/2, 1)]
R=PolynomialRing(RR, "x")
P=R.lagrange_polynomial(nodes)
A=plot(P, 0, pi, color="grey")
B=list_plot({0: 0, pi/6: 1/2, pi/4: sqrt(2)/2,
pi/3: sqrt(3)/2, pi/2: 1},
size=30, figsize=4, color="black")
C=plot(sin(x), 0, pi, color="black")
show(A+B+C, figsize=4)
```

We leave to the reader the implementation of this block.  $\square$

2.2.9). This exhibits the desired determinant as the polynomial

$$(1) \quad V(x_0, \dots, x_n) = (x_n)^n V(x_0, \dots, x_{n-1}) + \text{lower degree terms in } x_n.$$

This is a polynomial of degree  $n$  since its coefficient at  $(x_n)^n$  is non-zero, by the induction hypothesis. Evidently, it vanishes at any point  $x_n = x_i$  for  $i < n$  because in that case, the original determinant contains two identical rows. The polynomial is thus divisible by the expression

$$(x_n - x_0)(x_n - x_1) \cdots (x_n - x_{n-1}),$$

which itself is of degree  $n$ . It follows that the Vandermonde determinant (as a polynomial in the variable  $x_n$ ) must, up to a multiplicative constant, be given by

$$V(x_0, \dots, x_n) = c \cdot (x_n - x_0)(x_n - x_1) \cdots (x_n - x_{n-1}).$$

Comparing the coefficients at the highest power in (1) with this expression yields  $c = 1$ , which completes the proof.  $\square$

Notice that the value of the determinant is small if the points  $x_i$  are close together.

**5.1.6. Derivatives of polynomials.** The values of polynomials rapidly tend to infinite values as the input variable grows. Hence polynomials are unable to describe periodic events, such as the values of the trigonometric functions. One could say that we will achieve much better results, at least between the points  $x_i$ , if we look not only at the function values, but also at the rate of increase of the function at those points.

For this purpose, we introduce (only intuitively, for the time being) the concept of a *derivative* for polynomials. Again, we can work with real, complex or rational polynomials. The rate of increase of a real-valued polynomial  $f(x)$  at a point  $x \in \mathbb{R}$  should be related to the values

$$(1) \quad \frac{f(x + \delta x) - f(x)}{\delta x},$$

where  $\delta x$  is a small value in  $\mathbb{K}$  expressing the increment of the argument  $x$ . Since we can calculate (over an arbitrary ring)

$$(x + \delta x)^k = x^k + \cdots + \binom{k}{l} x^l (\delta x)^{k-l} + \cdots + (\delta x)^k,$$

The Lagrange interpolation method comes with an interpolation error (and an error bound), which we will briefly analyze in the final section E of this chapter (see 5.E.9, 5.E.10 and 5.E.11).

It is now reasonable to discuss problems where we should also regard the slope of the tangents to our polynomial at the given points. This amounts at employing the derivatives of the polynomials (see 5.1.6 if necessary), and it can be handled by the very same methods as before. Thus next we will meet the so called Hermite interpolation, a method introduced in 5.1.7 (see also 5.1.8).

**5.A.12. Hermite interpolation.** Find a polynomial  $P$  satisfying the following conditions:  $P(1) = 0$ ,  $P'(1) = 1$ ,  $P(2) = 3$ ,  $P'(2) = 3$ .

**Solution.** We provide two methods of finding the solution. 1st approach: The given conditions give rise to four linear equations in the coefficients of  $P$ . If we seek for a polynomial of degree less than four, we get the same number of equations and unknown coefficients. Hence assuming that  $P(x) = a_3x^3 + a_2x^2 + a_1x + a_0$  for some reals  $a_0, \dots, a_3$ , we get the equations

$$\begin{aligned} P(1) &= a_3 + a_2 + a_1 + a_0 = 0, \\ P'(1) &= 3a_3 + 2a_2 + a_1 = 1, \\ P(2) &= 8a_3 + 4a_2 + 2a_1 + a_0 = 3, \\ P'(2) &= 12a_3 + 4a_2 + a_1 = 3. \end{aligned}$$

Solving quickly this linear system by Sage, we get  $P(x) = -2x^3 + 10x^2 - 13x + 5$ .

2nd approach: This is based on Hermite's interpolation, which requires the description of the so-called *fundamental Hermite interpolation polynomials*  $h_i^{(1)}$  and  $h_i^{(2)}$  ( $i = 0, 1$ ), see 5.1.7. By assumption,  $x_0 = 1$ ,  $x_1 = 2$ , and we may set  $y_0 = P(x_0) = 0$ ,  $y_1 = P(x_1) = 3$ ,  $y'_0 = P'(x_0) = 1$  and  $y'_1 = P'(x_1) = 3$ . For an application of the Hermite's interpolation method one needs the function

$$\ell(x) = (x - x_0)(x - x_1) = (x - 1)(x - 2) = x^2 - 3x + 2.$$

Obviously  $\ell'(x) = 2x - 3$ , with  $\ell'(x_0) = -1$  and  $\ell'(x_1) = 1$ . Moreover, the second derivative is a constant function,  $\ell''(x) = 2$ . We also need the elementary Lagrange polynomials induced by the nodes  $x_0, x_1$ :

$$\ell_0(x) = \frac{x - x_1}{x_0 - x_1} = (2 - x), \quad \ell_1(x) = \frac{x - x_0}{x_1 - x_0} = (x - 1).$$

we get for the polynomial  $f(x) = a_nx^n + \dots + a_0$ , the above quotient (1) in the form

$$\begin{aligned} \frac{f(x+\delta x) - f(x)}{\delta x} &= a_n \frac{nx^{n-1}\delta x + \dots + (\delta x)^k}{\delta x} + \dots + a_1 \frac{\delta x}{\delta x} \\ &= na_nx^{n-1} + (n-1)a_{n-1}x^{n-2} + \dots + a_1 + \delta x(\dots) \end{aligned}$$

where the expression in parentheses in the end of the expression is polynomially dependent on  $\delta x$ . Clearly, for values  $\delta x$  very close to zero, there is a value arbitrarily close to the value in the following definition:

DERIVATIVES OF POLYNOMIALS

The derivative of the polynomial  $f(x) = a_nx^n + \dots + a_0$  with respect to the variable  $x$  is the polynomial

$$f'(x) = na_nx^{n-1} + (n-1)a_{n-1}x^{n-2} + \dots + a_1.$$

From the definition, it is clear that it is just the value  $f'(x_0)$  of the derivative which gives a good approximation of the polynomial's behaviour near the point  $x_0$ . More precisely, the lines

$$y = \frac{f(x_0 + \delta x) - f(x_0)}{\delta x}(x - x_0) + f(x_0),$$

that is, the secant lines of the graph of the polynomial going through the points  $[x_0, f(x_0)]$  and  $[x_0 + \delta x, f(x_0 + \delta x)]$  approach, as  $\delta x$  decreases, to the line

$$y = f'(x_0)(x - x_0) + f(x_0),$$

which is the "tangent" to the graph of the polynomial  $f$ . This is *linear approximation* to the polynomial  $f$  by its *tangent line*. Exact meaning to all these concepts is given later.

The derivative of polynomials is a linear mapping which, to polynomials of degree at most  $n$ , assigns polynomials of degree at most  $n - 1$ .

Iterating this procedure, there are the second derivative  $f''$ , the third derivative  $f^{(3)}$ , and generally after  $k$ -tuple iteration, the polynomial  $f^{(k)}$  of degree  $n - k$ . Thus the  $(n+1)$ -st derivative is the zero polynomial. This linear mapping is an example of cyclic nilpotent mappings, which are more thoroughly examined in paragraph 3.4.10.

The derivative behaves well also with respect to the multiplication of polynomials. A straightforward combinatorial check reveals the *derivation property* or *Leibniz rule* for this linear operator :

$$(f(x) \cdot g(x))' = f'(x) \cdot g(x) + f(x) \cdot g'(x).$$

Actually this is a purely algebraic result (which holds over any ring of scalars!) and you may either check it yourself or consult the formal proof in 12.3.7.

**5.1.7. Hermite's interpolation problem.** Consider  $m + 1$  pairwise distinct real numbers  $x_0, \dots, x_m$ , i.e.  $x_i \neq x_j$  for all  $i \neq j$ . It is desired to place polynomials through given values at these points, but to determine also the first derivatives of the interpolating polynomial in these points. Set  $y_i$  and  $y'_i$  for all  $i$ .

Now, according to the formulas given in 5.1.7 we have

$$\begin{aligned}
 h_0^{(1)}(x) &:= \left(1 - \frac{\ell''(x_0)}{\ell'(x_0)}(x - x_0)\right) (\ell_0(x))^2 \\
 &= (2x - 1)(x - 2)^2, \\
 h_1^{(1)}(x) &:= \left(1 - \frac{\ell''(x_1)}{\ell'(x_1)}(x - x_1)\right) (\ell_1(x))^2 \\
 &= (5 - 2x)(x - 1)^2, \\
 h_0^{(2)}(x) &:= (x - x_0)(\ell_0(x))^2 = (x - 1)(x - 2)^2, \\
 h_1^{(2)}(x) &:= (x - x_1)(\ell_1(x))^2 = (x - 2)(x - 1)^2.
 \end{aligned}$$

The polynomial  $P(x)$  is then given by the expression  $y_0 \cdot h_0^{(1)}(x) + y_1 \cdot h_1^{(1)}(x) + y'_0 \cdot h_0^{(2)}(x) + y'_1 \cdot h_1^{(2)}(x)$ , and we arrive to the same expression as above:

$$\begin{aligned}
 P(x) &= 0 \cdot h_0^{(1)}(x) + 3 \cdot h_1^{(1)}(x) + 1 \cdot h_0^{(2)}(x) \\
 &\quad + 3 \cdot h_1^{(2)}(x) = -2x^3 + 10x^2 - 13x + 5.
 \end{aligned}$$

In fact, one could avoid to compute explicitly  $h_0^{(1)}$ , since  $y_0 = 0$  by assumption. Notice also that our final computation can be verified quickly in Sage, via the block

```

h01(x)=(2*x-1)*(x-2)^2; h11(x)=(5-2*x)*(x-1)^2
h02(x)=(x-1)*(x-2)^2; h12(x)=(x-2)*(x-1)^2
y0=0; y1=3; dy0=1; dy1=3
P(x)=y0*h01(x)+y1*h11(x)+dy0*h02(x)+dy1*h12(x)
show(P(x).expand())
    
```

□

 *The next exercises on Hermite interpolation are helpful for a better understanding of the method but also for improving your computational skills (we suggest to treat these tasks with the help of Sage, as well). One can find further problems related to Hermite interpolation also in Section E, see 5.E.1.*

**5.A.13.** Determine the Hermite interpolation polynomial  $Q$  satisfying  $Q(-1) = -9$ ,  $Q(1) = -1$ ,  $Q'(-1) = 10$ ,  $Q'(1) = 2$ . ○

**5.A.14.** Replace the function  $f$  with a Hermite polynomial, having as initial data the following values of  $f$ :

$x_i$	-1	1	2
$f(x_i)$	4	-4	-8
$f'(x_i)$	8	-8	11

○

*Let us now focus on splines, a notion introduced in 5.1.9. Shortly, we look for (cubic) polynomials on intervals, prescribing the values and requesting the first and second derivatives to be shared in the boundary points. Splines are very popular in environmental research for image processing, where smooth interpolation becomes essential, e.g., for computational animation and image scaling.*

*However, a formal description of the spline through a given data can be often a tedious task. For instance, if we are*

A polynomial  $f$  is wanted which will satisfy these conditions on the values and derivatives.

As in the case of interpolating the values only, we obtain the following system of  $2(m+1)$  equations for the coefficients of the polynomial  $f(x) = a_n x^n + \dots + a_0$ :

$$\begin{aligned}
 a_0 + x_0 a_1 + \dots + (x_0)^n a_n &= y_0 \\
 &\vdots \\
 a_0 + x_m a_1 + \dots + (x_m)^n a_n &= y_m \\
 a_1 + 2x_0 a_2 + \dots + n(x_0)^{n-1} a_n &= y'_0 \\
 &\vdots \\
 a_1 + 2x_m a_2 + \dots + n(x_m)^{n-1} a_n &= y'_m.
 \end{aligned}$$

We could verify that with the choice  $n = 2m + 1$ , the determinant of this system is non-zero, and thus there is exactly one solution.

The polynomial  $f$  can be constructed immediately. Simply create a set of polynomials with values 0 or 1 respectively for the derivatives and the values, in order to express the desired values as the linear combination. We sketch briefly, how to construct them now, leaving the details to the reader.

The elementary Lagrange polynomials serve well for this purpose. The derivative of  $f(x) = (\ell_i(x))^2$  is  $2\ell'_i(x)\ell_i(x)$  and thus all  $x_j$  are roots of this polynomial, except for  $j = i$ . Similarly for the derivative  $f'(x)$ . But a polynomial of degree  $2m + 1$  is wanted. So we consider rather  $g(x) = (x - x_i)f(x)$ . Now the values will be all zero, while the derivative  $g'(x) = f(x) + (x - x_i)f'(x)$  has the required properties too. Thus we take  $h_i^{(2)}(x) = (x - x_i)(\ell_i(x))^2$ . This is called the *fundamental Hermitian polynomial*<sup>2</sup> of the second type.

Finally we look for a polynomial which has zero derivatives at all points  $x_i$  with the same values as  $\ell_i$  at the given points  $x_i$ . We can apply a very similar trick. Look for polynomials of the form  $h_i^{(1)}(x) = (1 - a(x - x_i))(\ell_i(x))^2$ . All  $x_j$  will be roots of this polynomial, except for  $j = i$  where

<sup>2</sup>Charles Hermite (1822-1901) was a Frenchman active in many areas of Mathematics. His name is mostly linked to the Hermitian operators and matrices, cf. 3.4.6.

given  $n \geq 2$  points and values in them, then we need to solve  $4n - 4$  linear equations. Fortunately, using computers we may establish algorithms which lead to much faster computer implementations. In order to illustrate this situation, below we proceed by combining the appropriate syntax of Sage. But let us first present a more basic example.

**5.A.15. Splines.** Find a natural cubic spline  $S$  satisfying  $S(-1) = 0$ ,  $S(0) = 1$ ,  $S(1) = 0$ , and present its graph for  $x$  in the closed interval  $[-1, 1]$ .

**Solution.** We have three nodes and the intervals  $[x_0, x_1] = [-1, 0]$  and  $[x_1, x_2] = [0, 1]$ , that is,  $n = 2$  in terms of the paragraph 5.1.9. Thus the spline that we are looking for consists of two cubic polynomials, say  $S_1(x) = ax^3 + bx^2 + cx + d$ , and  $S_2(x) = ex^3 + fx^2 + gx + h$ , with domain the intervals  $[-1, 0]$  and  $[0, 1]$ , respectively, with  $a, b, \dots, h \in \mathbb{R}$ . Applying the definition of cubic splines for  $n = 2$ , one obtains six linear equations in terms of  $a, b, \dots, h$ :

$$S_1(-1) = 0, S_2(0) = 1, S_1(0) = 1, S_2(1) = 0, \\ S_1'(0) = S_2'(0), S_1''(0) = S_2''(0).$$

In addition,  $S$  must be a natural spline, and this corresponds to the vanishing of the second derivatives of  $S_1 = ax^3 + bx^2 + cx + d$  and  $S_2 = ex^3 + fx^2 + gx + h$  at the points  $-1$  and  $1$ , respectively:  $S_1''(-1) = 0$  and  $S_2''(1) = 0$ . Hence we arrive to a system of eight equations, which in fact we can reduce in the following way. Thanks to the given value at  $0$ , we know that the absolute coefficients of both the polynomials are  $1$ . The resulting spline has to be symmetric along the  $y$  axis, otherwise we would get two splines satisfying the condition by the reflection along the axis. Here we are based on the fact that a natural cubic spline is unique. Thus, the only possibility for the common values for the first derivatives of  $S_1$  and  $S_2$  at zero is zero, further the second derivatives in zero have to agree, that is  $b = d$ , and the symmetry gives also  $a = -c$ .

So far we have  $S_1(x) = ax^3 + bx^2 + 1$  and  $S_2(x) = -ax^3 + bx^2 + 1$ . Now the conditions  $S_1(-1) = 0$  and  $S_1'(-1) = 0$  correspond to the equations  $-a + b + 1 = 0$  and  $-6a + 2b = 0$ , respectively. Solving this system we obtain  $S_1(x) = -\frac{1}{2}x^3 - \frac{3}{2}x^2 + 1$ ,  $S_2(x) = \frac{1}{2}x^3 - \frac{3}{2}x^2 + 1$ . Altogether,

$$S(x) = \begin{cases} -\frac{1}{2}x^3 - \frac{3}{2}x^2 + 1, & \text{if } x \in [-1, 0], \\ \frac{1}{2}x^3 - \frac{3}{2}x^2 + 1, & \text{if } x \in [0, 1]. \end{cases}$$

For the graph of the spline via Sage, we obtain the figure presented below (we used blue colour for  $S_1$  and green for  $S_2$ )

the value is  $1$ . The derivative is

$$(h_i^{(1)}(x))' = -a(\ell_i(x))^2 + (1 - a(x - x_i))2\ell_i(x)\ell_i'(x).$$

All  $x_j, j \neq i$ , are roots of  $\ell_i(x)$ , thus they are also roots of this polynomial. Finally, at the point  $x_i$  we want  $0 = -a + 2\ell_i'(x_i)$ . Thus we choose  $a = 2\ell_i'(x_i)$ .

The combinatorial check that  $2\ell_i'(x_i) = \frac{\ell''(x_i)}{\ell'(x_i)}$  is left to the reader. We summarize:

#### HERMITE'S 1ST ORDER INTERPOLATION POLYNOMIAL

The *fundamental Hermite polynomials* are defined as follows:

$$h_i^{(1)}(x) = \left(1 - \frac{\ell''(x_i)}{\ell'(x_i)}(x - x_i)\right) (\ell_i(x))^2 \\ h_i^{(2)}(x) = (x - x_i) (\ell_i(x))^2,$$

where  $\ell(x) = \prod_{i=0}^m (x - x_i)$ ,  $\ell_i(x)$  is the elementary Lagrange polynomial. These polynomials satisfy:

$$h_i^{(1)}(x_j) = \delta_i^j = \begin{cases} 1 & \text{for } i = j \\ 0 & \text{for } i \neq j \end{cases} \\ (h_i^{(1)})'(x_j) = 0 \\ h_i^{(2)}(x_j) = 0 \\ (h_i^{(2)})'(x_j) = \delta_i^j.$$

The *Hermite's interpolation polynomial* is given by the expression

$$f(x) = \sum_{i=0}^m (y_i h_i^{(1)}(x) + y_i' h_i^{(2)}(x)).$$

**5.1.8. Examples of Hermite's polynomials.** The simplest example is the one of prescribing the value and the derivative at one point. This determines a polynomial of degree one

$$f(x) = f(x_0) + f'(x_0)(x - x_0).$$

This is exactly the equation of the straight line given by the value and slope at the point  $x_0$ . When we set the values and the derivatives at two points, i.e.  $y_0 = f(x_0)$ ,  $y_0' = f'(x_0)$ ,  $y_1 = f(x_1)$ ,  $y_1' = f'(x_1)$  for two distinct points  $x_i$ , we still obtain an easily computable problem.

Consider the simple case when  $x_0 = 0$ ,  $x_1 = 1$ . Then the matrix of the system and its inverse is

$$A = \begin{pmatrix} 0 & 0 & 0 & 1 \\ 1 & 1 & 1 & 1 \\ 0 & 0 & 1 & 0 \\ 3 & 2 & 1 & 0 \end{pmatrix}, A^{-1} = \begin{pmatrix} 2 & -2 & 1 & 1 \\ -3 & 3 & -2 & -1 \\ 0 & 0 & 1 & 0 \\ 1 & 0 & 0 & 0 \end{pmatrix}.$$

The multiplication  $A^{-1} \cdot (y_0, y_1, y_0', y_1')^T$  gives the vector  $(a_3, a_2, a_1, a_0)^T$  of coefficients of the polynomial  $f$ , i.e.

$$f(x) = (2y_0 - 2y_1 + y_0' + y_1')x^3 \\ + (-3y_0 + 3y_1 - 2y_0' - y_1')x^2 + y_0'x + y_0.$$

**5.A.16. Splines via Sage.** Splines can be treated in Sage via the command `spline`. For instance, a graphical implementation of the previous example in Sage relies on the given interpolated points and goes as follows:

```
pts=[(-1, 0), (0, 1), (1, 0)]; S=spline(pts)
a=plot(S, -1, 1, color="darkgray", figsize=4)
show(points(pts)+a)
```

Verify yourself that for the spline in question this syntax gives us the same graph (so this provides a graphical verification of our previous computation).

Changing the points of the spline causes of course the spline to be recomputed. Notice also that this syntax does not return the explicit form of  $S$ , as a cubic polynomial. However, it allows us to compute the values of the spline, e.g., by adding the syntax

```
show(S(0.4)); show(S(0.5)); show(S(0.6))
```

This returns the values of  $S$  at the chosen points, and one can easily verify that these values coincide with the values that we obtain by applying the given solution in 5.A.15 at the same points. Notice however that we cannot compute the value of the spline at points that are not included in between the given interpolated points.

**5.A.17.** Find a (cubic) spline  $S$  which satisfies  $S(-1) = 0$ ,  $S(0) = 1$ ,  $S(1) = 0$ ,  $S'(-1) = -1$ ,  $S'(1) = 1$ . Hint: Apply the same trick as in 5.A.15. ○

**5.A.18.** Interpolate the function  $f(x) = e^{x^2} - e$  on the interval  $[-6/5, 6/5]$  by the (unique) natural cubic spline  $S$  corresponding to the partition  $x_0 = -1.2$ ,  $x_1 = -1$ ,  $x_2 = 0$ ,  $x_3 = 1$ ,  $x_4 = 1.2$ . Next, using Sage plot the functions  $f$  and  $S$  (together with the interpolated nodes), and based on the “`spline`” method described in 5.A.16, verify your result.

**Solution.** By assumption we have five nodes,  $x_0 = -1.2$ ,  $x_1 = -1$ ,  $x_2 = 0$ ,  $x_3 = 1$ ,  $x_4 = 1.2$ , and so four intervals  $[x_0, x_1]$ ,  $[x_1, x_2]$ ,  $[x_2, x_3]$ ,  $[x_3, x_4]$ . Thus, in terms of the definition of cubic splines given in paragraph 5.1.9 we have

**5.1.9. Spline interpolation.** We can prescribe any finite number of derivatives at the particular points and a convenient choice for the upper bound on the degree of the desired polynomial, leading to a unique interpolation. Unfortunately, these interpolations do not solve the problems mentioned already – complexity of the computations and instability. However, a smarter usage of derivatives allows an improvement.

As we have seen, small local changes of the values may dramatically affect the overall changes of the behaviour of the resulting polynomial. In particular, this may happen outside of the interval covered by the points  $x_i$ . We try gluing together polynomial pieces of low degree.

The simplest possibility is to interpolate each pair of adjacent points by a polynomial of degree at most one. This corresponds either to the interpolation by values with two points, or by guessing the slope and employing Hermite’s first order interpolation at a single point. This is a common way of displaying data. This means that derivatives will be constant on each of the segments, with a discontinuous ‘jump’ at the given points. There is no freedom for improvements.

A more sophisticated method is to prescribe the value and the derivative at each point. We have then four values for each pair of neighbouring points. As seen earlier, this uniquely determines Hermite’s polynomial of degree three. This polynomial can then be used for all the values of the input variable between the distinguished points  $x_0 < x_1$ . Such a piece-wise polynomial approximation has the property that the first derivatives will be compatible (equal) at the meeting points  $x_i$  in the interval  $[x_0, x_1]$ .

In practice, mere compatibility of the first derivatives is often insufficient. Consider for instance railway tracks, where the second derivative corresponds to acceleration. Discontinuous jumps would be very undesirable for the second derivative. So instead of requiring fixed values of the first derivatives, we request equality of both first and second derivatives at adjacent pieces of the cubic polynomials, as well as fixing the values at the given points. This requirement yields the same number of equations and unknowns, and so the problem is solvable similarly to the 1st order Hermite interpolation problem:

CUBIC SPLINES

Let  $x_0 < x_1 < \dots < x_n$  be real values at which the required values  $y_0, \dots, y_n$  are given. A *cubic interpolation spline* for this assignment is a function  $S : \mathbb{R} \rightarrow \mathbb{R}$  which satisfies the following conditions:

- the restrictions of  $S$  on the intervals  $[x_{i-1}, x_i]$  are polynomials  $S_i$  of degree at most three, for all  $i = 1, \dots, n$
- $S_i(x_{i-1}) = y_{i-1}$  and  $S_i(x_i) = y_i$  for all  $i = 1, \dots, n$ ,
- $S'_i(x_i) = S'_{i+1}(x_i)$  for all  $i = 1, \dots, n - 1$ ,
- $S''_i(x_i) = S''_{i+1}(x_i)$  for all  $i = 1, \dots, n - 1$ .

$n = 4$ . This means that the spline  $S(x)$  has the form

$$\begin{cases} S_1(x) = a_3x^3 + a_2x^2 + a_1x + a_0, & x \in [-\frac{6}{5}, -1], \\ S_2(x) = b_3x^3 + b_2x^2 + b_1x + b_0, & x \in [-1, 0], \\ S_3(x) = c_3x^3 + c_2x^2 + c_1x + c_0, & x \in [0, 1], \\ S_4(x) = d_3x^3 + d_2x^2 + d_1x + d_0, & x \in [1, \frac{6}{5}], \end{cases}$$

with  $a_i, b_i, c_i, d_i \in \mathbb{R}$  for all  $i = 0, 1, 2, 3$ . In our terms, we also have  $y_0 = f(x_0) \approx 1.502$ ,  $y_1 = f(x_1) = 0$ ,  $y_2 = f(x_2) \approx -1.718$ ,  $y_3 = f(x_3) = 0$ ,  $y_4 = f(x_4) \approx 1.502$ . Let us summarize the sixteen conditions that determine  $S$ :

$$\begin{aligned} S_1(x_0) = y_0 &\Leftrightarrow -(\frac{6}{5})^3 a_3 + (\frac{6}{5})^2 a_2 - \frac{6}{5} a_1 + a_0 = 1.502, \\ S_2(x_1) = y_1 &\Leftrightarrow -b_3 + b_2 - b_1 + b_0 = 0, \\ S_3(x_2) = y_2 &\Leftrightarrow c_0 = -1.718, \\ S_4(x_3) = y_3 &\Leftrightarrow d_3 + d_2 + d_1 + d_0 = 0, \\ S_1(x_1) = y_1 &\Leftrightarrow -a_3 + a_2 - a_1 + a_0 = 0, \\ S_2(x_2) = y_2 &\Leftrightarrow b_0 = -1.718, \\ S_3(x_3) = y_3 &\Leftrightarrow c_3 + c_2 + c_1 + c_0 = 0, \\ S_4(x_4) = y_4 &\Leftrightarrow (\frac{6}{5})^3 d_3 + (\frac{6}{5})^2 d_2 + \frac{6}{5} d_1 + d_0 = 1.502, \\ S'_1(x_1) = S'_2(x_1) &\Leftrightarrow 3a_3 - 2a_2 + a_1 = 3b_3 - 2b_2 + b_1, \\ S'_2(x_2) = S'_3(x_2) &\Leftrightarrow b_1 = c_1, \\ S'_3(x_3) = S'_4(x_3) &\Leftrightarrow 3c_3 + 2c_2 + c_1 = 3d_3 + 2d_2 + d_1, \\ S''_1(x_1) = S''_2(x_1) &\Leftrightarrow -6a_3 + 2a_2 = -6b_3 + 2b_2, \\ S''_2(x_2) = S''_3(x_2) &\Leftrightarrow b_2 = c_2, \\ S''_3(x_3) = S''_4(x_3) &\Leftrightarrow 6c_3 + 2c_2 = 6d_3 + 2d_2, \\ S''_1(x_0) = 0 &\Leftrightarrow -(\frac{36}{5})a_3 + 2a_2 = 0, \\ S''_4(x_4) = 0 &\Leftrightarrow (\frac{36}{5})d_3 + 2d_2 = 0. \end{aligned}$$

Solving in Sage this system of linear equations we get a unique solution given by

$$\begin{aligned} S_1(x) &= \frac{4933}{380}x^3 + \frac{44397}{950}x^2 + \frac{228243}{4750}x + \frac{135841}{9500}, \\ S_2(x) &= -\frac{28837}{9500}x^3 - \frac{3129}{2375}x^2 - \frac{859}{500}, \\ S_3(x) &= \frac{28837}{9500}x^3 - \frac{3129}{2375}x^2 - \frac{859}{500}, \\ S_4(x) &= -\frac{4933}{380}x^3 + \frac{44397}{950}x^2 - \frac{228243}{4750}x + \frac{135841}{9500}. \end{aligned}$$

Hence the plot of  $S(x)$  in  $[-1.2, 1.2]$  is given by

The cubic spline<sup>3</sup> for  $n + 1$  points consists of  $n$  cubic polynomials. There are  $4n$  free parameters (the first condition from the definition). The other conditions then yield  $2n + (n - 1) + (n - 1)$  more equalities. Two parameters remain free. The values of the derivatives at the marginal points may be prescribed explicitly (the *complete spline*), or the second derivatives can be set to zero (the *natural spline*).

Unfortunately, the computation of the whole spline is not as easy as with the independent computations of Hermite's cubic polynomials because the data mingles between adjacent intervals. However, ordering the variables and equations properly, gives a matrix of the system such that all of its non-zero elements appear only on three diagonals. These matrices are nice enough to be solved in a time proportional to the number of points, using a suitable numerical method. The results are stunning.

For comparison, look at the interpolation of the same data as in the case of the Lagrange polynomial, now using splines. The spline is the solid line, the interpolated function is again the dotted line.

Although the diagrams look nearly identical, the data is different.

## 2. Real numbers and limit processes

Polynomials and splines do not supply a sufficiently large stock of functions to express many dependencies.

Actually, the first problem to solve is how to define the values of more general functions at all. In principle, all we can get with a finite number of multiplications and additions is polynomial functions. Perhaps division by polynomial quantities, and some efficient manipulation with rational numbers can be done. However, we cannot restrict ourselves to rational numbers. For instance,  $\sqrt{2}$  is not a rational number.

Thus the first step is a thorough introduction to limit processes. We define precisely what it means for a sequence of numbers to approach another number.

<sup>3</sup>The name comes from the name of an elastic ruler used by engineers to draw smooth curve interpolation points. In fact, the requirement on the equality of the first and second derivatives is a good model for natural elasticity behaviour.

Using the command `spline` one can obtain a graphical verification, as before. Although the code is given below, we leave to the reader to check the result alone.

```
f(x)=e^(x^2)-e
plf=plot(f, x, -1.2, 1.2, color="black")
pts=[(-1.2, f(-1.2)), (-1, f(-1)), (0, f(0)),
(1, f(1)), (1.2, f(1.2))]
S=spline(pts)
sps=plot(S, -1.2, 1.2, color="steelblue")
show(points(pts, size=40)+sps+plf)
```

□

**5.A.19.** Without calculation, construct the natural cubic interpolation spline for the points  $x_0 = -1$ ,  $x_1 = 0$  and  $x_2 = 2$  and the value  $y_0 = y_1 = y_2 = 1$  at these points.

**Solution.** The natural splines request the second derivative in the outer boundary points to vanish. Thus, the constant spline  $S_1(x) \equiv 1$ ,  $S_2(x) \equiv 1$  satisfies all conditions and thus it must be the unique solution. □

**5.A.20.** Construct the natural cubic interpolation spline for the function  $f(x) = 1/(1 + x^2)$  selecting the nodes  $x_0 = 0$ ,  $x_1 = 1$ , and  $x_2 = 3$ . ○

*Addition problems concerning polynomial interpolation can be found in the final section E, see also Chapter 6.*

## B. Real numbers and limit processes

*In this section we treat limits of sequences and of functions. We will also discuss some basic topological notions about subsets of the real line  $\mathbb{R}$  or the complex plane  $\mathbb{C}$ . In this way we will establish the foundations of calculus, but also become familiar with elementary ideas from mathematical analysis, that we will revise finally later, in Chapter 7.*

*Functions and limits are some of the most fundamental concepts in mathematics and are ideas that came of age in the 17th century.<sup>3</sup> The French mathematician Augustin-Louis*

<sup>3</sup> The French mathematician Pierre de Fermat (1607-1665) was one of the first realizing the importance of limits. When later Newton and Leibniz invented the calculus they don't use "delta-epsilon" proofs, and it took more than a century to develop them. From this perspective, it should be no wonder that often modern students find an introduction to calculus difficult. Hence you should not worry much whenever some of the notions that we discuss

An important property of polynomials is the “continuous” dependency of their values on the input variable. We expect intuitively that if  $x$  is changed by a little, then the value of  $f(x)$  also changes only a little. This behaviour is not possessed by piece-wise constant functions  $f : \mathbb{R} \rightarrow \mathbb{R}$  near the “jump discontinuities”. For instance, the *Heaviside function*<sup>4</sup>

$$f(x) = \begin{cases} 0 & \text{for all } x < 0, \\ 1/2 & \text{for } x = 0, \\ 1 & \text{for all } x > 0 \end{cases}$$

has this type of “discontinuity” for  $x = 0$ .

We formalize these intuitive statements.

**5.2.1. Real numbers.** We have dealt with algebraic properties of real numbers, summarized by the claim that  $\mathbb{R}$  is a field. However, we have also used the relation of the standard (total) ordering of the real numbers, denoted by “ $\leq$ ”. See the paragraph 1.6.3 on the page 43.

The properties (axioms) of the real numbers, including the connections between the relations and other operations, are enumerated in the following table. The bars indicate how the axioms guarantee that the real numbers form an abelian (commutative) group with respect to addition, that  $\mathbb{R} \setminus \{0\}$  is an abelian group with respect to multiplication, that  $\mathbb{R}$  is a field, that the set  $\mathbb{R}$  together with the operations  $+$ ,  $\cdot$  and the order relation is an *ordered field*. The last axiom can be considered as claiming that  $\mathbb{R}$  is “sufficiently dense”.

<sup>4</sup> Oliver Heaviside was an unconventional English electrical engineer (1850-1925) with an innovative and very original approach to practical mathematical modelling. His famous sayings include “*Mathematics is an experimental science, and definitions do not come first, but later on*”. Or, defending his incomplete argumentation, “*I do not refuse my dinner simply because I do not understand the process of digestion*”. Is this suggestive of the methodology of this textbook?

Cauchy (1789-1867) was probably the first who put the calculus in a rigorous basis. To be more specific, Cauchy introduced the “delta-epsilon” notation commonly encountered in the definition of limits. While such proofs are presented here, we have chosen to de-emphasize them after a certain point. This is because many calculus problems can be approached in various alternative ways. Additionally, this approach allows us to conserve space, which is then utilized to implement solutions using Sage

Our initial tasks involve the concepts of the supremum ( $\sup A$ ) and the infimum ( $\inf A$ ) of a subset  $A$  of real or complex numbers, which are elementary notions discussed in 5.2.1. These represent the smallest upper bound and the largest lower bound of  $A$ , respectively. They always exist when  $A$  is a bounded subset, but they do not necessarily belong to  $A$ , as they can be either limit points or isolated points of  $A$ , see 5.2.5 and 5.2.7.

5.B.1. Find  $\sup A$  and  $\inf A$ , if they exist, for

$$A = \left\{ n + \frac{(-1)^n}{n} : n \in \mathbb{N}^* \right\} \subset \mathbb{R},$$

where as usual we set  $\mathbb{N}^* = \mathbb{N} \setminus \{0\} = \mathbb{Z}_+$ .

5.B.2. Determine the infima and suprema of the sets

$$B = \left\{ \frac{(-1)^n}{n^2} : n \in \mathbb{Z}_+ \right\}, \quad C = (-9, 9) \cap \mathbb{Q},$$

$$X = \left\{ -\frac{1}{n} : n \in \mathbb{Z}_+ \right\}, \quad Y = (0, 2] \cup [3, 5] \setminus \{4\},$$

and look whether they belong to them or not.

Sequence are functions defined on the set of natural numbers. Next we are interesting in the behaviour of such functions as  $n$  tends to infinity, see also the discussion in 5.2.3, 5.2.9 and 5.2.10. To begin with, recall that for any subset  $A$  of reals or complex numbers we can assign the notion of “limit points” of  $A$ . These are points  $x$  for which each of their  $\varepsilon$ -neighbourhoods  $\mathcal{O}_\varepsilon(x) = \{z : |z - x| < \varepsilon\}$  contains at least one point from  $A$  other than  $x$ . Be aware that limit points may not belong to  $A$ . Having in hand this definition of limit points we can define a “convergent sequence”  $(x_n)$  of real or complex numbers, as a sequence approaching its only limit point  $x$ , as  $n$  tends to infinity, see 5.2.3. In this case we say that  $(x_n)$  converges to  $x$  (or that tends to  $x$ ), and write  $x_n \rightarrow x$ , or  $\lim_{n \rightarrow \infty} x_n = x$ . When the limit does not exist as a real, or complex number, or is  $\pm\infty$ , the sequence  $(x_n)$  is called divergent, see also below.

Notice that in our definition of limits points the neighbourhood  $\mathcal{O}_\varepsilon(x)$  is either an open interval in  $\mathbb{R}$ , or an open disc in  $\mathbb{C}$ . The related topological notion of open sets is introduced in 5.2.7, see also 5.2.5. To make the description in this

below seem difficult. To master with limits, it takes a little while. Once it is mastered, however, it becomes easier to understand differentiation and integration.

AXIOMS OF THE REAL NUMBERS

- (R1)  $(a + b) + c = a + (b + c)$ , for all  $a, b, c \in \mathbb{R}$
- (R2)  $a + b = b + a$ , for all  $a, b \in \mathbb{R}$
- (R3) there is an element  $0 \in \mathbb{R}$  such that for all  $a \in \mathbb{R}$ ,  $a + 0 = a$
- (R4) for all  $a \in \mathbb{R}$ , there is an additive inverse  $(-a) \in \mathbb{R}$  such that  $a + (-a) = 0$
- (R5)  $(a \cdot b) \cdot c = a \cdot (b \cdot c)$ , for all  $a, b, c \in \mathbb{R}$
- (R6)  $a \cdot b = b \cdot a$  for all  $a, b \in \mathbb{R}$
- (R7) there is an element  $1 \in \mathbb{R}$ ,  $1 \neq 0$ , such that for all  $a \in \mathbb{R}$ ,  $1 \cdot a = a$
- (R8) for all  $a \in \mathbb{R}$ ,  $a \neq 0$ , there is a multiplicative inverse  $a^{-1} \in \mathbb{R}$  such that  $a \cdot a^{-1} = 1$
- (R9)  $a \cdot (b + c) = a \cdot b + a \cdot c$ , for all  $a, b, c \in \mathbb{R}$
- (R10) the relation  $\leq$  is a total order, i.e. reflexive, anti-symmetric, transitive, and total on  $\mathbb{R}$
- (R11) for all  $a, b, c \in \mathbb{R}$ ,  $a \leq b$  implies  $a + c \leq b + c$
- (R12) for all  $a, b \in \mathbb{R}$ ,  $a > 0$  and  $b > 0$  implies  $a \cdot b > 0$
- (R13) every non-empty set  $A \subset \mathbb{R}$  which has an upper bound has a least upper bound.

The concept of a least upper bound from axiom (R13), also called the *supremum*, is very important. It makes sense for any partially ordered set. This is a set with a (not necessarily total) ordering relation. Recall that an ordering relation is a binary relation on a set which is reflexive, antisymmetric, and transitive; see the paragraph 1.6.3.

SUPREMUM AND INFIMUM

Consider a subset  $A \subset B$  in a partially ordered set  $B$ . An *upper bound* of the set  $A$  is any element  $b \in B$  such that  $b \geq a$  for all  $a \in A$ .

Similarly, a *lower bound* of the set  $A$  is an element  $b \in B$  such that  $b \leq a$  for all  $a \in A$ .

The least upper bound of the set  $A$ , if it exists, is called its *supremum* and it is denoted by  $\sup A$ . Similarly, the greatest lower bound, if it exists, is called the *infimum* and it is denoted by  $\inf A$ .

Thus, the last axiom (R13) from the table of properties of the real numbers can be reformulated as follows: *Every non-empty bounded set  $A$  of real numbers has a supremum. This means that if there is a number  $a$  which is larger than or equal to all numbers  $x \in A$ , then there is a smallest number with this property.*

For instance, the choice  $A = \{x \in \mathbb{Q}, x^2 < 2\}$  gives the supremum  $\sup A$  which is called  $\sqrt{2}$ ; the square root of two.

An immediate consequence of this axiom is the existence of the infima for any non-empty set of real numbers bounded from below. Observe that changing the sign of all the numbers in a set interchanges suprema and infima.

For the formal construction, it is necessary to know whether or not there is such a set  $\mathbb{R}$  with the operations and ordering relation which satisfies the thirteen axioms. So far,

column more functional, we decided to present problems related to such (and other) topological notions a few later, after mastering the notion of limits.

**5.B.3. Convergence and divergence.** Based on the formal definition of the convergence or the divergence of a sequence, prove the following:

- (a)  $a_n = \frac{1}{n} \rightarrow 0$ , as  $n \rightarrow +\infty$ ,
- (b)  $a_n = \frac{1}{n^2} \rightarrow 0$ , as  $n \rightarrow +\infty$ ,
- (c)  $a_n = \frac{n}{n+1} \rightarrow 1$ , as  $n \rightarrow +\infty$ ,
- (d) if  $0 < x < 1$  then  $a_n = x^n \rightarrow 0$ , as  $n \rightarrow +\infty$ ,
- (e) if  $x > 1$  then  $a_n = x^n \rightarrow +\infty$ , as  $n \rightarrow +\infty$ ,
- (f)  $a_n = n^2 \rightarrow +\infty$ , as  $n \rightarrow +\infty$ .

**Solution.** (a) Let  $\varepsilon > 0$  be given. We have to find some positive integer  $N$  such that  $|\frac{1}{n} - 0| < \varepsilon$  for all  $n \geq N$ . Clearly, the condition  $|\frac{1}{n} - 0| < \varepsilon$  is equivalent to  $\frac{1}{n} < \varepsilon$ , i.e.,  $n > \frac{1}{\varepsilon}$ . Hence taking  $N \in \mathbb{Z}_+$  with  $N > \frac{1}{\varepsilon}$  we see that  $\frac{1}{n} \leq \frac{1}{N} < \varepsilon$  so that  $|\frac{1}{n} - 0| < \varepsilon$  for all  $n \geq N$ . This means that  $\frac{1}{n} \rightarrow 0$ .

(b) For any  $\varepsilon > 0$  we see that  $\frac{1}{n^2} < \varepsilon$  is equivalent to  $n^2 > \frac{1}{\varepsilon}$ , that is,  $n > \frac{1}{\sqrt{\varepsilon}}$ . Thus, taking  $N \in \mathbb{Z}_+$  with  $N \geq 1/\sqrt{\varepsilon}$  we have  $\frac{1}{n^2} < \varepsilon$ , for all  $n \geq N$ . It follows that  $\frac{1}{n^2} \rightarrow 0$ .

(c) Again, for given  $\varepsilon > 0$  we wish to find some  $N \in \mathbb{Z}_+$  such that  $|\frac{n}{n+1} - 1| < \varepsilon$ , provided that  $n \geq N$ . Notice that the condition  $|\frac{n}{n+1} - 1| < \varepsilon$  is equivalent to  $\frac{1}{n+1} < \varepsilon$ , i.e.,  $\frac{1}{\varepsilon} < n + 1$ . Hence, choosing  $N$  with  $N > \frac{1}{\varepsilon} - 1$  we see that the inequality  $n \geq N$  implies  $n + 1 > \frac{1}{\varepsilon}$ , and hence  $|\frac{n}{n+1} - 1| < \varepsilon$ . Thus  $\frac{n}{n+1} \rightarrow 1$ .

(d) We have  $0 < x < 1$  and thus  $\frac{1}{x} > 1$ . Hence  $\frac{1}{x} = 1 + h$ , for some  $h > 0$ , and by applying the binomial rule  $\sum_{k=0}^n \binom{n}{k} a^{n-k} b^k$  for the power  $(\frac{1}{x})^n$  we get

$$\frac{1}{x^n} = (1 + h)^n = (1 + nh + \dots + h^n) > 1 + nh.$$

Thus  $0 < x^n < \frac{1}{1+nh}$ . Since  $\frac{1}{1+nh} \rightarrow 0$  we will also have  $x^n \rightarrow 0$ , as  $n \rightarrow \infty$ . For instance, given some  $\varepsilon > 0$  we see that  $0 < x^n < \varepsilon$  is true whenever  $\frac{1}{1+nh} < \varepsilon$ . Hence for  $n \geq N$  with  $N$  being the least positive integer larger than  $\frac{(1/\varepsilon)-1}{h}$ , we are done.

(e) Let us describe a proof that again is based on the binomial theorem. Since  $x > 1$  we may write  $x = 1 + h$  for some  $h > 0$  and by the binomial rule we deduce that  $x^n \geq nh$  for all  $n$ . Since  $nh \rightarrow \infty$  it follows that  $x^n \rightarrow \infty$  as well. In fact in this case we say that the sequence  $(x^n)$  “diverges to infinity”. It is useful to state this as a general rule: For a sequence  $(a_n)$  saying that  $a_n \rightarrow +\infty$  we essentially mean that for any given  $\zeta > 0$  there exists some  $N \in \mathbb{Z}_+$  such that  $a_n > \zeta$  for all  $n \geq N$ . Similarly, saying that a sequence  $(a_n)$  diverges to  $-\infty$  we essentially mean that for any given  $\zeta > 0$  there exists  $N \in \mathbb{Z}_+$  such that  $a_n < -\zeta$  for all  $n \geq N$ .

Let us finally consider case (f). Given  $\zeta > 0$ , the condition

only the rational numbers have been constructed formally. These form an ordered field. This means that  $\mathbb{Q}$  satisfies the axioms (R1) – (R12), and this can easily be verified.

We do not go into details here of the consistent construction of the real numbers now. We will be satisfied with an intuitive idea of the real line, and we will work with the axioms (R1) through R(13). But we shall come back to this issue in a more general framework in chapter 7, see the paragraph 5.2.4 and the discussion started in 7.3.6. Actually, we shall see, that if the real numbers can be constructed, then the construction is unique up to isomorphism. This is a bijection preserving all algebraic structures of two different realizations of the field  $\mathbb{R}$ .

**5.2.2. The complex plane.** Recall that the complex numbers are given as pairs of real numbers. We usually write them as  $z = \text{Re } z + i \text{Im } z$ . Therefore, the plane  $\mathbb{C} = \mathbb{R}^2$  is an appropriate image of the complex numbers.

With addition and multiplication, the complex numbers satisfy the axioms (R1)-(R9) and thus form a field. There is, however, no natural ordering defined on them which would satisfy the axioms (R10)-R(13). Nevertheless, we work with them, since extending real scalars to the complex numbers is highly advantageous or sometimes even necessary.

There is an important operation on the complex numbers called *complex conjugation*. It is the reflection symmetry with respect to the line of real numbers. We denote it by a bar over the number  $z \in \mathbb{C}$ :

$$\bar{z} = \text{Re } z - i \text{Im } z.$$

It changes the sign of the imaginary part. Since for  $z = x + iy$ ,

$$z \cdot \bar{z} = (x + iy)(x - iy) = x^2 + y^2,$$

this value expresses the squared distance of the complex numbers from the origin. The square root of this non-negative real number is called the absolute value of the complex number  $z$ ; written

$$(1) \quad |z|^2 = z \cdot \bar{z}.$$

The absolute value can be defined on any ordered field of scalars  $\mathbb{K}$ . Define the *absolute value*  $|a|$  as follows:

$$|a| = \begin{cases} a & \text{if } a \geq 0 \\ -a & \text{if } a < 0. \end{cases}$$

For any numbers  $a, b \in \mathbb{K}$ ,

$$(2) \quad |a + b| \leq |a| + |b|.$$

This property is called the *triangle inequality*. It holds also for the absolute value of the complex numbers.

For the fields of rational numbers or real numbers, both of which are subfields of the complex numbers, both definitions of the absolute value coincide. The absolute value must be understood in the context of which ever field  $\mathbb{K}$  of rational, real, or complex numbers is involved. The triangle inequality holds in all these cases.

$n^2 > \zeta$  is satisfied if  $n > \sqrt{\zeta}$ . Thus, for  $N > \sqrt{\zeta}$  we see that  $n^2 > \zeta$  for all  $n \geq N$ . This implies that  $n^2 \rightarrow +\infty$ .  $\square$

**5.B.4.** Use Sage to plot the first 30 terms of the sequence  $(a_n)$  given in Problem 5.B.3, case (c).

**Solution.** Sage provides many alternatives to plot a sequence  $(a_n)$ . Here we utilized a method based on the object `Graphics()`, which is employed when initializing a for loop of various graphics objects (further techniques will be analyzed in the sequel). Therefore, to plot the first 30 terms of the sequence  $(\frac{n}{n+1})_{n \in \mathbb{Z}_+}$ , type

```
p=Graphics()
for n in xrange(1, 30+1):
    p=p+points((n, n/(n+1)), color="black")
show(p)
```

This produces the figure given here

For many of the solutions presented in 5.B.3, we have repeatedly used the fact that for every real number  $x$  there exists a natural number  $n \in \mathbb{N}^*$  such that  $n > x$ . This is the so-called Archimedean property of  $\mathbb{R}$ , and it will be used also below without mentioning it explicitly. In fact, it is not hard to prove that the Archimedean property is equivalent to say that for each positive real  $x$  there exists  $n \in \mathbb{N}^*$  such that  $\frac{1}{n} < x$ .

**5.B.5. Infinite limits.** Show that if  $a_n \rightarrow +\infty$  and  $b_n \rightarrow +\infty$ , then  $a_n \cdot b_n \rightarrow +\infty$ . Also, assuming  $a_n \rightarrow a > 0$  and  $b_n \rightarrow +\infty$ , show that  $a_n \cdot b_n \rightarrow +\infty$ . What is the situation for  $a < 0$  and for  $a = 0$ ?

**Solution.** (Hints) First, note that in this context the rule of product of limits must be carefully extended (see 5.2.13 for the product rule). This is because at least one of the limits in the given statements is infinite, refer to the discussion in 5.2.14 for further details. To prove the statement we will apply the definition given in case (e) in 5.B.3. We will describe the proof for the second statement only, and the proof of the first is left for practice.

**5.2.3. Convergence of a sequence.** We wish to formalize the notion of a sequence of numbers approaching a limit. The key object of interest is a sequence of numbers  $a_i$ , where the index  $i$  usually goes through all the natural numbers. Denote the sequences loosely either as  $a_0, a_1, \dots$ , or as infinite vectors  $(a_0, a_1, \dots)$ , or as  $(a_i)_{i=1}^\infty$ .

CAUCHY<sup>5</sup> SEQUENCES

Consider a sequence  $(a_0, a_1, \dots)$  of elements of  $\mathbb{K}$  such that for any fixed positive number  $\varepsilon > 0$ ,

$$|a_i - a_j| < \varepsilon.$$

for all but finitely many terms  $a_i, a_j$  of the sequence.

In other words, for any fixed  $\varepsilon > 0$ , there is an index  $N$  such that the above inequality holds for all  $i, j > N$ . Loosely put, the elements of the sequence are eventually arbitrarily close to each other. Such a sequence is called a *Cauchy sequence*.

Intuitively, either all but finitely many of the sequence's terms are equal, (then  $|a_i - a_j| = 0$  from some index  $N$  on), or they "approach" some particular value. This is easily imaginable in the complex plane. Choose an arbitrarily small disc (with radius equal to  $\varepsilon$ ). Suppose a Cauchy sequence is given. It must be possible to put the disc into the complex plane in such a way that it covers all but finitely many of the elements of the infinite sequence  $a_i$ . Imagine that such discs have very small radii, and all contain a number  $a$ ; see the diagram. If such a value  $a \in \mathbb{K}$  exists for a Cauchy sequence, we would expect the sequence to have the property of *convergence*:

CONVERGENT SEQUENCES

A sequence  $(a_i)_{i=0}^\infty$  converges to a value  $a$  if and only if for any positive real number  $\varepsilon$ ,

$$|a_i - a| < \varepsilon$$

for all but finitely many indices  $i$ . Notice that the set of those  $i$  for which the inequality does not hold may depend on  $\varepsilon$ . The number  $a$  is called the *limit* of the sequence  $(a_i)_{i=0}^\infty$ , we write

$$\lim_{i \rightarrow \infty} a_i = a.$$

If a sequence  $a_i \in \mathbb{K}, i = 0, 1, \dots$ , converges to  $a \in \mathbb{K}$ , then for any fixed positive  $\varepsilon, |a_i - a| < \varepsilon$  for all  $i$  greater than

<sup>5</sup>Augustin-Louis Cauchy (1789-1857) was a French mathematician pioneering a rigorous approach to infinitesimal analysis. He was very productive, wrote about 800 research articles. There are dozens of concepts and theorems named after him.

By assumption,  $\lim_{n \rightarrow +\infty} a_n = a > 0$ , so choosing  $\varepsilon = a/2 > 0$  we can find  $N \in \mathbb{Z}_+$  such that  $|a_n - a| < \frac{a}{2}$  for all  $n \geq N$ . This implies that  $\frac{a}{2} < a_n < \frac{3a}{2}$ , for all  $n \geq N$ , and so  $a_n > \frac{a}{2}$  for  $n \geq N$ . Also, choosing any  $\zeta > 0$  there exists  $M \in \mathbb{Z}_+$  such that  $b_n > \zeta$  for all  $n \geq M$ . Hence, for  $n \geq L := \max\{M, N\}$  both conditions hold and in particular  $a_n \cdot b_n > \frac{a}{2} \cdot \zeta > 0$ . Taking  $\zeta = \frac{2\tilde{\zeta}}{a}$  for some  $\tilde{\zeta} > 0$  we get  $a_n \cdot b_n > \tilde{\zeta}$  for all  $n \geq L$ . Thus  $a_n \cdot b_n \rightarrow +\infty$ , and  $a \cdot (+\infty) = +\infty$  for  $a > 0$ . For  $a < 0$  we have  $a_n \cdot b_n \rightarrow -\infty$ , and thus  $a \cdot (+\infty) = -\infty$ , for  $a < 0$ . However, the case  $a = 0$  will produce a so-called *indeterminate form*, namely  $0 \cdot (+\infty)$ , which is excluded.  $\square$

**5.B.6.** Using the results from 5.B.3 explain why:

- (a) The sequence  $(a_n = \frac{1}{n} + 3^n)$  diverges to  $+\infty$ .
- (b) The sequence  $(b_n = n^2 + 2^n)$  diverges to  $+\infty$ .
- (c) The sequence  $(c_n = n^2 \cdot 3^n)$  diverges to  $+\infty$ .
- (d) The sequence  $(d_n = \frac{n \cdot 4^n}{n+1})$  diverges to  $+\infty$ .  $\circ$

- 5.B.7.** (a) Prove that  $(a_n = \frac{1}{2^n})$  tends to zero as  $n \rightarrow \infty$ .  
 (b) Prove that  $(b_n = (-1)^{n+1})$  is divergent.  
 (c) Prove that  $(c_n = \sin(n\pi/2))$  is divergent.  
 (d) Find sequences  $(x_n)$  and  $(y_n)$  with infinite limits, such that  $\lim_{n \rightarrow \infty} (x_n + y_n) = 1$  and  $\lim_{n \rightarrow \infty} (x_n y_n^2) = +\infty$ .  $\circ$

**5.B.8.** Show that  $\lim_{n \rightarrow \infty} \sqrt[n]{n} = 1$  (notice  $\sqrt[n]{n} = n^{\frac{1}{n}}$ ). Then present a proof via Sage.

**Solution.** Apparently, for all naturals  $n \geq 1$  we have  $\sqrt[n]{n} \geq 1$ . So we can set  $\sqrt[n]{n} = 1 + a_n$  for certain numbers  $a_n \geq 0$ . Now, by the binomial theorem we see that

$$n = (1 + a_n)^n = 1 + \binom{n}{1} a_n + \binom{n}{2} a_n^2 + \dots + a_n^n,$$

for all natural numbers  $n \geq 2$ . Hence we have the bound

$$n \geq \binom{n}{2} a_n^2 = \frac{n(n-1)}{2} a_n^2,$$

for all naturals  $n \geq 2$ , which leads to  $0 \leq a_n \leq \sqrt{\frac{2}{n-1}}$  for all such  $n$ . Having established these inequalities, we can now use the squeeze theorem (see 5.2.12). This implies that  $\lim_{n \rightarrow \infty} a_n = 0$ , and hence  $\lim_{n \rightarrow \infty} \sqrt[n]{n} = \lim_{n \rightarrow \infty} (1 + a_n) = 1$ . One should finally mention that it is possible to prove the result by means of the so called ‘l’Hopital’s rule’, introduced in 5.3.10. However, such a procedure is based on the notion of derivatives and hence we will return to this later, see 5.E.109.

For computing limits in Sage we use the command `limit` or its alias `lim`. We also recall that the mathematical symbol  $\infty$  is represented either by `oo` or by `Infinity` (or `infinity`). Let us now illustrate the implementation of these rules via our example. So, an appropriate cell has the form

```
n=var("n"); a(n)=n**(1/n); lim(a(n), n=oo)
```

Or, as we said, one could replace the last command by `lim(a(n), n = Infinity)`. Notice that first one should introduce the variable  $n$ , as a symbolic variable. This is because

a certain  $N \in \mathbb{N}$ . By the triangle inequality,

$$|a_i - a_j| = |a_i - a + a - a_j| < |a_i - a| + |a - a_j| < 2\varepsilon,$$

for all pairs of indices  $i, j \geq N$ . Thus:

**Lemma.** Every convergent sequence is a Cauchy sequence.

However, in the field of rational numbers, it can happen that for a Cauchy sequence a corresponding value  $a$  does not exist. For instance, the number  $\sqrt{2}$  can be approached by a sequence of rational numbers  $a_i$ , thereby obtaining a sequence converging to  $\sqrt{2}$ , but the limit is not rational.

Ordered fields of scalars in which every Cauchy sequence converges are called *complete*. The following theorem states that the axiom (R13) guarantees that the real numbers are such a field:

**Theorem.** Every Cauchy sequence of real numbers  $a_i$  converges to a real number  $a \in \mathbb{R}$ .

**PROOF.** The terms of any Cauchy sequence form a bounded set since any choice of  $\varepsilon$  bounds all but finitely many of them. Let  $B$  be the set of those real numbers  $x$  for which  $x < a_j$  for all but finitely many terms  $a_j$  of the sequence.  $B$  has an upper bound, and thus  $B$  has a supremum as well, by (R13).

Define  $a = \sup B$ . Fix  $\varepsilon > 0$ , and choose  $N$  so that  $|a_i - a_j| < \varepsilon$  for all  $i, j \geq N$ . Then  $a_j > a_N - \varepsilon$  and  $a_j < a_N + \varepsilon$  for all indices  $j > N$ , and so  $a_N - \varepsilon$  belongs to  $B$ , while  $a_N + \varepsilon$  does not. Hence  $|a - a_N| \leq \varepsilon$ , and thus

$$|a - a_j| \leq |a - a_N| + |a_N - a_j| \leq 2\varepsilon$$

for all  $j > N$ . So  $a$  is the limit of the given sequence.  $\square$

**Corollary.** Every Cauchy sequence of complex numbers  $z_i$  converges to a complex number  $z$ .

**PROOF.** Write  $z_i = a_i + i b_i$ . Since  $|a_i - a_j|^2 \leq |z_i - z_j|^2$  and similarly for the values  $b_i$ , both sequences of real numbers  $a_i$  and  $b_i$  are Cauchy sequences. They converge to  $a$  and  $b$ , respectively. It is easily verified that  $z = a + i b$  is the limit of the sequence  $z_i$ .  $\square$

**5.2.4. Remark.** The previous discussion proposes a construction method for the real numbers. Proceed similarly to building the integers from the natural numbers (adding in all additive inverses). Build the rational numbers from the integers (adding all multiplicative inverses of non-zero numbers). Then ‘complete’ the rational numbers by adding in all limits of Cauchy sequences.

Cauchy sequences  $(a_i)_{i=0}^\infty$  and  $(b_i)_{i=0}^\infty$  of rational numbers are equivalent if and only if the distances  $|a_i - b_i|$  converge to zero. This is the same as the condition that merging these sequences into a single sequence also yields a Cauchy sequence. For example, a sequence can be formed by selecting alternately terms from the first sequence and the second sequence. Check the properties of the equivalence relations. Clearly the relation is reflexive, it is symmetric (since the distance of the rational numbers is symmetric in its arguments)

our goal is to view  $a(n)$  as a function of  $n$ . Execute yourself the given syntax to practice with Sage.  $\square$

**5.B.9. Limits of sequences.** Compute the following limits, and next verify your answers via Sage:

- (a)  $\lim_{n \rightarrow \infty} \frac{2n^2+3n+1}{n+1}$ , (d)  $\lim_{n \rightarrow \infty} \frac{n+1}{2n^2+3n+1}$ ,  
 (b)  $\lim_{n \rightarrow \infty} \sqrt[n]{1^2 + 2^2 + \dots + n^2}$ , (e)  $\lim_{n \rightarrow \infty} \frac{5^n+1}{7^n+1}$ ,  
 (c)  $\lim_{n \rightarrow \infty} \sqrt{4n^2 + n} - 2n$ , (f)  $\lim_{n \rightarrow \infty} \frac{\sqrt{4n^2+n}}{n}$ .

**Solution.** (a) Set  $a_n = \frac{2n^2+3n+1}{n+1}$ . Multiplying both the numerator and denominator by  $1/n$ , we have

$$\lim_{n \rightarrow \infty} a_n = \lim_{n \rightarrow \infty} \frac{2n + 3 + \frac{1}{n}}{1 + \frac{1}{n}} = \frac{\infty + 3 + 0}{1 + 0} = \infty.$$

To confirm this result in Sage, give the cell

```
n=var("n"); a(n)=(2*n^2+3*n+1)/(n+1)
lim(a(n), n=infinity)
```

Sage’s answer is +Infinity.

(b) Let us present a solution based on a very useful theoretical result, the so called “squeeze theorem” presented in 5.2.12. In particular, set  $a_n = \sqrt[n]{1^2 + 2^2 + \dots + n^2}$ . Then for any positive natural  $n$  we have

$$b_n = \sqrt[n]{n} \leq a_n \leq c_n = \sqrt[n]{\underbrace{n^2 + n^2 + \dots + n^2}_{n\text{-terms}}} = \sqrt[n]{n^3}.$$

By 5.B.8 we know that  $b_n \rightarrow 1$ . Moreover, since  $\sqrt[n]{n^3} = (n^3)^{\frac{1}{n}} = n^{\frac{3}{n}} = (n^{\frac{1}{n}})^3$ , we also conclude that  $c_n \rightarrow 1$ , as  $n \rightarrow +\infty$ . The squeeze theorem now applies and gives that  $a_n \rightarrow 1$ .

In Sage one can verify these claims as follows:

```
n, k=var("n, k")
a(n)=sum(k^2, k, 1, n)**(1/n) # declare (a_n)
f(n)=(n^3)**(1/n); g(n)=n**(1/n)
print(bool(a(n)<=f(n) for n in range(1, 1000)))
print(bool(a(n)>=g(n) for n in range(1, 1000)))
print(lim(a(n), n=oo))
```

Notice in the fourth and fifth line we used the bool command to test the two posed inequalities, for many  $n$ . However, one could directly compute the limit in question (hence, one may avoid to include these two lines, together with the definition of the sequences  $f(n)$  and  $g(n)$ ).

(c) Set  $a_n = \sqrt{4n^2 + n} - 2n$ . Here it applies the following classical trick:

$$\begin{aligned} \lim_{n \rightarrow \infty} a_n &= \lim_{n \rightarrow \infty} \frac{(\sqrt{4n^2 + n} - 2n)(\sqrt{4n^2 + n} + 2n)}{\sqrt{4n^2 + n} + 2n} \\ &= \lim_{n \rightarrow \infty} \frac{n}{\sqrt{4n^2+n}+2n} = \lim_{n \rightarrow \infty} \frac{1}{\frac{\sqrt{4n^2+n}}{n} + 2} = \frac{1}{4}. \end{aligned}$$

(d) We leave this for practice, since can be treated as case (a). Verify yourself that the given limit equals to  $\frac{1}{\infty} = 0$ .

and transitivity follows easily from the triangle inequality. Thus, we may define  $\mathbb{R}$  as the set of equivalence classes on the above set of sequences.

We introduce algebraic structures on this set  $\mathbb{R}$  and check their properties. Of course, the rational numbers can be represented by constant sequences, so that  $\mathbb{Q} \subset \mathbb{R}$ , as expected. Next, define the sum and product of sequences representing them, respectively. It is easy to check that the results represent a class independent of the choices.

Ordering is dealt with similarly. Here it is required to prove that  $a \leq b$  if and only if there are representatives with  $a_i \leq b_i$ . Finally it is necessary to show that all Cauchy sequences in  $\mathbb{R}$  converge. We do not go into details now and advise the reader to return back and check all the details when going through the full discussion of the completion of metric spaces in the paragraph 7.3.6. The arguments used there with the real scalars replaced by rational ones provide an adequate proof. The arguments proving that the axioms (R1)–(R13) define the real numbers uniquely up to isomorphism are also to be found there.

**5.2.5. Closed sets.** For further work with real or complex numbers, we need to understand the notions of closeness, boundedness, convergence, and so on. These concepts belong to the topic “topology”<sup>6</sup>. As before, we work with  $\mathbb{K} = \mathbb{R}$  or  $\mathbb{K} = \mathbb{C}$ . We advise the reader to draw many diagrams for all the concepts and their properties for both the real line and the complex plane.

For any subset  $A$  of points in  $\mathbb{K}$ , we are interested not only in the points belonging to  $a \in A$ , but also in the ones which can be approached by limits of sequences in  $A$ .

LIMIT POINTS OF A SET

Let  $A$  be a subset of  $\mathbb{K}$ . A point  $x \in \mathbb{K}$  is called a *limit point* of  $A$  if and only if there is a sequence  $a_0, a_1, \dots$  of elements in  $A$  such that all its terms differ from  $x$ , yet its limit is  $x$ .

Notice that a limit point of a set may or may not belong to the set.

For every non-empty set  $A \subset \mathbb{K}$  and a fixed point  $x \in \mathbb{K}$ , the set of all distances  $|x - a|, a \in A$ , is a set of real numbers bounded from below, and so it has an infimum  $d(x, A)$ , which is called the *distance of the point  $x$  from the set  $A$* . Notice that  $d(x, A) = 0$  if and only if either  $x \in A$  or if  $x$  is a limit point of  $A$ . (We suggest the reader proves this in detail directly from the definitions.)

<sup>6</sup>The name of this mathematical discipline comes from the Greek “studying the shape” (topos + logos). The main concepts are built on the formalism of open and closed sets, compactness etc. We use the same names here but only in the realm of real and complex numbers. Later on, we go further in metric spaces in chapter 7.

(e) This case can be treated using the conclusions of 5.B.3. Hence we get

$$\lim_{n \rightarrow \infty} \frac{5^n + 1}{7^n + 1} = \lim_{n \rightarrow \infty} \frac{\left(\frac{5}{7}\right)^n + \frac{1}{7^n}}{1 + \frac{1}{7^n}} = \frac{0 + 0}{1 + 0} = 0.$$

In Sage for this result work as above, i.e.,

```
n=var("n"); f(n) = ((-5)^n + 1) / ((7^n) + 1)
lim(f(n), n=oo)
```

(f) Set  $a_n = \frac{\sqrt{4n^2+n}}{n}$ . For any positive natural  $n$  we have that

$$b_n = \frac{\sqrt{4n^2}}{n} < a_n < c_n = \frac{\sqrt{4n^2 + n + \frac{1}{16}}}{n}.$$

Moreover, it is easy to see that  $\lim_{n \rightarrow \infty} b_n = 2 = \lim_{n \rightarrow \infty} c_n$ . Thus, by the squeeze theorem it follows that  $\lim_{n \rightarrow \infty} a_n = 2$ .  $\square$

**5.B.10.** Given a non-empty bounded set  $A \subseteq \mathbb{R}$ , set  $a := \sup A$ . Show that there exists a sequence  $(a_n)$  of  $A$  tending to  $a$  (notice a similar statement holds for  $\inf A$ ).

**Solution.** By assumption  $a$  is the supremum of  $A$ , so  $a$  is an upper bound of  $A$  and for every  $\zeta > 0$  there exists  $x \in A$  such that  $x > a - \zeta$ . To prove this fix some  $\zeta > 0$  and suppose in the contrary that  $x \leq a - \zeta$ . Then  $a - \zeta$  must be also an upper bound of  $A$ , a contradiction since  $a = \sup A$ , so  $a$  is the least upper bound. Thus we can find some  $x \in A$  with  $x > a - \zeta$  (note that the converse is also true). Choosing now  $\zeta = 1/n$  for  $n \in \mathbb{Z}_+$ , so  $\zeta > 0$ , we may denote this element by  $x_n \in A$ , such that  $x_n > a - \frac{1}{n}$ . Since  $x_n \leq a$ , we finally arrive to the inequality  $0 \leq a - x_n < 1/n$ . Fix now some  $\varepsilon > 0$  and choose  $N \in \mathbb{Z}_+$  with  $1/N < \varepsilon$ . Then for all  $n \geq N$  we get  $|a - x_n| < 1/n \leq 1/N < \varepsilon$ , hence  $x_n \rightarrow a$  as  $n \rightarrow \infty$ .  $\square$

A sequence  $(a_n)$  is said to be bounded above (respectively, bounded below), if there exists  $M \in \mathbb{R}$  such that  $a_n \leq M$  (respectively,  $a_n \geq M$ ), for all  $n$  that  $(a_n)$  is defined. A sequence that is bounded above and below is called bounded.

Obviously, a sequence that diverges to  $+\infty$  (respectively,  $-\infty$ ) is not bounded above (respectively, is not bounded below). A sequence  $(a_n)$  is said to be increasing (respectively, decreasing) if  $a_n \leq a_{n+1}$  (respectively,  $a_n \geq a_{n+1}$ ) for all  $n$  that  $(a_n)$  is defined. If we have  $a_n < a_{n+1}$  (respectively,  $a_n > a_{n+1}$ ) for all  $n$ , then the sequence  $(a_n)$  is called strictly increasing (respectively, strictly decreasing). For instance, the sequence  $(n^2)$  is strictly increasing, while the sequence  $(1/n)$  is strictly decreasing.

**5.B.11. Monotone sequence theorem.** Show that every bounded monotonic sequence is convergent.

**Solution.** This extremely useful result can be equivalently rephrased as follows: “Every increasing sequence  $(a_n)$  which is bounded above converges to  $\sup\{a_n : n \in \mathbb{N}^*\}$ , and similarly every decreasing sequence  $(b_n)$  that is bounded below

CLOSED SETS

The closure  $\bar{A}$  of a set  $A \subset \mathbb{K}$  is the set of those points which have zero distance from  $A$  (note that the distance from the empty set of points is undefined, therefore  $\bar{\emptyset} = \emptyset$ ).

A closed subset in  $\mathbb{K}$  is a set which coincides with its closure. A set is closed if it contains all of its limit points.

On the real line, a closed interval

$$[a, b] = \{x \in \mathbb{R}, a \leq x \leq b\}$$

of real numbers, where  $a$  and  $b$  are fixed real numbers is a closed set.

The sets  $(-\infty, b]$ ,  $[a, \infty)$ , and  $(-\infty, \infty)$  are also closed sets.

A closed set may also be formed by a sequence of real numbers without a limit point, or a sequence with a finite number of limit points together with these points.

The unit disc (including its boundary circle) in the complex plane is another example of a closed set.

An arbitrary intersection of closed sets is again a closed set. A finite union of closed sets is again a closed set. Indeed, if all of the points of some sequence belong to the considered intersection of closed sets, then they belong to each of the sets, and so do all the limit points. However, if we wanted to say the same about an arbitrary union, we would get in trouble: singleton sets are closed, but a sequence of points created from them may not be. On the other hand, if we restrict our attention to finite unions and consider a limit point of some converging sequence lying in this union, then the limit point must also be the limit point of any subsequence, especially the one lying in only one of the united sets. As this set is assumed to be closed, the limit point lies in it, and thus it lies in the union.

**5.2.6. Open sets.** There is another useful type of subset of the real numbers: open intervals

$$(a, b) = \{x \in \mathbb{R}; a < x < b\},$$

where, again,  $a$  and  $b$  are fixed real numbers or infinite values  $\pm\infty$ . It is an open set, in the following sense:

OPEN SETS AND NEIGHBOURHOODS OF POINTS

An open set in  $\mathbb{K}$  is a set whose complement is a closed set.

A neighbourhood of a point  $a \in \mathbb{K}$  is an open set  $\mathcal{O}$  which contains  $a$ . If the neighbourhood is defined as

$$\mathcal{O}_\delta(a) = \{x \in \mathbb{K}, |x - a| < \delta\}$$

for some positive number  $\delta$ , then we call it the  $\delta$ -neighbourhood of the point  $a$ .

For real numbers, the  $\delta$ -neighbourhood of a point  $a$  is the open interval of length  $2\delta$ , centered at  $a$ . In the complex plane, it is the disc of radius  $\delta$ , also centered at  $a$ .

Notice that for any set  $A$ ,  $a \in \mathbb{K}$  is a limit point of  $A$  if and only if every neighbourhood of  $a$  contains at least one point  $b \in A$ ,  $b \neq a$ .

**Lemma.** A set  $A \subset \mathbb{K}$  of numbers is open if and only if every point  $a \in A$ , has a neighbourhood contained in  $A$ .

converges to  $\inf\{b_n : n \in \mathbb{N}^*\}$ . We will prove the first statement and an analogous method applies for the second one. Let  $(a_n)$  be a sequence and assume for simplicity that  $n \in \mathbb{N}^*$ . Assume also that  $(a_n)$  is bounded above with  $a_n \leq a_{n+1}$  for all  $n \in \mathbb{N}^*$ . Since  $(a_n)$  is bounded above, its range  $\{a_n : n \in \mathbb{N}^*\}$  is also bounded above (as a set), and hence  $\sup\{a_n : n \in \mathbb{N}^*\}$  exists. Set  $a := \sup\{a_n : n \in \mathbb{N}^*\}$ . Recall that if  $a$  is the supremum of a non-empty set  $A$ , then  $a$  is an upper bound of  $A$  and for every  $\zeta > 0$  there exists  $x \in A$  such that  $x > a - \zeta$  (see the proof of 5.B.10). In our case this means that for  $\zeta > 0$  be given, it exists a natural  $N$  with  $a - \zeta < a_N$ , that is,  $a - a_N < \zeta$ . However,  $(a_n)$  is increasing, so for all  $n \geq N$  we have  $a_n \geq a_N$  and in particular  $a - \zeta < a_N \leq a_n \leq a < a + \zeta$ , for all such  $n$ . Thus  $|a_n - a| < \zeta$  for all  $n \geq N$ , i.e.,  $a_n \rightarrow a$ .  $\square$

**5.B.12.** Present a “counterexample” verifying that the converse of the monotone sequence theorem fails. Moreover, give an example of a monotone sequence which is not convergent.  $\circ$

**5.B.13.** Given the sequences  $(a_n = \frac{\sin(n)}{n})$ ,  $(b_n = n^2 + 1)$  and  $(c_n = \frac{(-1)^{n+n}}{n})$ , with  $n \in \mathbb{Z}_+$  for all three cases, locate them which are bounded.  $\circ$

**5.B.14.** Indicate the convergent sequences between those given in the previous problem 5.B.13, and determine their limits. Repeat for the sequences  $f_n = \frac{1}{\sqrt{n}}$  and  $g_n = \frac{n!}{n^n}$ , where  $n \in \mathbb{Z}_+$ .  $\circ$

**5.B.15.** Let  $a > 0$ . Show that  $\lim_{n \rightarrow \infty} \sqrt[n]{a} = 1$ .

**Solution.** Once more, squeeze theorem provides a traditional way to treat this limit, as in 5.B.8. Let us however discuss a different method. First notice that we may assume that  $0 < a < 1$ , since otherwise the argument applies for  $1/a$ . For such  $a$  it is easy to see that given sequence  $(a_n = \sqrt[n]{a})_{n \in \mathbb{Z}_+}$  is monotonically increasing. Moreover, it is bounded above by 1. A proof of this fact is left to the reader, but one may like to illustrate the situation in Sage, either via the cell

```
n=var("n"); a=0.2; a(n)=a**(1/n)
bool(a(n)<1 for n in range(1, 5000))
```

which returns True, or by plotting many terms of  $(a_n)$  (continue typing in the previous cell)<sup>4</sup>

```
list_plot([a(n) for n in range(1, 100)])
```

Thus  $(a_n)$  converges, and we may assume that  $\lim_{n \rightarrow +\infty} a_n = \ell \in \mathbb{R}$ .

Assume that  $\ell < 1$ . Using the inequality  $\sqrt[n]{a} \leq \ell$  we get  $a \leq \ell^n$ , with  $\ell^n \rightarrow 0$  by 5.B.3. This gives a contradiction, since  $a > 0$ . Taking into account that  $(a_n)$  is bounded above by 1, we deduce that  $\ell = 1$ . For a Sage verification one can continue in the very first cell used above, by adding the following command: `lim(a(n), n = oo)`.  $\square$

<sup>4</sup>Notice this gives an alternative to plot sequences via Sage.

**PROOF.** Let  $A$  be an open set and let  $a \in A$ . If there is no neighbourhood of the point  $a$  inside  $A$ , then there is a sequence  $a_n \notin A$ ,  $|a - a_n| \leq 1/n$ . But then the point  $a \in A$  is a limit point of the set  $\mathbb{K} \setminus A$ , which is impossible since the complement of  $A$  is closed.

Suppose every  $a \in A$  has a neighbourhood contained in  $A$ . This prevents a limit point  $b$  of the set  $\mathbb{K} \setminus A$  to lie in  $A$ . Thus the set  $\mathbb{K} \setminus A$  is closed, and so  $A$  is open.  $\square$

From this lemma, it follows immediately that any union of open sets is an open set. A finite intersection of open sets is also an open set.

**5.2.7. Bounded and compact sets.** The closed and open sets are basic concepts of *topology*. Without going into deeper connections, the above material describes the *topology of the real line* and the *topology of the complex plane*. The following concepts are extremely useful:

#### BOUNDED AND COMPACT SETS

A set  $A$  of rational, real, or complex numbers is called *bounded* if and only if there is a positive real number  $r$  such that  $|z| \leq r$  for all numbers  $z \in A$ . Otherwise, the set is called *unbounded*.

A set which is both bounded and closed is called *compact*.

An *interior point* of a set  $A$  is a point such that one of its neighbourhoods is contained in  $A$ .

A *boundary point* of a set  $A$  is a point for which all its neighbourhoods have a non-trivial intersection with both  $A$  and its complement  $\mathbb{K} \setminus A$ . A boundary point of the set  $A$  may or may not belong to it.

An *open cover* of a set  $A$  is such a collection of open sets  $U_i, i \in I$ , that its union contains the whole of  $A$ .

An *isolated point* of a set  $A$  is a point  $a \in A$  such that there is a neighbourhood  $N$  of  $a$  satisfying  $N \cap A = \{a\}$ .

**5.2.8. Theorem.** All subsets  $A \subset \mathbb{K}$  of real or complex numbers satisfy:

- (1) a non-empty set  $A \subset \mathbb{R}$  is open if and only if it is a union of countably (or finitely) many open intervals; similarly

Often we are interested in the limit of a sequence  $s_n$ , where the terms are partial sums of some other given sequence  $a_n$ . Let us describe such an example and more applications are described in Section D, which is about infinite series.

**5.B.16. Geometric series.** Find the limit of the sequence with general term

$$s_n = 1 + x + x^2 + \cdots + x^n, \quad n = 0, 1, 2, \dots,$$

for  $x$  with  $|x| < 1$ .

**Solution.** First observe that

$$\begin{aligned} s_n(1-x) &= (1+x+\cdots+x^n) - x(1+x+\cdots+x^n) \\ &= 1+x+\cdots+x^n - x - \cdots - x^n - x^{n+1} \\ &= 1 - x^{n+1}. \end{aligned}$$

So for  $x \neq 1$  we have  $s_n = \frac{1-x^{n+1}}{1-x}$ , with  $n \in \mathbb{N}$ . Recall now by 5.B.3 that  $\lim_{n \rightarrow \infty} x^n = 0$ , provided that  $|x| < 1$ . Thus for such  $x$  we get

$$\lim_{n \rightarrow \infty} s_n = \lim_{n \rightarrow \infty} \frac{1-x^{n+1}}{1-x} = \frac{1}{1-x},$$

and it follows that

$$\sum_{n=0}^{\infty} x^n = \lim_{n \rightarrow \infty} s_n = \frac{1}{1-x}, \quad |x| < 1.$$

This is the so called *geometric series* and for those  $x$  satisfying  $|x| < 1$ , the geometric series is a finite number. For instance

$$\sum_{n=1}^{\infty} \left(\frac{1}{2}\right)^n = \sum_{n=0}^{\infty} \left(\frac{1}{2}\right)^n - 1 = \frac{1}{1-\frac{1}{2}} - 1 = 2 - 1 = 1,$$

that is,

$$\frac{1}{2} + \frac{1}{4} + \frac{1}{8} + \frac{1}{16} + \frac{1}{32} + \cdots = 1.$$

Very often Sage allows us to compute such sums, by applying for example the following cell (which indeed returns  $\frac{-1}{x-1}$ ):

```
x, n=var("x, n"); assume(abs(x) < 1)
print(sum(x^n, n, 0, oo))
```

This is preliminary example of the `sum` method in Sage, which we will analyze more in Section D. On the other hand, the geometric series will appear in the foreground very often, hence we encourage you to devote some additional time with it (e.g., compute in Sage some of its partial sums).  $\square$

**5.B.17.** Consider the sequence  $(a_n)$  with

$$a_n = \frac{8}{10} + \frac{8}{10^2} + \cdots + \frac{8}{10^n}, \quad n = 1, 2, \dots$$

that is,  $a_n = 0.88 \cdots 8$ , with 8 repeated  $n$  times. Show that  $a_n$  tends to  $\frac{8}{9}$  as  $n$  tends to  $\infty$ , and then give a proof via Sage.

$A \subset \mathbb{C}$  is open if and only if it is a union of countably (finite) many open discs.

- (2) every point  $a \in A$  is either an interior or a boundary point,
- (3) every boundary point of  $A$  is either an isolated point or a limit point of  $A$ ,
- (4)  $A$  is compact if and only if every infinite sequence contained in  $A$  has a subsequence converging to a point in  $A$ .<sup>7</sup>
- (5)  $A$  is compact if and only if each of its open covers contains a finite subcover of  $A$ .

**PROOF.** (1) Every open set is a union of some neighbourhoods of its points, i.e., we may consider open intervals in reals, or open discs in  $\mathbb{C}$ . So the question that remains is whether it suffices to take countably many of them. Let us first prove the claim for the complex plane. For each  $z \in A$ , there is an open disc  $\mathcal{O}_\delta(z)$  contained in  $A$ , with some  $\delta > 0$ , and let  $\delta_z$  be the supremum of the values of such  $\delta$ . Clearly,  $A = \cup_{z \in A} \mathcal{O}_{\delta_z}(z)$ . Consider an arbitrary  $z \in A$  and pick up  $w$  with both real and imaginary parts rational, such that  $|w - z| < \delta_z/4$ . Thus,  $z \in \mathcal{O}_{\delta_w}(w)$  (draw a picture!) and we have checked that actually  $A$  is the union of the countably many open discs  $\mathcal{O}_{\delta_w}(w)$  for all  $w \in A$  with rational real and imaginary coordinates.

If  $A$  is an open subset in  $\mathbb{R}$ , then we may repeat the above argument with the discs  $\mathcal{O}_\delta(z)$  replaced by the intervals  $\mathcal{O}_\delta(x)$  and  $x \in A$ . Think about the details!

(2) It follows immediately from the definitions that no point can be both an interior and boundary point. Let  $a \in A$  be a point that is not interior. Then there is a sequence of points  $a_i \notin A$  with  $a$  as its limit point. At the same time,  $a$  belongs to each of its neighbourhoods. Thus  $a$  is a boundary point.

(3) Suppose that  $a \in A$  is a boundary point but not isolated. Then, similarly to the reasoning from the previous paragraph, there are points  $a_i$ , this time inside  $A$ , whose limit point is  $a$ .

(4) Suppose  $A \subset \mathbb{R}$  is a compact set, i.e., both closed and bounded. Consider an infinite sequence of points  $a_i \in A$ .  $A$  has both a supremum  $b$  and an infimum  $a$ . Divide the interval  $[a, b]$  into halves:  $[a, \frac{1}{2}(b-a)]$  and  $[\frac{1}{2}(b-a), b]$ . At least one of them contains infinitely many of the terms  $a_i$ . Select this half and one of the terms contained in it; then cut the selected interval into halves. Again, select such a half which contains infinitely many of the sequence's terms and select one

<sup>7</sup>This result for real numbers is usually referred to as the Bolzano-Weierstrass theorem. Karl Weierstrass was a famous German mathematician (1815-1897) and his name is linked to many theorems in Mathematics. Bernard Bolzano (1781-1848) was a Bohemian mathematician, logician, philosopher, theologian and Catholic priest working in Prague at the beginning of the 19th century. He laid the basis of rigorous mathematical analysis a few decades before all the theory was worked out by Weierstrass and others. In particular he was skeptical about the effective use of Leibniz's infinitesimals without the necessary rigour.

**Solution.** We see that

$$\begin{aligned} a_n &= \frac{8}{10} \left( 1 + \frac{1}{10} + \cdots + \frac{1}{10^{n-1}} \right) = \frac{8}{10} \left( \frac{1 - \frac{1}{10^n}}{1 - \frac{1}{10}} \right) \\ &= \frac{8}{9} \left( 1 - \frac{1}{10^n} \right) = \frac{8}{9} - \frac{8}{9} \cdot \frac{1}{10^n}. \end{aligned}$$

This gives  $|a_n - \frac{8}{9}| = \frac{8}{9} \cdot \frac{1}{10^n}$  and hence it is easy to see that the condition  $|a_n - \frac{8}{9}| < \varepsilon$  is equivalent to the inequality  $10^n > \frac{8}{9\varepsilon}$ . Therefore, if  $N$  is a natural satisfying  $10^N > \frac{8}{9\varepsilon}$ , then we have  $|a_n - \frac{8}{9}| < \varepsilon$ , for all  $n \geq N$ . Thus we are done.

An alternative relies on the fact  $\frac{1}{10^n} \rightarrow 0$  as  $n \rightarrow \infty$ . To prove this, notice that for given  $\varepsilon > 0$  and for all  $n \geq N := \log_{10}(1/\varepsilon)$  one has  $|1 - \frac{1}{10^n}| = \frac{1}{10^n} \leq \frac{1}{10^N} = \frac{1}{1/\varepsilon} = \varepsilon$ .

Finally, the following block confirms the result by a less obvious technique (explain why this is true).

```
var ("n, k") ; a=sum(8/(10)^n, n, 1, oo)
bool(a==lim(sum(8/(10)^k, k, 1, n), n=oo))
```

□

 The binomial theorem often combines with the monotone sequence theorem and together provide elegant techniques for studying the convergence of sequences. Such an example encodes our next task, which is about a famous number, the so called “Euler number” denoted by  $e$ , that is, the base of the natural logarithm, see 5.4.1. This satisfies  $2 < e < 3$ , approximately equals to  $e \approx 2.7183$ , and is the limit of the sequence  $(e_n)_{n=1}^\infty$  featured in 5.B.18.<sup>5</sup>

**5.B.18.** (The Euler number) Combining the binomial theorem with the monotone sequence theorem, see 5.B.11, show that the sequence  $e_n$  given below is convergent:

$$e_n = \left( 1 + \frac{1}{n} \right)^n, \quad n = 1, 2, \dots$$

○

 Roughly speaking, Cauchy sequences are sequences whose all but a finite number of elements sit from each other less than a given distance  $\varepsilon > 0$ . A general result states that any convergent sequence is Cauchy, while over the reals  $\mathbb{R}$  or the complex numbers  $\mathbb{C}$  the converse is also true, see 5.2.3. Thus we say that  $\mathbb{R}$  or  $\mathbb{C}$  are complete fields, instead of  $\mathbb{Q}$ , for example. We can often use this result, to decide about the convergence/divergence of a given sequence of real or complex numbers. Let us describe such an example, and for more advanced tasks check the final section with the extra material, see 5.E.29, 5.E.30, for example.

<sup>5</sup>Good to know that the proof given here as a solution of 5.B.18, differs from those given in 5.4.1. Can you establish the different points between the two methods?

of those points. By this procedure, a Cauchy sequence is established. Cauchy sequences have limit points or are constant up to finitely many exceptions. Thus there is a subsequence with the desired limit. The fact that  $A$  is closed implies that the point obtained lies in  $A$ .

Now the other direction: if every infinite subset of  $A$  has a limit point in  $A$ , then all limit points are in  $A$ , and so  $A$  is closed. If  $A$  were not bounded, we would be able to find an increasing or decreasing sequence such that the differences of absolute values of adjacent numbers would be at least 1, for instance. However, such a sequence of points in  $A$  cannot have a limit point at all.

Finally, we have to deal with the general case  $A \subset \mathbb{C}$ . The arguments of the latter implication remain the same. Thus we have to show that any sequence  $z_n$  of complex numbers in  $A$  has got a limit point in  $A$ . Consider the sequences of real and imaginary parts,  $x_n$  and  $y_n$ . Since they both have to be in the bounded subsets  $A_{\mathbb{R}}$  and  $A_{i\mathbb{R}}$  of the real and imaginary projections of  $A$ , there is a subsequence  $z_{n_k} = (x_{n_k}, y_{n_k})$  such that  $x_{n_k} \rightarrow x$ ,  $y_{n_k} \rightarrow y$  with the limits sitting in the closures of  $A_{\mathbb{R}}$  and  $A_{i\mathbb{R}}$ , by virtue of the already proved real case. Obviously,  $z_{n_k} \rightarrow z = (x, y)$ , but the latter limit has to sit in  $A$  since  $A$  is closed.

(5) First, focus on the easier implication. That is, suppose that every open cover contains a finite subcover. It is required to prove that  $A$  is both closed and bounded.  $A \subset \mathbb{C}$  can be covered by a countable union of neighbourhoods  $\mathcal{O}_n(z)$ , with integers  $n$  and centers  $z$  with integral real and imaginary parts. Any choice of a finite subcover of them witnesses that  $A$  is bounded. If  $A \subset \mathbb{R}$ , then the same argument applies with intervals  $\mathcal{O}_n(x)$ ,  $n, x \in \mathbb{Z}$ .

Now suppose that  $a \in \mathbb{C} \setminus A$  is the limit point of a sequence  $a_i \in A$ . Further, assume that  $|a - a_n| < \frac{1}{n}$  (otherwise select a subsequence satisfying this property). The sets

$$J_n = \mathbb{C} \setminus \overline{\mathcal{O}_{1/n}(a)}$$

for all  $n \in \mathbb{N}$ ,  $n > 0$ , are open and they also cover our set  $A$ . Since it is possible to choose a finite cover of  $A$ , the point  $a$  is inside the complement  $\mathbb{C} \setminus A$ , including one of its neighbourhoods, and thus it is not a limit point. Therefore, all of  $A$ 's limit points must again lie in  $A$ . Hence  $A$  is closed.

If  $A \subset \mathbb{R}$ , the same argument applies with closed discs replaced by closed intervals.

Finally, we have to prove the other implication. So assume  $A \subset \mathbb{C}$  is complete and bounded, but there is an open covering  $U_\alpha$ ,  $\alpha \in I$ , of  $A$ , which does not contain any finite covering. Consider the sequence of positive real numbers  $\varepsilon_n = 1/n$  converging to 0 and sets

$$B_n = \{z = (\frac{k}{n}, \frac{m}{n}) \in A, k, m \in \mathbb{Z}\}$$

of complex numbers with real and imaginary parts in the “ $1/n$ -net of coordinates”. Clearly all sets  $B_n$  are finite. Further, for each  $k$ , consider the system  $\mathcal{A}_k$  of closed discs with centres in the points of  $B_k$  and diameters  $2\varepsilon_k$ . Clearly each such system  $\mathcal{A}_k$  covers the entire set  $A$ . Altogether, there

**5.B.19. Harmonic numbers.** Consider the sequence  $(H_n)_{n=1}^\infty$  with general term

$$H_n = \sum_{k=1}^n \frac{1}{k}, \quad n = 1, 2, \dots$$

Decide about the convergence of  $(H_n)_{n=1}^\infty$  in terms of Cauchy sequences.

**Solution.** The term  $H_n$  is the so-called *n*th harmonic number. The first harmonic numbers are given by

$$H_1 = 1, \quad H_2 = \frac{3}{2} = H_1 + \frac{1}{2}, \quad H_3 = \frac{11}{6} = H_2 + \frac{1}{3},$$

and by induction over  $n$  we can show that  $H_{n+1} = H_n + \frac{1}{n+1}$ , for all naturals  $n \geq 1$ . Harmonic numbers are the partial sums of the *harmonic series* that we will meet later in Section D. Now, for convenience set  $b = |H_{2n} - H_n|$ . Then

$$\begin{aligned} b &= \left| 1 + \frac{1}{2} + \dots + \frac{1}{n} + \frac{1}{n+1} + \dots + \frac{1}{2n} - H_n \right| \\ &= \frac{1}{n+1} + \frac{1}{n+2} + \dots + \frac{1}{2n} \\ &> \underbrace{\frac{1}{2n} + \frac{1}{2n} + \dots + \frac{1}{2n}}_{n\text{-terms}} = \frac{1}{2}. \end{aligned}$$

Thus taking  $\varepsilon = 1/2$  we see that there is no positive integer  $N$  satisfying  $|H_m - H_n| < 1/2$ , for all  $m, n \geq N$ . This means that  $(H_n)$  is not a Cauchy sequence. Thus  $(H_n)$  diverges (to  $+\infty$  since all of its terms are positive). We may verify the situation in Sage, by giving the cell

```
var("n");sum(1/n, n, 1, oo)
```

Sage after returning some “Runtime Errors”, types

```
ValueError: Sum is divergent.
```

□

Let us now present exercises having a bit more topological character, and are about limit, interior, boundary or isolated points of certain subsets of  $\mathbb{R}$  or  $\mathbb{C}$ . Here one should refresh the formal definitions given in 5.2.5, 5.2.7, and read carefully the proof of the Theorem 5.2.8. Mastering these notions may needs some effort, and thus we have included a series of exercises (see also the problems 5.E.36, 5.E.37, 5.E.38, and 5.E.39 in Section E).

**5.B.20. Limit, interior and isolated points.** Find all limit, isolated, and interior points of the set  $\mathbb{N}^* \subset \mathbb{R}$  of non-zero natural numbers (i.e., positive integers), and of the set  $\mathbb{Q} \subset \mathbb{R}$  of rational numbers.

**Solution.** Any  $n \in \mathbb{N}^*$  admits a neighbourhood in  $\mathbb{R}$  containing only the number  $n$ , i.e.,  $\mathcal{O}_1(n) \cap \mathbb{N}^* = (n-1, n+1) \cap \mathbb{N}^* = \{n\}$ . This means that every point  $n \in \mathbb{N}^*$  is isolated, and there are no interior points (since an isolated point cannot be an interior point). Moreover  $\mathbb{N}^*$  provides an example of an infinite set having no limits points. Indeed, if  $x_0$  is a

must be at least one closed disc  $C$  in the system  $\mathcal{A}_1$  which is not covered by a finite number the sets  $U_\alpha$ . Call it  $C_1$  and notice that  $\text{diam } C_1 = 2\varepsilon_1$ .

Next, consider the sets  $C_1 \cap C$ , with discs  $C \in \mathcal{A}_2$  which cover the entire set  $C_1$ . Again, at least one of them cannot be covered by a finite number of  $U_\alpha$ , we call it  $C_2$ . This way, we inductively construct a sequence of sets  $C_k$  satisfying  $C_{k+1} \subset C_k$ ,  $\text{diam } C_k \leq 2\varepsilon_k$ ,  $\varepsilon_k \rightarrow 0$ , and none of them can be covered by a finite number of the open sets  $U_\alpha$ .

Finally we choose one point  $z_k \in C_k$  in each of these sets. By construction, this must be a Cauchy-sequence. Consequently, this sequence of complex numbers has a limit  $z$ . Thus there is  $U_{\alpha_0}$  containing  $z$  and containing also some  $\delta$ -neighbourhood  $\mathcal{O}_\delta(z)$ . But now, if  $\text{diam } C_k \leq 2\varepsilon_k < \delta$ , then  $C_k \subset \mathcal{O}_\delta(z) \subset U_{\alpha_0}$ , which is a contradiction. The proof is complete when considering  $A \subset \mathbb{C}$ .

Dealing with real subset  $A \subset \mathbb{R}$ , again the same line of arguments applies, just the 2-dimensional nets  $B_k$  become 1-dimensional and the open discs are replaced by open intervals. □

**5.2.9. Limits of functions and sequences.** For the discussion of limits, it is advantageous to extend the set  $\mathbb{R}$  of real numbers by the two infinite values  $\pm\infty$  as we have done when defining intervals.

A neighbourhood of infinity is any interval  $(a, \infty)$ . Similarly, any interval  $(-\infty, a)$  is a neighbourhood of  $-\infty$ . Further, we will extend the concept of a limit point so that  $\infty$  is a limit point of a set  $A \subset \mathbb{R}$  if and only if every neighbourhood of  $\infty$  has a non-empty intersection with it, i.e. if the set  $A$  is unbounded from above. Similarly for  $-\infty$ . We talk about the infinite limit points, sometimes also called *improper limit points* of the set  $A$ .

“CALCULATIONS” WITH INFINITIES

We also introduce rules for calculation with the formally added values  $\pm\infty$  and arbitrary “finite” numbers  $a \in \mathbb{R}$ :

$$\begin{aligned} a + \infty &= \infty \\ a - \infty &= -\infty \\ a \cdot \infty &= \infty, \text{ if } a > 0 \\ a \cdot \infty &= -\infty, \text{ if } a < 0 \\ a \cdot (-\infty) &= -\infty, \text{ if } a > 0 \\ a \cdot (-\infty) &= \infty, \text{ if } a < 0 \\ \frac{a}{\pm\infty} &= 0, \text{ for all } a \neq 0. \end{aligned}$$

The following definition covers many cases of limit processes and needs to be thoroughly understood. Some particular cases are considered in great detail below.

limit point of  $\mathbb{N}^*$  then for some  $\varepsilon > 0$  we should have a natural (and in particular an infinite number of natural numbers) in distance smaller than  $\varepsilon$ , which is impossible.

Now for  $\mathbb{Q}$ , recall by 1.A.1 that this is a *dense* subset of  $\mathbb{R}$ . This means that each neighbourhood  $\mathcal{O}_\varepsilon(x)$  of any  $x \in \mathbb{R}$  contains rational numbers, that is for any  $x \in \mathbb{R}$  and every  $\varepsilon > 0$  there exists  $q \in \mathbb{Q}$  with  $q \in \mathcal{O}_\varepsilon(x) = (x - \varepsilon, x + \varepsilon)$ . Thus, for every  $x \in \mathbb{R}$ , there is a sequence of rational numbers  $a_n \neq x$ , converging to it. For instance, imagine the decimal representation of a real number  $x \notin \mathbb{Q}$ , and the corresponding sequence whose  $k$ th term will be the representation truncated to the first  $k$  decimal digits. If  $x$  was rational, we could clearly consider the sequence  $a_n = x + \frac{1}{n}$ . The set of all limit points of  $\mathbb{Q}$  is thus the whole real line  $\mathbb{R}$ . There are no isolated points in  $\mathbb{Q}$ , and in particular any rational number is also a limit point of the complement  $\mathbb{R} \setminus \mathbb{Q}$ . Finally, there are no interior points of  $\mathbb{Q}$  (this is because between any two rational numbers, there is an irrational number, and so it is impossible for a rational  $a \in \mathbb{Q}$  to be an interior point of  $\mathbb{Q}$ ).  $\square$

**5.B.21.** Find all limit, isolated, boundary and interior points of the sets  $X = \{x \in \mathbb{R} : 0 \leq x < 1\} \subset \mathbb{R}$  and  $Y = \{z \in \mathbb{C} : 0 \leq |z| < 1\} \subset \mathbb{C}$ .

**Solution.** Let  $a \in [0, 1)$  be an arbitrary number. Apparently, the sequences  $\{a + \frac{1}{n}\}_{n=1}^\infty$ ,  $\{1 - \frac{1}{n}\}_{n=1}^\infty$  converge to  $a$  and 1, respectively. So we have easily shown that the set of  $X$ 's limit points contains the interval  $[0, 1]$ . There are no other limit points: for any  $b \notin [0, 1]$  there is  $\delta > 0$  such that  $\mathcal{O}_\delta(b) \cap [0, 1] = \emptyset$  (for  $b < 0$  it suffices to take  $\delta = -b$ , and for  $b > 1$  we can choose  $\delta = b - 1$ ). Since every point of the interval  $[0, 1)$  is a limit point, there are no isolated points. For  $a \in (0, 1)$ , let  $\delta_a$  be the smaller one of the two positive numbers  $a$ ,  $1 - a$ . Considering  $\mathcal{O}_{\delta_a}(a) = (a - \delta_a, a + \delta_a) \subseteq (0, 1)$  for  $a \in (0, 1)$ , we see that every point of the interval  $(0, 1)$  is an interior point of  $X$ . For every  $\delta \in (0, 1)$ , we have that

$$\begin{aligned} \mathcal{O}_\delta(0) \cap [0, 1) &= (-\delta, \delta) \cap [0, 1) = [0, \delta), \\ \mathcal{O}_\delta(1) \cap [0, 1) &= (1 - \delta, 1 + \delta) \cap [0, 1) = (1 - \delta, 1), \end{aligned}$$

so every  $\delta$ -neighborhood of the point 0 contains some points of the interval  $[0, 1)$  and some points of the interval  $(-\delta, 0)$ , and every  $\delta$ -neighborhood of 1 has a non-empty intersection with the intervals  $[0, 1)$ ,  $[1, 1 + \delta)$ . Therefore, 0 and 1 are boundary points. Altogether, we have found that the interior points of  $X$  coincide with the interval  $(0, 1)$  while the two-element set  $\{0, 1\}$  consists of the boundary points of  $X$  (as we know that no point can be both interior and boundary and that a boundary point must be an isolated or a limit point). The case of  $Y$  is very similar and we leave most of the details to the reader. It is the open unit disk in the complex plane, all its points are interior (as with all open sets). The boundary points form the unit circle. Thus, the set of limit points is the closed unit disc and there are no isolated points there.  $\square$

**Definition.** Consider a subset  $A \subset \mathbb{R}$  and a real-valued function  $f : A \rightarrow \mathbb{R}$  or a complex-valued function  $f : A \rightarrow \mathbb{C}$ , defined on  $A$ . Further, consider a limit point  $x_0$  of the set  $A$  (i.e. a real number or  $\pm\infty$ ).

We say that  $f$  has *limit*  $a \in \mathbb{R}$  (or a complex limit  $a \in \mathbb{C}$ ) at  $x_0$  and write

$$\lim_{x \rightarrow x_0} f(x) = a$$

if and only if for every neighbourhood  $\mathcal{O}(a)$  of the point  $a$ , there is a neighbourhood  $\mathcal{O}(x_0)$  of  $x_0$  such that for all  $x \in A \cap (\mathcal{O}(x_0) \setminus \{x_0\})$ ,  $f(x) \in \mathcal{O}(a)$ .

In the case of a real-valued function,  $a = \pm\infty$  can also be the limit. Such a limit is called *infinite* or *improper*. In the other case, i.e.  $a \in \mathbb{R}$ , we say the limit is *finite* or *proper*.

It is important to notice that the value of  $f$  at  $x_0$  does not occur in the definition, and that the function  $f$  may even not be defined at this limit point (and in the case of an improper limit point, it cannot be defined, of course!).

We shall not deal with improper limits of complex functions now.

**5.2.10. The most important cases of domains.** Our definition of a limit covers several very dissimilar situations:

(1) **Limits of sequences.** If  $A = \mathbb{N}$ , i.e. the function  $f$  is defined for the natural numbers only, we talk about limits of sequences of real or complex numbers. In this case, the only limit point of the domain is  $\infty$ , and we mostly write the values (terms) of the sequence as  $f(n) = a_n$  and the limit in the form

$$\lim_{n \rightarrow \infty} a_n = a.$$

According to the definition, this means that for any neighbourhood  $\mathcal{O}(a)$  of the limit value  $a$ , there is an index  $N \in \mathbb{N}$  such that  $a_n \in \mathcal{O}(a)$  for all  $n \geq N$ . Actually, we have only reformulated the definition of convergence of a sequence (see 5.2.3). We have only added the possibility of infinite limits. As before, we also say that the *sequence*  $a_n$  *converges* to  $a$ .

We can easily see from our definition for complex numbers that a sequence of complex values has limit  $a$  if and only if the real parts of  $a_i$  converge to  $\operatorname{Re} a$  and the imaginary parts converge to  $\operatorname{Im} a$ .

(2) **Limits of functions at interior points of intervals.** If  $f$  is defined on the interval  $A = (a, b)$  and  $x_0$  is an interior point of this interval, we talk about the limit of a function at an interior point of its domain. Usually, we write

$$\lim_{x \rightarrow x_0} f(x) = a.$$

Let us examine why it is important to require  $f(x) \in \mathcal{O}(a)$  only for the points  $x \neq x_0$  in this case as well. As an example, let us consider the function  $f : \mathbb{R} \rightarrow \mathbb{R}$

$$f(x) = \begin{cases} 0 & \text{if } x \neq 0 \\ 1 & \text{if } x = 0. \end{cases}$$

*If all limit points of a subset  $A$  of  $\mathbb{R}$  or of  $\mathbb{C}$  belong to  $A$ , then the subset is said to be closed. This means that we cannot run away from  $A$  by a sequence  $(x_n) \in A$  to a limit not belonging to  $A$ . If the complement of  $A$  in the real line or in the complex plane is closed, then clearly each  $x \in A$  has a neighbourhood  $\mathcal{O}_\varepsilon(x) \subset A$ , for some  $\varepsilon > 0$ . In this case  $A$  is called open, see 5.2.5, 5.2.7 and 5.2.8 for further details. Observe that the empty set  $\emptyset$  and  $\mathbb{R}$  (or  $\mathbb{C}$ ) itself are both open and closed (for instance,  $\mathbb{C}$  has no boundary points). If a subset  $A$  in  $\mathbb{R}$  or  $\mathbb{C}$  is closed and bounded (the latter means that  $A \subset \mathcal{O}_r(x)$  for some  $x$  and big enough  $r > 0$ ), then each sequence  $(x_n) \in A$  has a limit point in  $A$ , i.e., there is a convergent subsequence in  $A$ . Such sets are called compact sets.*

**5.B.22. Closed and open subsets.** Verify that an open interval  $I = (a, b) = \{x \in \mathbb{R} : a < x < b\}$  of the real line is an open set, and moreover that a closed interval  $J = [a, b] = \{x \in \mathbb{R} : a \leq x \leq b\}$  is a closed set. Is the interval  $(0, 1]$  a closed set?

**Solution.** Given some  $x \in I$  we should show that  $x$  is an interior point of  $I$ . Set  $\varepsilon = \frac{1}{2} \min\{x - a, b - x\} > 0$  and note that  $\varepsilon$  depends on  $x$ . Then we have  $a \leq x - \varepsilon < x + \varepsilon \leq b$ , and so  $(x - \varepsilon, x + \varepsilon) \subset (a, b)$ . Therefore, we have constructed an open neighbourhood  $\mathcal{O}_\varepsilon(x) \subset I$  around  $x$ , contained in  $I$ , and since this works for any  $x \in I$ , the set  $I$  is open. Next, the complement of  $J$  is  $J^c = (-\infty, a) \cup (b, \infty)$  which is open as a union of open intervals. Thus  $J$  is closed. Finally, the interval  $(0, 1]$  cannot be a closed set; For instance, the sequence  $(x_n) = (1/n) \in (0, 1]$  satisfies  $(1/n) \rightarrow 0$  as  $n \rightarrow \infty$ , but  $0 \notin (0, 1]$ .  $\square$

**5.B.23.** Decide which of the following sets are open or closed:

- (a)  $A = \mathbb{Z} \subset \mathbb{R}$ ;
- (b)  $B = [2, +\infty) \subset \mathbb{R}$ ;
- (c)  $C = \{z \in \mathbb{C} : |z - 1| + |z + 1| < 5\} \subset \mathbb{C}$ .

**Solution.** (a) It is not hard to see that the complement of  $\mathbb{Z}$  in  $\mathbb{R}$  is given by the union  $\cup_{k \in \mathbb{Z}} (k, k + 1)$ . Hence the set  $\mathbb{R} \setminus \mathbb{Z}$  is open, as the union of open sets. It follows that  $\mathbb{Z}$  is closed in  $\mathbb{R}$ .

(b) The complement of  $B$  in  $\mathbb{R}$  is the set  $(-\infty, 2)$ , which is open. Thus  $B$  itself is a closed subset of  $\mathbb{R}$ . In a similar way one can show that the following sets are closed:  $[a, +\infty)$ , and  $(-\infty, b]$ , with  $a, b \in \mathbb{R}$ .

(c) Let us treat this case based on the notion of continuity, that we will essentially analyze a few below. Consider the function  $f : \mathbb{C} \rightarrow \mathbb{R}$  given by  $f(z) = |z - 1| + |z + 1|$ . As a challenge for you, prove that this function is continuous. Moreover, show that  $C = f^{-1}((-\infty, 5))$ . Then, the claim follows by 5.2.18; The set  $(-\infty, 5)$  is open and  $f$  is continuous, hence  $C$  is open, as well.  $\square$

**5.B.24.** Is the range of  $f(x) = x^2$  a closed subset of  $\mathbb{R}$ ?  $\circ$

Apparently, the limit at zero is well-defined, and in accordance with our expectations,  $\lim_{x \rightarrow 0} f(x) = 0$  even though the value  $f(0) = 1$  does not belong into small neighbourhoods of the limit value 0.

An equivalent definition using  $\varepsilon$ -neighbourhoods of the limits  $a$  and  $\delta$ -neighbourhoods of the limit points  $x_0$  is the following:  $\lim_{x \rightarrow x_0} f(x) = a$  if for each  $\varepsilon > 0$  there is a  $\delta > 0$  such, that for all  $x \neq x_0$  satisfying  $|x - x_0| < \delta$ ,  $|f(x) - a| < \varepsilon$ .

(3) **One-sided limits.** If  $A = [a, b]$  is a bounded interval and  $x_0 = a$  or  $x_0 = b$ , we talk about a one-sided limit of the function  $f$  at the point  $x_0$ , from the right and from the left respectively.

If the point  $x_0$  is an interior point of the domain of  $f$ , we can, in order to determine the limit, consider the domain restricted to  $[x_0, b]$  or  $[a, x_0]$ . The resulting limits are also called a *right-sided limit* and *left-sided limit*, respectively, of the function  $f$  at the point  $x_0$ . We denote them by  $\lim_{x \rightarrow x_0^+} f(x)$  and  $\lim_{x \rightarrow x_0^-} f(x)$ , respectively. As an example, we can consider the one-sided limits at  $x_0 = 0$  for Heaviside's function  $h$  from the introduction to this part. Apparently,

$$\lim_{x \rightarrow 0^+} h(x) = 1, \quad \lim_{x \rightarrow 0^-} h(x) = 0.$$

However, the limit  $\lim_{x \rightarrow 0} f(x)$  does not exist.

It follows from the definitions that *the limit at an interior point of the domain of an arbitrary function  $f$  exists if and only if both one-sided limits exist and are equal.*

**5.2.11. Further examples of limits.** (1) The limit of a complex function  $f : A \rightarrow \mathbb{C}$  in a limit point  $x_0$  of its domain exists if and only if the limits of both the real part and the imaginary part exist. In this case, we have

$$\lim_{x \rightarrow x_0} f(x) = \lim_{x \rightarrow x_0} (\operatorname{Re} f(x)) + i \lim_{x \rightarrow x_0} (\operatorname{Im} f(x)).$$

The proof is straightforward and makes direct use of the definitions of distances and neighbourhoods of the points in the complex plane. Indeed, the membership into a  $\delta$ -neighbourhood of a complex value  $z$  is guaranteed by the real  $(1/\sqrt{2})\delta$ -neighbourhoods of the real and the imaginary parts of  $z$ . Hence the proposition follows immediately.

(2) Let  $f$  be a real or complex polynomial. Then for every point  $x \in \mathbb{R}$ ,

$$\lim_{x \rightarrow x_0} f(x) = f(x_0).$$

Really, if  $f(x) = a_n x^n + \dots + a_0$ , then the identity  $(x_0 + \delta)^k = x_0^k + k\delta x_0^{k-1} + \dots + \delta^k$ , substituted for  $k = 0, \dots, n$ , gives that choosing a sufficiently small  $\delta$  makes the values arbitrarily close to  $f(x_0)$ .

(3) Now consider the following function defined on the whole real line

$$f(x) = \begin{cases} 1 & \text{if } x \in \mathbb{Q} \\ 0 & \text{if } x \notin \mathbb{Q}. \end{cases}$$

It is apparent from the definition that this function cannot have (even one-sided) limits at any point of its domain.

**5.B.25.** Decide which of the following sets is compact:

- (a)  $I = (0, 1)$ ;
- (b)  $J = [0, 1]$ ;
- (c)  $A = \mathbb{N}^*$ ;
- (d)  $B = \{1/n : n \in \mathbb{N}^*\}$ ;
- (e)  $C = B \cup \{0\}$ .

**Solution.** Recall by (4) in Theorem 5.2.8 (Bolzano-Weierstrass theorem), that a subset  $A \subset \mathbb{R}$  is compact if and only if every finite sequence contained in  $X$  has a subsequence converging to a point in  $X$ . We can use the Bolzano-Weierstrass theorem as criterium to decide which of the given sets is compact or not.

- (a) The open set  $I = (0, 1)$  is not compact: Consider for example the sequence  $(x_n) = (\frac{1}{n})$ , as above. We know that in  $I$  this sequence converges to 0, but  $0 \notin I$ . Thus, for  $(x_n)$  there is no convergent subsequence whose limit belongs to  $I$ .
- (b) The closed set  $J = [0, 1]$  is compact, as every bounded closed interval  $[a, b] \subset \mathbb{R}$ , see 5.E.39.
- (c) The set of non-zero naturals  $\mathbb{N}^*$  is not compact. For instance, the sequence  $(y_n = n)$  has no convergent subsequence. This is because every subsequence diverges to infinity.
- (d) The set  $B$  is not closed, so cannot be compact either.
- (e) Obviously, the set  $C$  is closed and bounded, and hence compact.  $\square$

Given a sequence  $(a_n)$  in 5.4.6 we consider the so called “upper limit” and “lower limit”, also called *limes superior* and *inferior* of  $(a_n)$ , and denoted by  $\limsup_{n \rightarrow \infty} a_n$  and  $\liminf_{n \rightarrow \infty} a_n$ . These limits always exists and have many important applications (see for example in Section D), and see also 5.E.32 and 5.E.34 for more details.

**5.B.26.** Compute the limes superior and inferior of the sequence

$$a_n = \frac{n^2 + 4n - 5}{n^2 + 9} \sin^2\left(\frac{n\pi}{4}\right), \quad n \in \mathbb{N}^*.$$

**Solution.** Recall that the limes superior/inferior are the largest/smallest limit point of the sequence. For the given task to compute them we may split the sequence  $(a_n)$  into several subsequences according the the value of  $(\sin \frac{n\pi}{4})^2$ , e.g., 0,  $\frac{1}{2}$ , and 1. All of them are converging to different limits and the result is  $\limsup_{n \rightarrow \infty} a_n = 1$  and  $\liminf_{n \rightarrow \infty} a_n = 0$ , respectively.  $\square$

Additional exercises on limes superior/inferior and most of the directions analyzed above are presented in Section E. Later, in Chapter 7, we will revise most of the topological notions analyzed in this chapter (using  $\mathbb{R}$  or  $\mathbb{C}$ ), in terms of the more general notion of “metric spaces”. But to do so, we first need to learn for limits of functions and continuous functions.

(4) The following function is even trickier than the previous one. Let  $f : \mathbb{R} \rightarrow \mathbb{R}$  be the function defined as follows:<sup>8</sup>

$$f(x) = \begin{cases} 1 & \text{if } x = 0 \\ \frac{1}{q} & \text{if } x = \frac{p}{q} \in \mathbb{Q}, p, q \in \mathbb{Z}, q > 0 \text{ are co-prime,} \\ 0 & \text{if } x \notin \mathbb{Q}. \end{cases}$$

Choose any point  $x_0$ , no matter whether rational or irrational. Our goal is to show that  $\lim_{x \rightarrow x_0} f(x) = 0$ . Thus fix any  $\varepsilon > 0$  and look at the possible values of  $f(x)$  close to  $x_0$ . Notice that  $f(x) \geq \varepsilon$ , i.e.  $\frac{1}{q} \geq \varepsilon$  can be true for only finite number of  $q \in \mathbb{N}$ . This behaviour is illustrated on the diagram. In particular, there can be only a finite number of points  $x$  in the interval  $(x_0 - 1, x_0 + 1)$  for which  $f(x) \geq \varepsilon$ . Label them  $x_1, \dots, x_n$ . Finally, choose  $\delta$  smaller than the minimum of the distances of any two different points  $x_i$ . Then  $f(x) < \varepsilon$  for all  $x \in \mathcal{O}_\delta(x_0) \setminus \{x_0\}$ . This finishes the proof.

Notice that this limit equals the function value only at the irrational points.

**5.2.12. The squeeze theorem.** The following result is elementary, but extremely useful. We meet it when computing limits of all types discussed above, i.e. limits of sequences, limits of functions at interior points, one-sided limits, and so on.

**Theorem.** Let  $f, g, h$  be three real-valued functions with the same domain  $A$  and such that there is a neighbourhood of a limit point  $x_0 \in \mathbb{R}$  of the domain where

$$f(x) \leq g(x) \leq h(x),$$

for all  $x \neq x_0$ . Suppose there are limits

$$\lim_{x \rightarrow x_0} f(x) = f_0, \quad \lim_{x \rightarrow x_0} h(x) = h_0$$

and  $f_0 = h_0$ . Then the limit

$$\lim_{x \rightarrow x_0} g(x) = g_0$$

exists, and it satisfies  $g_0 = f_0 = h_0$ .

<sup>8</sup>This function is called the *Thomae function* after the German mathematician J. Thomae, 1840–1921. You may find it under many other names too: e.g. *Riemann function*, *pop-corn function*, *raindrop function* etc. It illustrates how badly dense the “discontinuity” points of a function can be even though it has limits everywhere.

Limits of functions enable us to investigate the behaviour of functions (and hence their graph), in the neighbourhood of some given point. They form the basis of the notion of differentiation that we will discuss in the forthcoming section, and establishes one of the most beautiful themes in mathematical analysis and in many other areas (e.g., numerical analysis).

Most of the tasks presented below are based on theoretical results from the sections 5.2.9, 5.2.12, 5.2.13, 5.2.16, 5.2.18, and 5.2.20. All these results will gradually become more evident, as we explore them by examples. We recall however that limits are well defined in the limit points of the given domain of a function, and the function is called continuous at  $x$ , if its limit equals the function value there (be aware however, that in general a function does not need to be defined at the point where we seek for the limit). Recall also that from the topological point of view (see 5.2.18), a function  $f : A \subset \mathbb{R} \rightarrow \mathbb{R}$  is continuous if and only if the pre-image  $f^{-1}(U)$  is an open subset of  $A$ , for every open set  $U \subset \mathbb{R}$ . To verify that  $f^{-1}(U)$  is open it suffices to show that any point  $x \in f^{-1}(U)$  lies on an open interval of  $f^{-1}(U)$ .

**5.B.27. Limit of functions.** Find the following limits or explain why they do not exist:

- (a)  $\lim_{x \rightarrow c} x^2$ ,
- (b)  $\lim_{x \rightarrow c} (x^6 - x^3 - \sqrt{6})$ ,
- (c)  $\lim_{x \rightarrow 2} \frac{x^2 + x - 6}{x^2 - 3x + 2}$ ,
- (d)  $\lim_{x \rightarrow 0} \sin\left(\frac{1}{x}\right)$ ,
- (e)  $\lim_{x \rightarrow 2^+} \frac{x^2 + 2x - 8}{|x - 2|}$ ,
- (f)  $\lim_{x \rightarrow 2^-} \frac{x^2 + 2x - 8}{|x - 2|}$ ,
- (g)  $\lim_{x \rightarrow 3} \frac{x - 3}{\sqrt{x + 1} - (x - 1)}$ ,
- (k)  $\lim_{x \rightarrow 0} x \cos\left(\frac{1}{x}\right)$ .

**Solution.** (a) We can treat this limit by basic principles, as for example the Cauchy definition for limits of functions. Let us however rely on topology, as it was mentioned a few above, to show that  $f(x) = x^2$  is continuous and hence  $\lim_{x \rightarrow c} x^2 = c^2$ , where  $c$  is any real number. Let  $I = (a, b) \subset \mathbb{R}$  be an open interval with  $a < b$  and  $a, b \in \mathbb{R}$ . By definition,  $f^{-1}(I) = \{x \in \mathbb{R} : x^2 \in (a, b)\}$ , hence obviously for  $b \leq 0$  it should be  $f^{-1}(I) = \emptyset$  (since  $x^2 \geq 0$  for any  $x$ ), which is open. For  $a < 0 < b$ , one gets  $f^{-1}(I) = (-\sqrt{b}, \sqrt{b}) \subset \mathbb{R}$ , since any  $x \in (-\sqrt{b}, \sqrt{b})$  satisfies  $f(x) \in (a, b)$ . Thus again  $f^{-1}(I)$  is open as an open interval of  $\mathbb{R}$ . Finally, for  $0 \leq a < b$  the preimage  $f^{-1}(I)$  is the union  $(-\sqrt{b}, -\sqrt{a}) \cup (\sqrt{a}, \sqrt{b})$  which is again open as the union of two open intervals of  $\mathbb{R}$ . (b) For the second limit one simply applies sum and difference rules (see also below), and get benefit from the fact that the  $n$ th power  $x \mapsto x^n$  ( $n = 0, 1, 2, \dots$ ) is a continuous function. Or you can directly rely on the fact that polynomials are continuous everywhere in  $\mathbb{R}$ , see 5.2.11. Hence  $\lim_{x \rightarrow c} (x^6 - x^3 + x - \sqrt{6}) = c^6 - c^3 - \sqrt{6}$ . (c) The substitution  $x = 2$  leads to both zero numerator and zero denominator. Despite of that, the problem can be solved

**PROOF.** From the assumptions of the theorem, it follows that for any  $\varepsilon > 0$ , there is a neighbourhood  $\mathcal{O}(x_0)$  of the point  $x_0 \in A \subset \mathbb{R}$  in which both  $f(x)$  and  $h(x)$  lie in the interval  $(f_0 - \varepsilon, f_0 + \varepsilon)$ , for all  $x \neq x_0$ . From the condition  $f(x) \leq g(x) \leq h(x)$ , it follows that  $g(x) \in (f_0 - \varepsilon, f_0 + \varepsilon)$ , and so  $\lim_{x \rightarrow x_0} g(x) = f_0$ .

The above reasoning is easily modified for infinite limit values or for limits at infinite points  $x_0$ . In the first case, choose a large  $N$  instead of  $\varepsilon$ . The condition on the values reads: both  $f(x)$  and  $h(x)$  have values larger than  $N$  on the neighbourhood  $\mathcal{O}(x_0) \setminus \{x_0\}$ , and thus the same will be true for  $g(x)$ . In the second case, the neighbourhood  $\mathcal{O}$  will be an interval  $(M, \infty)$ . The other infinite limit point  $-\infty$  is dealt with similarly.  $\square$

The next theorem reveals the elementary properties of limits, again for all types together. Think about the individual cases, including the limits taken at  $x_0 = \pm\infty$ !

**5.2.13. Theorem.** Let  $A \subset \mathbb{R}$  be the domain of real or complex functions  $f$  and  $g$ , let  $x_0$  be a limit point of  $A$  and let the limits

$$\lim_{x \rightarrow x_0} f(x) = a \in \mathbb{K}, \quad \lim_{x \rightarrow x_0} g(x) = b \in \mathbb{K}$$

exist. Then:

- (1) the limit  $a$  is unique,
- (2) the limit of the sum  $f + g$  exists and satisfies

$$\lim_{x \rightarrow x_0} (f(x) + g(x)) = a + b,$$

- (3) the limit of the product  $f \cdot g$  exists and satisfies

$$\lim_{x \rightarrow x_0} (f(x) \cdot g(x)) = a \cdot b.$$

In particular, if  $f(x) = a$  is a constant function then  $\lim_{x \rightarrow x_0} a \cdot g(x) = a \cdot b$ ,

- (4) if  $b \neq 0$ , the limit of the quotient  $f/g$  exists and satisfies

$$\lim_{x \rightarrow x_0} \frac{f(x)}{g(x)} = \frac{a}{b}.$$

**PROOF.** (1) Suppose  $a$  and  $a'$  are two values of the limit  $\lim_{x \rightarrow x_0} f(x)$ . If  $a \neq a'$ , then there are disjoint neighbourhoods  $\mathcal{O}(a)$  and  $\mathcal{O}(a')$ . However, for sufficiently small neighbourhoods of  $x_0$ , the values of  $f$  should lie in both neighbourhoods. This is a contradiction. Thus  $a = a'$ .

(2) Choose a neighbourhood of  $a+b$ , for instance  $\mathcal{O}_{2\varepsilon}(a+b)$ . For a sufficiently small neighbourhood of  $x_0$  and  $x \neq x_0$ ,

very easily by factorization:

$$\lim_{x \rightarrow 2} \frac{x^2 + x - 6}{x^2 - 3x + 2} = \lim_{x \rightarrow 2} \frac{(x-2)(x+3)}{(x-2)(x-1)} = \frac{2+3}{2-1} = 5.$$

(d) We will prove that this limit does not exist, using  $\varepsilon$ -neighbourhoods, see 5.2.9 and 5.2.10. Set  $f(x) = \sin(1/x)$  and assume, in contrast, that  $\lim_{x \rightarrow 0} f(x) = \ell$  for some real number  $\ell$ . This means that for  $\varepsilon = \frac{1}{2}$  there exists  $\delta > 0$  such that for any  $x$  with  $0 < |x - 0| < \delta$  we have  $|f(x) - \ell| < \frac{1}{2}$ . Then there exist some  $n \in \mathbb{N}$  and reals  $x_1 = \frac{1}{2n\pi}$  and  $x_2 = \frac{1}{2n\pi + \frac{\pi}{2}}$ , such that  $0 < |x_1| < \delta$  and  $0 < |x_2| < \delta$ . Hence,  $|f(x_1) - \ell| < \frac{1}{2}$ ,  $|f(x_2) - \ell| < \frac{1}{2}$ , and using the triangle inequality we see that

$$\begin{aligned} \Delta &= |(f(x_1) - \ell) + (\ell - f(x_2))| \\ &\leq |f(x_1) - \ell| + |\ell - f(x_2)| \\ &= |f(x_1) - \ell| + |f(x_2) - \ell| < \frac{1}{2} + \frac{1}{2} = 1, \end{aligned}$$

where for simplicity we set  $\Delta := |f(x_1) - f(x_2)|$ . Since  $f(x_1) = \sin(2n\pi) = 0$  and  $f(x_2) = \sin(2n\pi + \frac{\pi}{2}) = \sin(\frac{\pi}{2}) = 1$ , the last inequality gives  $|f(x_1) - f(x_2)| = |0 - 1| = 1 < 1$ , a contradiction.

(e) By the definition of the absolute value we have

$$\begin{aligned} \lim_{x \rightarrow 2^+} \frac{x^2 + 2x - 8}{|x - 2|} &= \lim_{x \rightarrow 2^+} \frac{(x-2)(x+4)}{x-2} \\ &= \lim_{x \rightarrow 2^+} (x+4) = 6. \end{aligned}$$

(f) Similarly

$$\lim_{x \rightarrow 2^-} \frac{x^2 + 2x - 8}{|x - 2|} = \lim_{x \rightarrow 2^-} \frac{(x-2)(x+4)}{-(x-2)} = -6.$$

Thus, a comparison with the result from case (e) implies that the function  $f(x) = \frac{x^2 + 2x - 8}{|x - 2|}$  cannot be continuous at  $x_0 = 2$  (since the one sided limits are not equal).

(g) Set for simplicity  $f(x) = \frac{x-3}{\sqrt{x+1} - (x-1)}$ . When  $x \rightarrow 3$  we see that both the numerator and denominator tend to 0, which gives the indeterminate form  $\frac{0}{0}$  (see also below). One can treat such cases by multiplying both the numerator and denominator by the “conjugate expression” of the denominator. For our case this means  $\sqrt{x+1} + (x-1)$  with

$$(\sqrt{x+1} - (x-1))(\sqrt{x+1} + (x-1)) = -x(x-3).$$

Thus

$$\begin{aligned} \lim_{x \rightarrow 3} f(x) &= \lim_{x \rightarrow 3} \frac{(x-3)(\sqrt{x+1} + (x-1))}{-x(x-3)} \\ &= -\lim_{x \rightarrow 3} \frac{\sqrt{x+1} + (x-1)}{x} = -\frac{4}{3}. \end{aligned}$$

(k) Recall that  $|\cos(x)| \leq 1$  for any  $x \in \mathbb{R}$  and hence  $|x \cos(\frac{1}{x})| \leq |x|$ . By the squeeze theorem (5.2.12) this gives  $\lim_{x \rightarrow 0} x \cos(\frac{1}{x}) = 0$ .  $\square$

both  $f(x)$  and  $g(x)$  will lie in  $\varepsilon$ -neighbourhoods of the points  $a$  and  $b$ . Hence their sum will lie in the  $2\varepsilon$ -neighbourhood of  $a + b$ . The proposition is proved.

(3) We have to be a bit more careful here. Let us look, what we can do with an assumption  $|f(x) - a| < \varepsilon$ ,  $|g(x) - b| < \varepsilon$  for  $x \in \mathcal{O}(x_0)$ , i.e. choosing a small enough neighbourhood of the limit point  $x_0$ . Estimate:

$$\begin{aligned} |f(x)g(x) - ab| &= |f(x)(g(x) - b) + b(f(x) - a)| \\ &\leq |f(x)|\varepsilon + |b|\varepsilon \leq |f(x) - a|\varepsilon + |a|\varepsilon + |b|\varepsilon \\ &\leq \varepsilon^2 + \varepsilon(|a| + |b|) \end{aligned}$$

Now we easily conclude. Choosing any  $\tilde{\varepsilon} > 0$ , there is unique  $\varepsilon > 0$  with  $\tilde{\varepsilon} = \varepsilon^2 + \varepsilon(|a| + |b|)$ . Thus using this  $\varepsilon$  for the choice of  $\mathcal{O}(x_0)$  above, we arrive at the required condition from the definition of the limit.

Clearly, the limit of the constant function  $f(x) = a$  is  $a$  at all limit points of its domain.

(4) In view of the previous results, it suffices to prove  $\lim_{x \rightarrow x_0} \frac{1}{g(x)} = \frac{1}{b}$  for  $|b| > 0$ . We need to be careful when considering complex valued functions. We need to estimate

$$\left| \frac{1}{g(x)} - \frac{1}{b} \right| = \left| \frac{b - g(x)}{g(x) \cdot b} \right|.$$

Since  $|b| > 0$ , we may restrict ourselves to a neighbourhood  $U$  of  $x_0$  such that  $|g(x)| > \frac{|b|}{2}$ . Then  $|g(x)| \cdot |b| > \frac{|b|^2}{2}$ . Thus, if  $|g(x) - b| < \varepsilon$ , then

$$\left| \frac{1}{g(x)} - \frac{1}{b} \right| < \frac{2|b - g(x)|}{|b|^2} < \frac{2\varepsilon}{|b|^2}.$$

This verifies the claim as in the previous case.  $\square$

**5.2.14. Remarks on infinite values of limits.** The statement of the theorem can be extended to some infinite values of the limits of real-valued functions: For sums, either at least one of the two limits must be finite or both limits share the same sign. Then the limit of the sum is the sum of the limits, with the conventions from 5.2.9. However, “ $\infty - \infty$ ” is excluded.

For products, if one of the limits is infinite, then the other limit must be non-zero. Then the limit of the product is the product of the limits. The case “ $0 \cdot (\pm\infty)$ ” is excluded.

For a quotient, it may be that  $a \in \mathbb{R}$  and  $b = \pm\infty$ , then the resulting limit will be zero; or  $a = \pm\infty$  and  $b \in \mathbb{R}$ , then it will be  $\pm\infty$  according to the signs of the numerator and the denominator. The case “ $\frac{\infty}{\infty}$ ” is excluded.

The theorem also covers, as a special case, the corresponding statements about the convergence of sequences as well as about one-sided limits of functions defined on an interval.

The following provides a “convergence test” useful in many situations. It relates to limits of sequences and functions in general.

**5.2.15. Proposition.** Consider a real or complex valued function  $f$  defined on a set  $A \subset \mathbb{R}$  and a limit point  $x_0$  of the set  $A$ .  $f$  has a limit  $y$  at  $x_0$  if and only if for every sequence of

**5.B.28.** Compute the limit

$$\lim_{x \rightarrow 1} \frac{3x^3 + 2x^2 - 2x - 3}{5x^3 + 2x^2 - 2x - 5},$$

if it is known that  $\rho = 1$  is a root of both the numerator and denominator. Next use Sage to confirm your computations.

**Solution.** First notice that the function  $f(x) = \frac{3x^3+2x^2-2x-3}{5x^3+2x^2-2x-5}$  is not defined at  $x = 1$ , and moreover this limit has again the indeterminate form  $\frac{0}{0}$ . However, the statement already motivates a method for solving the task: Use the Horner's scheme and factorize the numerator and the denominator, i.e.,

$$\begin{aligned} 3x^3 + 2x^2 - 2x - 3 &= (x - 1)(3x^2 + 5x + 3), \\ 5x^3 + 2x^2 - 2x - 5 &= (x - 1)(5x^2 + 7x + 5). \end{aligned}$$

Then it is easy to see that the limit at hand equals to  $11/17$ .

In fact, you can easily do all the computations that we omitted via Sage, where you can still use the command `limit` to compute limits of functions, as in the case of sequences. Here it is however necessary to specify the limit point  $x_0$ , and the exact syntax for computing the limit  $\lim_{x \rightarrow x_0} f(x)$  is `limit(f(x), x = x_0)`. In addition, you can program Sage to compute the left and right side limits, by adding the options `dir = "left"` and `dir = "right"`, respectively. For our task the cell

```
g(x)=3*x^3+2*x^2-2*x-3; h(x)=5*x^3+2*x^2-2*x-5
show(factor(g(x))); show(factor(h(x)))
limit(g(x)/h(x), x=1)
```

verifies the factorizations given above and the explicit value of the limit, as you can easily check in your computer.

Finally, it is worth mentioning that one could compute the limit at hand by other methods. For instance, one can apply Proposition 5.2.15. Hence, let  $(x_n)$  be a sequence of real numbers with  $x_n \rightarrow 1$  as  $n \rightarrow \infty$ , and  $x_n \neq 1$  for all  $n = 1, 2, \dots$ . Then, for the induced sequence of values  $f(x_n)$  we see that

$$\begin{aligned} f(x_n) &= \frac{3x_n^3 + 2x_n^2 - 2x_n - 3}{5x_n^3 + 2x_n^2 - 2x_n - 5} \\ &= \frac{(x_n - 1)(3x_n^2 + 5x_n + 3)}{(x_n - 1)(5x_n^2 + 7x_n + 5)} = \frac{3x_n^2 + 5x_n + 3}{5x_n^2 + 7x_n + 5}. \end{aligned}$$

Taking the limit  $\lim_{n \rightarrow \infty} f(x_n)$  we get  $11/17$ , and according to Proposition 5.2.15 this implies that  $\lim_{x \rightarrow 1} f(x) = 11/17$ .  $\square$

**5.B.29.** Explain why the relation  $\lim_{x \rightarrow \pi/3} \sin(x) = \sin(\pi/3)$  is true. Next use Sage to confirm that  $\sin(x)$  is continuous at the chosen point by combining the `limit` command with the `bool` syntax.  $\circ$

*The Cauchy definition of limits of functions in terms of  $\varepsilon$  and  $\delta$  can be used to derive a number of elementary results. Let us describe such an example.*

points  $x_n \in A$  converging to  $x_0$ ,  $x_n \neq x_0$ , the sequence of the values  $f(x_n)$  has limit  $y$ .

### CONVERGENCE TEST

**PROOF.** Suppose first that the limit of  $f$  at  $x_0$  is  $y$ . Then for any neighbourhood  $U$  of the point  $y$ , there is a neighbourhood  $V$  of  $x_0$  such that for all  $x \in V \cap A$ ,  $x \neq x_0$ ,  $f(x) \in U$ . For every sequence  $x_n \rightarrow x_0$  of points different from  $x_0$ , the terms  $x_n$  lie in  $V$  for all  $n$  greater than a suitable  $N$ . Therefore, the sequence  $f(x_n)$  converges to  $y$ .

Now suppose that the function  $f$  does not converge to  $y$  at  $x \rightarrow x_0$ . Then for some neighbourhood  $U$  of  $y$ , there is a sequence of points  $x_m \neq x_0$  in  $A$  which are closer to  $x_0$  than  $1/m$ , with  $f(x_m)$  not belonging to  $U$ . In this way, there is constructed a sequence of points lying in  $A$  different from  $x_0$ , with  $\lim_{m \rightarrow \infty} x_m = x_0$ , for which the values  $f(x_n)$  do not converge to  $y$ . The proof is finished.  $\square$

**5.2.16. Continuity.** Continuity was discussed intuitively when polynomials were discussed. Now all the tools for a proper formulation of continuity are prepared. This is the basic class of functions in the sequel.

### CONTINUITY OF FUNCTIONS

**Definition.** Let  $f$  be a real or complex valued function defined on an interval  $A \subset \mathbb{R}$ .  $f$  is *continuous at a point*  $x_0 \in A$  if and only if

$$\lim_{x \rightarrow x_0} f(x) = f(x_0).$$

The function  $f$  is continuous on an interval  $A$  if and only if it is continuous at every point  $x_0 \in A$ .

The diagram explains the meaning of continuity. Firstly, the limit has to exist. Thus, after choosing a neighbourhood  $U$  of the limit value  $f(x_0)$  (the  $\varepsilon$ -neighbourhood  $\mathcal{O}_\varepsilon(f(x_0))$  is shown), there is a neighbourhood of  $x_0$  (the  $\delta$ -neighbourhood is shown), for which all images lie in  $U$ . In words, if we decide how close we want to be to  $f(x_0)$ , we always may choose a sufficiently small neighbourhood of  $x_0$  where this is guaranteed.

**5.B.30.** Let  $f : A \rightarrow \mathbb{R}$  be a function, where  $A$  is a subset of  $\mathbb{R}$  and let  $a$  be a limit point of  $A$ . Suppose that the limit  $\lim_{x \rightarrow a} f(x)$  exists and is a finite number. Show that  $f$  is bounded on the set  $(a - h, a + h) \cap A$  for some  $h > 0$ .

**Solution.** By assumption, the limit  $\lim_{x \rightarrow a} f(x)$  exists and is a finite number, hence suppose that  $\lim_{x \rightarrow a} f(x) = \ell$ . Then for every  $\varepsilon > 0$  there exists some  $\delta > 0$  such that  $|f(x) - \ell| < \varepsilon$ , for all  $x \in A$  satisfying  $0 < |x - a| < \delta$ . Hence, taking  $\varepsilon = 1$ , there exists some  $h > 0$  such that  $|f(x) - \ell| < 1$  for all  $x \in A$  with  $0 < |x - a| < h$ . By the triangle inequality this implies that  $|f(x)| < 1 + |\ell|$  for all such  $x$ . Set now  $L = 1 + |\ell|$  if  $a \notin A$ , otherwise set  $L = \max\{1 + |\ell|, f(a)\}$ . Then it is easy to see that  $|f(x)| \leq L$  for all  $x \in (a - h, a + h) \cap A$ .  $\square$

In the previous examples we often applied some basic rules, as the limit of a sum of functions is the sum of the limits, the limit of a product is the product of the limits, and the limit of a quotient is the quotient of the limits, provided that the particular limits exist and do not lead to one of the following expressions:  $0/0$ ,  $\infty/\infty$ ,  $0 \cdot \infty$ , and  $\infty - \infty$ .

These are called “indeterminate forms”, see also the discussion in 5.2.14 and their full list includes three more types:  $0^0$ ,  $1^\infty$  and  $\infty^0$ . To address many indeterminate forms (e.g., of type  $0/0$ ,  $\infty/\infty$ ,  $0 \cdot \infty$ , etc.), we use the so-called “l’Hopital’s rule”, which we will examine later (see 5.3.10). However, let us begin with an example that demonstrates a pedestrian approach to deal with an indeterminate form of type  $0/0$ .

**5.B.31.** Show that  $\lim_{x \rightarrow 0} \frac{\sin(x)}{x} = 1$ .

**Solution.** Consider the first quadrant in the unit circle  $S^1$ , and its arbitrary point  $P(x) = [\cos(x), \sin(x)]$ , where  $x$  is running in the open interval  $(0, \frac{2\pi}{2}) \subset \mathbb{R}$ . Obviously, the length of the arc joining the points  $P(x)$  and  $C := [1, 0]$ , equals to  $x$ . So we apparently have  $\sin(x) < x$  for all  $x \in (0, \frac{\pi}{2})$ , see also the figure given at the r.h.s. On the other hand, the value  $\tan(x)$  is the distance between the points  $Q(x) = [1, \tan(x)]$  and  $C$ , and we see that  $x < \tan(x)$ , for all  $x \in (0, \frac{\pi}{2})$ . Altogether,  $\sin(x) < x < \frac{\sin(x)}{\cos(x)}$  which implies that

$$\cos(x) < \frac{\sin(x)}{x} < 1,$$

Notice that for the boundary points of the interval  $A$ , the definition says that value of  $f$  equals the value of the one-sided limit there. The function is said to be *right-continuous* or *left-continuous* at such a point. Every polynomial is a continuous function on the whole  $\mathbb{R}$ , see 5.2.11(2). The Thomae function is continuous at irrational real numbers only although it has limits at all rational points as well, see 5.2.11(4).

The previous theorem 5.2.13 about limit properties implies immediately all of the following claims. The same properties are true for right-continuity or left-continuity, as is easily checked.

**5.2.17. Theorem.** Let  $f$  and  $g$  be (real or complex valued) functions defined on an interval  $A \subset \mathbb{R}$  and continuous at a point  $x_0 \in A$ . Then

- (1) the sum  $f + g$  is continuous at  $x_0$
- (2) the product  $f \cdot g$  is continuous at  $x_0$
- (3) if  $g(x_0) \neq 0$ , then the quotient  $f/g$  is well-defined on some neighbourhood of  $x_0$  and is continuous at  $x_0$ .
- (4) If a continuous function  $h$  is defined on a neighbourhood of  $f(x_0)$  of the real-valued function  $f$ , then the composite function  $h \circ f$  is defined on a neighbourhood of  $x_0$  and is continuous at  $x_0$ .

**PROOF.** Statements (1) and (2) are clear. For property (3): if  $g(x_0) \neq 0$ , then the  $\varepsilon$ -neighbourhood of the number  $g(x_0)$  does not contain zero for a sufficiently small  $\varepsilon > 0$ . By the continuity of  $g$ , it follows that on a sufficiently small  $\delta$ -neighbourhood of the point  $x_0$ ,  $g$  is non-zero and the quotient  $f/g$  is thus well-defined there. It is continuous at  $x_0$  by the previous theorem.

(4) Choose a neighbourhood  $\mathcal{O}$  of  $h(f(x_0))$ . By the continuity of  $h$ , there is a neighbourhood  $\mathcal{O}'$  of  $f(x_0)$  which is mapped into  $\mathcal{O}$  by  $h$ . The continuous function  $f$  maps some sufficiently small neighbourhood of the point  $x_0$  into the neighbourhood  $\mathcal{O}'$ . This is the definition property of continuity, so the proof is finished.  $\square$

**5.2.18.** We consider some basic relations between continuous mappings and the topology of the real numbers. They exploit the highly non-trivial characterization of compact sets in theorem 5.2.8.

for all  $x \in (0, \frac{\pi}{2})$ . Invoking now the squeeze theorem, one deduces that  $\lim_{x \rightarrow 0^+} \frac{\sin(x)}{x} = 1$ . Based then on the fact that the function  $f(x) = \sin(x)/x$  defined for all  $x \neq 0$  is even, i.e.,  $f(-x) = f(x)$ , we get

$$\lim_{x \rightarrow 0^-} \frac{\sin(x)}{x} = \lim_{x \rightarrow 0^+} \frac{\sin(x)}{x} = 1.$$

This shows that the both one-sided limits exist and have the same value, hence our claim follows. Notice that may exist other alternative ways to prove the statement.  $\square$

**5.B.32.** Based on the result from 5.B.31, show that:

(a)  $\lim_{x \rightarrow 0} \frac{1 - \cos(x)}{x} = 0;$

(b)  $\lim_{x \rightarrow 0} \frac{1 - \cos(x)}{x^2 \sin(x^2)} = \infty.$   $\circ$

**5.B.33.** Compute  $\lim_{x \rightarrow x_0} f(x)$  for the following cases:

(a)  $f(x) = \frac{x - 2}{\sqrt{x^2 - 4}}$ , and  $x_0 = 2$ ,

(b)  $f(x) = \frac{\sin(\sin(x))}{x}$ , and  $x_0 = 0$ ,

(c)  $f(x) = \frac{\sin^2(x)}{x}$ , and  $x_0 = 0$ .  $\circ$

**5.B.34.** Explain why the limit of the following functions as  $x \rightarrow 0$ , does not exist:

$$f(x) = \begin{cases} 1/x, & \text{if } x > 0, \\ 1, & \text{if } x \leq 0, \end{cases} \quad g(x) = \begin{cases} 1, & \text{if } x \geq 0, \\ 0, & \text{if } x < 0, \end{cases}$$

$$h(x) = \frac{|\sin(x)|}{\sin x}, \quad k(x) = \text{sign}(x). \quad \circ$$

**5.B.35.** Suppose that  $f : (0, +\infty) \rightarrow \mathbb{R}$  is a function satisfying  $|e^x f(x) - 2e^x| \leq |\sin(e^x)|$ , for any  $x \in (0, +\infty)$ . Show that  $\lim_{x \rightarrow +\infty} f(x) = 2$ .

**Solution.** The given relation  $|e^x f(x) - 2e^x| \leq |\sin(e^x)|$  can be equivalently written as

$$\begin{aligned} & -|\sin(e^x)| \leq e^x f(x) - 2e^x \leq |\sin(e^x)|, \\ \text{or} \quad & 2e^x - |\sin(e^x)| \leq e^x f(x) \leq |\sin(e^x)| + 2e^x, \\ \text{or} \quad & 2 - \left| \frac{\sin(e^x)}{e^x} \right| \leq f(x) \leq \left| \frac{\sin(e^x)}{e^x} \right| + 2. \quad (*) \end{aligned}$$

Now, it is easy to prove that  $\lim_{x \rightarrow +\infty} \frac{\sin(e^x)}{e^x} = 0$ , which also follows from the graph of this function, see here:

TOPOLOGICAL CHARACTERIZATION OF CONTINUITY

**Theorem.** Let  $f : A \subset \mathbb{R} \rightarrow \mathbb{R}$  be a function defined on an interval  $A$ . Then:

- (1)  $f$  is continuous if and only if the inverse image  $f^{-1}(U)$  of every open set  $U \subset \mathbb{R}$  is an open set in  $A$ .
- (2) If  $f$  is continuous, then the inverse image  $f^{-1}(W)$  of every closed set  $W \subset \mathbb{R}$  is a closed set in  $A$ .
- (3) If  $f$  is continuous, then the image  $f(K)$  of every compact set  $K \subset A$  is a compact set in  $A$ .
- (4) If  $f$  is continuous, then  $f$  attains both its maximum and its minimum on every compact set  $K$ .

**PROOF.** (1) Consider a point  $x_0 \in f^{-1}(U)$ . There is a neighbourhood  $\mathcal{O}$  of  $f(x_0)$  which is contained in  $U$  since  $U$  is open. Hence there is a neighbourhood  $\mathcal{O}'$  of  $x_0$  which is mapped into  $\mathcal{O}$  and thus is contained in the inverse image. Therefore, every point of the inverse image is an interior point, i.e.,  $f^{-1}(U)$  is open.

Conversely, if  $f^{-1}(U)$  is open for each open  $U$ , then taking any  $\varepsilon$ -neighbourhood of  $f(x_0)$ , its pre-image will be an open neighbourhood of  $x_0$  satisfying the condition from the definition of the continuity.

(2) Consider a limit point  $x_0$  of the inverse image  $f^{-1}(W)$  and a sequence  $x_i, f(x_i) \in W$ , which converges to  $x_0$ . From the continuity of  $f$ , it follows that  $f(x_i)$  converges to  $f(x_0)$  (cf. the convergence test 5.2.15). Since  $W$  is closed,  $f(x_0) \in W$ . Thus, all limit points of the inverse image of the set  $W$  are contained in  $f^{-1}(W)$ .

(3) Choose any open cover  $U_\alpha$  of  $f(K)$ . The inverse images of all  $U_\alpha$  are open and thus create an open cover of the set  $K$ . Select a finite subcover from it. Then finitely many of the corresponding images cover the original set  $f(K)$ .

(4) Since the image of a compact set is again a compact set, the image must be bounded and it contains both the supremum and the infimum. Hence it follows that these must also be the maximum and the minimum, respectively.  $\square$

Notice, a complex valued function is continuous if and only if its real and imaginary components are continuous. The first three claims of the theorem remain valid with very slight modification of the proof. (Check it yourselves!)

**5.2.19.** There are two very useful consequences of the previous theorem.

For instance, via the squeeze theorem one can show that

$$\lim_{y \rightarrow +\infty} \frac{\sin y}{y} = 0$$

and then the replacement  $y = e^x$  yields our claim, or directly, via Sage type:  $\lim(\sin(e^x)/e^x, x = +\infty)$ . Hence, we also deduce that

$$\lim_{x \rightarrow +\infty} \left( 2 - \left| \frac{\sin(e^x)}{e^x} \right| \right) = 2 = \lim_{x \rightarrow +\infty} \left( \left| \frac{\sin(e^x)}{e^x} \right| + 2 \right)$$

and by (\*) we are done via the squeeze theorem.  $\square$

**5.B.36.** For some  $\alpha > 0$  let  $g$  the function defined by

$$g(x) = \lim_{\alpha \rightarrow +\infty} \left( \frac{(2x-3)\alpha^2 + 4x\alpha + 2}{x+\alpha} \cdot \sin\left(\frac{1}{\alpha}\right) \right).$$

Show that  $g$  is a line which is a median of the triangle  $ABC$  with corners the points  $A = [1, -1]$ ,  $B = [6, 2]$ ,  $C = [-2, 0]$ .  $\circ$

*So far we tried to convince the reader to use common sense when reasoning about the limit behaviour of functions and prevent any mindless following of rules. On the other hand, beyond the l'Hopital's rule which is based on the notion of derivatives and we will discuss later (see also 5.3.10), there are diverse useful "rules" or "tricks" to deal with the indeterminate expressions, which are not necessarily based on derivatives. Let us mention some of them.*

a) Recall that if  $f(x) > 0$  for all  $x$  in the domain of  $f$ , then

$$f(x)^{g(x)} = e^{\ln(f(x)^{g(x)})} = e^{g(x) \cdot \ln(f(x))}.$$

Since the function  $e^x$  is continuous and injective on  $\mathbb{R}$ , we get

$$\lim_{x \rightarrow x_0} f(x)^{g(x)} = e^{\lim_{x \rightarrow x_0} (g(x) \ln(f(x)))} = e^{\lim_{x \rightarrow x_0} g(x) \cdot \lim_{x \rightarrow x_0} \ln(f(x))}.$$

Moreover, it is easy to prove that

$$\lim_{x \rightarrow x_0} (g(x) \cdot \ln f(x)) = a \in \mathbb{R} \implies \lim_{x \rightarrow x_0} f(x)^{g(x)} = e^a,$$

$$\lim_{x \rightarrow x_0} (g(x) \cdot \ln f(x)) = +\infty \implies \lim_{x \rightarrow x_0} f(x)^{g(x)} = +\infty,$$

$$\lim_{x \rightarrow x_0} (g(x) \cdot \ln f(x)) = -\infty \implies \lim_{x \rightarrow x_0} f(x)^{g(x)} = 0.$$

b) Some further useful rules to remember are here:

$$\lim_{x \rightarrow +\infty} \frac{c}{x^\alpha} = 0, \quad \lim_{x \rightarrow +\infty} \frac{x^\alpha}{x^\beta} = 0, \quad \lim_{x \rightarrow +\infty} \frac{x^\beta}{a^x} = 0,$$

$$\lim_{x \rightarrow +\infty} \frac{a^x}{b^x} = 0, \quad c \in \mathbb{R}, \quad 0 < \alpha < \beta, \quad 1 < a < b.$$

You may try to verify them (a way to determine the third limit is based on the l'Hopital's rule, for example).

**5.B.37.** Compute the following limits:

(a)  $\lim_{x \rightarrow +\infty} \frac{3^{x+1} + x^5 - 4x}{3^x + 2x + x^2},$

(b)  $\lim_{x \rightarrow +\infty} \frac{4^x - 8x^6 - 2^x - 167}{3^x - 45x - \sqrt{11}\pi^{x+12}},$

**Corollary.** Let  $f : \mathbb{R} \rightarrow \mathbb{R}$  be continuous. Then

- (1) the image of every interval is again an interval,
- (2)  $f$  takes all the values between the maximal and the minimal one on the closed interval  $[a, b]$ .

**PROOF.** (1) Consider an open interval  $A$  and suppose there is a point  $y \in \mathbb{R}$  such that  $f(A)$  contains points less than  $y$  as well as points greater than  $y$ , but  $y \notin f(A)$ . Put  $B_1 = (-\infty, y)$  and  $B_2 = (y, \infty)$ . These are open sets, and the union of their inverse images  $A_1 = f^{-1}(B_1) \subset A$  and  $A_2 = f^{-1}(B_2) \subset A$  contains  $A$ .  $A_1$  and  $A_2$  are open, disjoint, and they both have a non-empty intersection with  $A$ . Thus there is a point  $x \in A$  which does not lie in  $A_1$  but is a limit point of  $A_1$ . It is in  $A_2$ , which is impossible for two disjoint open sets.

Thus it is proved that if there is a point  $y$  which does not belong to the image of the interval, then either all of the values must be above  $y$  or they all must be below. It follows that the image is again an interval. Notice that the boundary points of this interval may or may not lie in the image.

If the domain interval  $A$  contains one of its boundary points, then the continuous function must map it to a limit point or an interior point of the image of the interior of  $A$ . This verifies the statement.

(2) This statement immediately follows from the previous one (and the above theorem) since the image of a closed bounded interval (i.e. a compact set) is again a closed interval.  $\square$

**5.2.20.** We conclude this introductory discussion by two more theorems which provide useful tools for calculating limits. Notice that we assume that functions are defined on all of  $\mathbb{R}$ . Actually we are only interested in  $f$  on a neighbourhood of one point  $a$ , while  $g$  has to be defined on a neighbourhood of one point  $b$  only.

#### LIMITS OF COMPOSITE FUNCTIONS

**Theorem.** Let  $f, g : \mathbb{R} \rightarrow \mathbb{R}$  be two functions and  $\lim_{x \rightarrow a} f(x) = b$ .

(1) If the function  $g$  is continuous at the point  $b$ , then

$$\lim_{x \rightarrow a} g(f(x)) = g\left(\lim_{x \rightarrow a} f(x)\right) = g(b).$$

(2) If the limit  $\lim_{y \rightarrow b} g(y)$  exists and  $f(x) \neq b$  holds for all  $x \neq a$  from some neighbourhood of the point  $a$ , then

$$\lim_{x \rightarrow a} g(f(x)) = \lim_{y \rightarrow b} g(y).$$

<sup>9</sup>This result is usually called the Weierstrass theorem, but it is also known (especially in Czech literature) as the Bolzano's theorem. Bernard Bolzano apparently used such result as a technical lemma when proving his Bolzano-Weierstrass theorem mentioned earlier.

(c)  $\lim_{x \rightarrow 0} \frac{\sqrt{1+x} - \sqrt{1-x}}{x}$ ,

(d)  $\lim_{x \rightarrow \pi/4} \frac{\cos x - \sin x}{\cos(2x)}$ . ○

**5.B.38.** Consider a polynomial function  $f : \mathbb{R} \rightarrow \mathbb{R}$  whose degree is determined by the result of rolling a die. Find the probability  $P(A)$ , where  $A$  denotes the following event:

$$\lim_{x \rightarrow +\infty} \frac{x^4 + x^2 + 1}{f(x)} = 0.$$

**Solution.** We have  $f(x) = a_n x^n + a_{n-1} x^{n-1} + \dots + a_1 x + a_0$ , where by assumption  $n \in \{1, 2, \dots, 6\}$  (and so  $f(x) \neq 0$ ). Thus one computes

$$\begin{aligned} \lim_{x \rightarrow +\infty} \frac{x^4 + x^2 + 1}{f(x)} &= \\ &= \lim_{x \rightarrow +\infty} \frac{x^4 + x^2 + 1}{a_n x^n + a_{n-1} x^{n-1} + \dots + a_1 x + a_0} \\ &= \lim_{x \rightarrow +\infty} \frac{x^4}{a_n x^n}. \end{aligned}$$

Hence we seek for the probability of having  $\lim_{x \rightarrow +\infty} \frac{x^4}{a_n x^n} = 0$ . It is now reasonable to consider the following cases:

1) For  $n = 1, 2, 3$  we get  $\lim_{x \rightarrow +\infty} \frac{x^4}{a_n x^n} = \pm\infty$ .

2) For  $n = 4$  we get  $\lim_{x \rightarrow +\infty} \frac{x^4}{a_4 x^4} = \frac{1}{a_4} \neq 0$ .

3) For  $n = 5, 6$  we obtain  $\lim_{x \rightarrow +\infty} \frac{x^4}{a_n x^n} = 0$ .

Therefore, the favourable cases are those with  $n = 5, 6$ . Since the sample space is  $\Omega = \{1, 2, \dots, 6\}$  we deduce that the probability in question equals to  $P(A) = \frac{2}{6} = \frac{1}{3}$ . □

**5.B.39.** Consider the functions  $f(x) = e^{4x+2}$  and  $g(x) = \ln(x^2)$ , defined on  $\mathbb{R} \setminus \{0\}$  and  $[1, e^8]$ , respectively.

(a) Show the composition  $\varphi = g \circ f$  is determined, and present its explicit form. Confirm your result via Sage and the command `compose`.

(b) Evaluate the limit  $L = \lim_{x \rightarrow 0} \frac{\varphi(x) - \sin^3(x) - 4}{x}$ .

**Solution.** (a) Let us denote by  $A = \mathbb{R} \setminus \{0\}$  and  $B = [1, e^8]$  the two given domains. The composition  $\varphi(x) = g(f(x))$  is determined, if the set  $X := \{x \in A : f(x) \in B\}$  is non empty, i.e.,  $X \neq \emptyset$ . We compute

$$\begin{aligned} X &= \{x \in \mathbb{R}^* : 1 \leq e^{4x+2} \leq e^8\} \\ &= \{x \in \mathbb{R}^* : e^0 \leq e^{4x+2} \leq e^8\} \\ &= \{x \in \mathbb{R}^* : 0 \leq 4x + 2 \leq 8\} \\ &= \left\{x \in \mathbb{R}^* : -\frac{1}{2} \leq x \leq \frac{3}{2}\right\} = \left[-\frac{1}{2}, 0\right) \cup \left(0, \frac{3}{2}\right], \end{aligned}$$

where here  $\mathbb{R}^* = \mathbb{R} \setminus \{0\}$ . Therefore, based on the basic properties of logarithms, we get  $\varphi : X \rightarrow \mathbb{R}$  with type

$$\varphi(x) = g(f(x)) = \ln(f(x)^2) = \ln e^{2(4x+2)} = 2(4x + 2).$$

**PROOF.** The first proposition can be proved similarly to 5.2.17(4). From the continuity of  $g$  at the point  $b$ , it follows that for any neighbourhood  $V$  of the value  $g(b)$ , we can find a sufficiently small neighbourhood  $U$  of the point  $b$  whose values of  $g$  lies in  $V$ . However, if  $f$  has limit  $b$  at the point  $a$ , then  $f$  will hit  $U$  by all its values  $f(x)$  for  $x \neq a$  from some sufficiently small neighbourhood of the point  $a$ , which verifies the first statement.

(2) Even if we cannot use the continuity of  $g$  at the point  $b$ , the previous reasoning will be true if we ensure that all points  $x \neq a$  from sufficiently small neighbourhoods of  $a$  are mapped into a neighbourhood of  $b$  by the function  $f$ , but  $f(x) \neq b$  for all such points. □

**5.2.21. Who or what is in the ZOO.** We have begun to

build a menagerie of functions with polynomials and functions which can be created from them “piece-wise”. Moreover, we have derived many properties for a huge class of continuous functions. However, except for polynomials, we do not have many practically manageable examples at our disposal. We consider the quotients of polynomials.

Let  $f$  and  $g$  be two polynomials in the real variable  $x$  with complex coefficients  $a_i \in \mathbb{C}$ .

The function  $h : \mathbb{R} \setminus \{x \in \mathbb{R}, g(x) = 0\} \rightarrow \mathbb{C}$ ,

$$h(x) = \frac{f(x)}{g(x)}$$

is well-defined for all real  $x$  except for the roots of the polynomial  $g$ . Such functions are called *rational functions*. From theorem 5.2.17, it follows that rational functions are continuous at all points of their domains. At the points where the denominators of real rational functions vanish, they can have

- a finite limit,
- an infinite limit, supposing the one-sided infinite limits are equal,
- different one-sided infinite limits.

For the case of a finite limit, it is necessary that the point is a common root of both  $f$  and  $g$  and that its multiplicity in  $f$  is at least as large as in  $g$ . Then the domain of the rational function can be extended by this point, defining it to take the value of the limit there. Then the new function is continuous at this point, too.

The possibilities are illustrated in the diagram showing the values of the function

$$h(x) = \frac{(x - 0.05a)(x - 2 - 0.2a)(x - 5)}{x(x - 2)(x - 4)}$$

To verify this very last computation in Sage, use the cell

```
f(x)=e**(4*x+2); ln(f(x)^2).simplify_full()
```

which returns  $8 * x + 4$ . The same returns the method suggested in the statement, via the command `compose`, which we implement by the cell

```
f(x)=e^(4*x+2); g(x)=ln(x^2)
h = compose(g, f)
show(h(x).simplify_full())
```

(b) The explicit form of  $\varphi$  is known by (a), which makes it easy to compute the limit at hand:

$$L = \lim_{x \rightarrow 0} \frac{8x - \sin^3(x)}{x} = \lim_{x \rightarrow 0} \left( 8 - \sin^2(x) \cdot \frac{\sin(x)}{x} \right)$$

$$= 8 - \lim_{x \rightarrow 0} \sin^2(x) \cdot \lim_{x \rightarrow 0} \frac{\sin(x)}{x} = 8 - 0 \cdot 1 = 8.$$

□

We have exploited the continuity of several functions in an implicit or explicit way many times already. Now it is time to return back to the essence and play a little bit with the concept itself.

**5.B.40.** The figure below shows the graph of a function  $y = f(x)$ . Indicate the points where  $f$  is discontinuous and explain why.

**Solution.** There is a discontinuity at  $x = 2$ , since there  $f$  is not defined (the graph has a break that is represented by the small circle). Another discontinuity appears at  $x = 3$  (a jump discontinuity). Indeed, although  $f(3)$  is defined (is a negative number), we see that the left and right limits are different, so  $\lim_{x \rightarrow 3} f(x)$  does not exist. Finally, according to the figure at  $x = 5$  the value  $f(5)$  is defined and moreover  $\lim_{x \rightarrow 5} f(x)$  exists. However, we see that  $\lim_{x \rightarrow 5} f(x) \neq f(5)$ . Thus  $f$  is discontinuous also at  $x = 5$  (we may refer to such a discontinuity by the term removable discontinuity). □

**5.B.41.** Sketch the graph of a function which is continuous everywhere, except of a removable discontinuity at  $x = 1$ , a jump discontinuity at  $x = 3$ , and a discontinuity at  $x = 4$  which is not of the two previous types.

**Solution.** There are of course many such functions. An example is given here:

for  $a = 0$  on the left (thus it is the simpler rational function  $(x - 5)/(x - 4)$ ) and for  $a = 5/3$  on the right.

Notice that the situation gets more complicated for the complex rational functions. Their real and imaginary parts are again (real) rational functions (see the exercise ??) and the above options are true for only each of the components separately.

**5.2.22. Power functions and the exponential.**

We have met the simple power functions  $x \mapsto x^n$  with natural exponents  $n = 0, 1, 2, \dots$  when building the polynomials. The meaning of the function  $x \mapsto x^{-1}$ , defined for all  $x \neq 0$ , is also clear.

Now, we extend this definition to a general power function  $x^y$  with an arbitrary (constant)  $y \in \mathbb{R}$  and  $x > 0$ .

Changing our mind about constants and variables, we obtain the values of exponential function  $x^y$  with arbitrary (constant)  $x > 0$  called the base.

With natural  $y$  and  $z$ , we know the following rule

(1)  $x^{y+z} = x^y \cdot x^z$

and its consequence

(2)  $x^{y \cdot z} = (x^y)^z.$

We shall extend this definition to all positive real  $x > 0$  and all real  $y$ .

EXPONENTIAL AND POWER FUNCTIONS

**Theorem.** There is the unique function  $f(y) = x^y$ , defined for all  $x > 0, y \in \mathbb{R}$ , separately continuous in both variables  $x$  and  $y$  (i.e. we consider the other one as a constant when checking the continuity) and satisfying (1),  $f(0) = 1$ , and  $f(1) = x$ . This function also satisfies (2).

We call this function the exponential function with the base  $x$ , or the power function with exponent  $y$ .

**PROOF.** Of course, we want to extend the well known values of the powers  $x^n$  with  $x$  rational and  $n$  integral, which are also direct consequences of (1) (and then automatically satisfy (2)).

For a negative integer  $-a$ , we have to define (in view of (1))

$$x^{-a} = (x^a)^{-1} = (x^{-1})^a.$$

Further, we want the equality  $b^n = x$  for  $n \in \mathbb{N}$  to imply that  $b$  is the  $n$ -th root of  $x$ , i.e.  $b = x^{1/n}$  (again a consequence of

Notice the discontinuity at  $x = 4$ : Can you analyze why this differs from the previous two?  $\square$

**5.B.42.** Explain why the functions  $f, g : (0, +\infty) \rightarrow \mathbb{R}$  defined by  $f(x) = x^x$  and  $g(x) = x^{\cos(x)}$ , respectively, are continuous.  $\circ$

**5.B.43.** If  $f, g : \mathbb{R} \rightarrow \mathbb{R}$  are continuous functions with  $f(2) = 6$  and  $\lim_{x \rightarrow 2} (4f(x) - g(x)) = 2$ , find  $g(2)$ .  $\circ$

**5.B.44.** Present an example of a function defined on  $\mathbb{R}$  which is everywhere continuous except at  $x = 0$ .  $\circ$

**5.B.45.** Consider the function  $f : \mathbb{R} \rightarrow \mathbb{R}$

$$f(x) = \begin{cases} x, & \text{if } x \in \mathbb{Q}, \\ -x, & \text{if } x \in \mathbb{R} \setminus \mathbb{Q}. \end{cases}$$

Determine the points  $x_0 \in \mathbb{R}$ , if any, where  $f$  is continuous.

**Solution.** The given function  $f$  is continuous only at  $x_0 = 0$ . For a confirmation, consider any sequence  $(x_n)$  or  $\mathbb{R}$  with  $x_n \rightarrow 0$  and  $x_n \neq 0$  for all  $n$ . Then obviously  $(-x_n) \rightarrow 0$  as well and hence  $f(x_n) \rightarrow 0$ . The claim now follows by combining the definition of continuity of a given function at a chosen point with Proposition 5.2.15. On the other hand, for any non-zero real number  $a$  we can find sequences  $(x_n)$  and  $(y_n)$  with  $x_n \rightarrow a$  and  $y_n \rightarrow a$ , which however satisfy  $f(x_n) \rightarrow a$  and  $f(y_n) \rightarrow -a$ , respectively. This implies that  $f$  is discontinuous at any  $a \in \mathbb{R} \setminus \{0\}$ .  $\square$

**5.B.46.** Determine the interval(s) on which each of the following functions is continuous:

$$f(x) = \begin{cases} \sin\left(\frac{1}{x}\right), & \text{if } x \neq 0, \\ 0, & \text{if } x = 0, \end{cases}$$

$$g(x) = \begin{cases} x \sin\left(\frac{1}{x}\right), & \text{if } x \neq 0, \\ 0, & \text{if } x = 0. \end{cases}$$

**5.B.47.** Consider the function

$$g(x) = \begin{cases} \frac{\tan(x)}{\pi - 2x} + x, & \text{if } x \in \left(0, \frac{\pi}{2}\right), \\ \frac{2x + 1}{2}, & \text{if } x \in \left[\frac{\pi}{2}, +\infty\right). \end{cases}$$

Show that  $g(x)$  is continuous at  $x_0$ , where  $x_0$  is the value of the determinant  $|A|$ , and  $A \in \text{Mat}_4(\mathbb{R})$  is a real  $4 \times 4$  invertible matrix satisfying  $A = (1/|A|)B$ , for some square matrix  $B \in \text{Mat}_4(\mathbb{R})$  with  $\det(B) = |B| = (\pi/2)^5$ .

(1) since this requests  $(x^{\frac{1}{n}})^n = x^{n \cdot \frac{1}{n}} = x$ . We verify that such  $b$ 's always exist for positive real numbers  $x$ .

By factoring out  $y_2 - y_1$  in  $y_2^n - y_1^n$ , or otherwise, we see that the function  $y \mapsto y^n$  is strictly increasing for  $y > 0$ . Choose  $x > 0$  and consider the set  $B = \{y \in \mathbb{R}, y > 0, y^n \leq x\}$ . This is a non-empty set bounded from above, so set  $b = \sup B$ . A power function with natural exponent  $n$  is continuous, thus  $b^n = x$ . Indeed, surely  $b^n \leq x$ . If the inequality is strict, then there is a number  $y$  such that  $b^n < y^n < x$ , which implies that  $b < y$ . This contradicts the definition of  $b$  as a supremum.

Thus the power function is suitably defined for all rational numbers  $a = \frac{p}{q}$ . For  $x > 0$ , we set  $x^a = (x^p)^{\frac{1}{q}} = (x^{\frac{1}{q}})^p$ .

Finally, we notice that for the values  $0 < a \in \mathbb{Q}$  and fixed  $x > 1$ ,  $x^a$  is strictly increasing for rational  $a$ 's. Therefore, for general  $0 < a \in \mathbb{R}$  and  $1 < x$  we can define

$$x^a = \sup\{x^y, y \in \mathbb{Q}, y \leq a\}.$$

As before,  $x^{-a} = \frac{1}{x^a}$ .

For  $0 < x < 1$ , proceed analogously with care for the inequality signs, or set  $x^a = \left(\frac{1}{x}\right)^{-a}$ . For  $x = 1$ , define  $1^a = 1$  for any  $a$ , while  $0^a = 0$ .

Now, the power function  $x \mapsto x^a$  is defined for all  $x \in [0, \infty)$  and  $a \in \mathbb{R}$ . Notice, the requested continuity in both parameters fixed all our choices above. In particular, our function is continuous also in the parameter  $a$  and we have constructed also the exponential functions  $c^y$  for constants  $c > 0$ .

The property (1) used when defining the power function  $x^a$  for integral  $a$  implied also (2), and they both manifestly survived through the construction for any choices of the values  $x, y$ .  $\square$

**5.2.23. Logarithmic functions.** The exponential function  $f(x) = a^x$  is increasing for  $a > 1$  and decreasing for  $0 < a < 1$ . Thus in both cases, there is a function  $f^{-1}(x)$  inverse to it. This function is called the *logarithmic function with base  $a$* .

We write  $\ln_a(x)$  and the defining property is

$$\ln_a(a^x) = x.$$

The equalities 5.2.22(1),(2) are thus equivalent to

$$\ln_a(x \cdot y) = \ln_a(x) + \ln_a(y), \quad \ln_a(x^y) = y \cdot \ln_a(x).$$

Logarithmic functions are defined only for positive arguments and they are, on the entire domain, increasing if  $a > 1$  and decreasing for  $0 < a < 1$ . Moreover,  $\ln_a(1) = 0$  holds for every  $a$ .

**Solution.** By assumption,  $A$  and  $B$  are real  $4 \times 4$  matrices satisfying the relation  $B = |A|A$ . In Chapter 2 we saw that  $\det(\lambda C) = \lambda^n \det(C)$  for any real  $n \times n$ -matrix  $C$  and  $\lambda \in \mathbb{R}$ , see ???. Thus we get  $|B| = \left| |A|A \right| = |A|^4 |A| = |A|^5$ , that is,  $(\pi/2)^5 = |A|^5$  or equivalently  $|A| = \pi/2$ . Hence  $x_0 = \pi/2$  and we see that

$$\begin{aligned} \lim_{x \rightarrow \frac{\pi}{2}^+} f(x) &= \lim_{x \rightarrow \frac{\pi}{2}^+} \left( x + \frac{1}{2} \right) = \frac{\pi}{2} + \frac{1}{2}, \\ \lim_{x \rightarrow \frac{\pi}{2}^-} f(x) &= \lim_{x \rightarrow \frac{\pi}{2}^-} \frac{\tan x}{\pi - 2x} + \lim_{x \rightarrow \frac{\pi}{2}^-} x \\ &= \frac{1}{2} \lim_{x \rightarrow \frac{\pi}{2}^-} \frac{\tan(\frac{\pi}{2} - x)}{(\frac{\pi}{2} - x)} + \frac{\pi}{2} = \frac{\pi}{2} + \frac{1}{2}. \end{aligned}$$

Here we have used the trigonometric identity  $\tan(\frac{\pi}{2} - x) = \tan(x)$  (try to prove this), and moreover that

$$\lim_{y \rightarrow 0} \frac{\tan y}{y} = 0, \quad (*)$$

where above one should replace  $\frac{\pi}{2} - x$  by  $y$  and  $x \rightarrow \frac{\pi}{2}^-$  with  $y \rightarrow 0$ . Therefore, the one-sided limits coincide and since they equal to  $f(\frac{\pi}{2}) = \frac{\pi}{2} + \frac{1}{2}$ ,  $f$  is continuous at  $x_0$ . To be complete, let us prove (\*). For this one uses the result from 5.B.31 and that the limit of a product is the product of the limits, if both limits are defined:

$$\begin{aligned} \lim_{y \rightarrow 0} \frac{\tan y}{y} &= \lim_{y \rightarrow 0} \frac{\sin y}{\cos y} = \lim_{y \rightarrow 0} \frac{\sin y}{y} \cdot \lim_{y \rightarrow 0} \frac{1}{\cos y} \\ &= 1 \cdot \frac{1}{\cos 0} = 1. \end{aligned}$$

□

Given a real number  $x \in \mathbb{R}$  its floor (also called the integer part of  $x$ ), denoted by  $\lfloor x \rfloor$  (or by  $[x]$ ), is the greatest integer which is less than or equal to  $x$ , i.e.,  $\lfloor x \rfloor = \max\{a \in \mathbb{Z} : a \leq x\}$ . Equivalently, we can view  $\lfloor x \rfloor$  as the unique integer satisfying  $\lfloor x \rfloor \leq x < \lfloor x \rfloor + 1$ . Hence for example we have  $\lfloor x \rfloor = 1$  for  $1 \leq x < 2$ ,  $\lfloor x \rfloor = 2$  for  $2 \leq x < 3$ , etc. The floor function or greatest integer function is then defined by  $f(x) = \lfloor x \rfloor \in \mathbb{Z}$ , for all  $x \in \mathbb{R}$ . Obviously, for any integer  $n \in \mathbb{Z}$  we have  $f(n) = \lfloor n \rfloor = n$ .

In the same vein one can define the “ceiling function” (also known as the “least integer function”)  $x \mapsto \lceil x \rceil$ , where  $\lceil x \rceil$  is the smallest integer  $\geq x$ , called the “ceiling of  $x$ ”, i.e.,  $\lceil x \rceil = \min\{a \in \mathbb{Z} : a \geq x\}$ . In addition,  $\{x\} = x - \lfloor x \rfloor$  is called the “fractional part of  $x$ ”, and the assignment  $x \mapsto \{x\}$  induces the so called “fractional part function”. Obviously,  $0 \leq \{x\} < 1$  and for nonnegative real numbers, the fractional part is just the part of the number after the decimal (but this is not the case for negative real numbers).

Nevertheless, together with the floor function for which we devote some space in 5.B.48, these functions are some of the simplest examples of discontinuous functions, and they can be quite useful in constructing more wild examples. Moreover, they have all important applications in integral

There is an extremely important value of  $a$ , namely the number  $e$ , see the paragraph 5.4.1, also known as Euler’s number. The function  $\ln_e(x)$  is called the *natural logarithm* and is denoted by  $\ln(x)$  (i.e., omitting the base  $e$ ).

### 3. Derivatives

When talking about polynomials, the rate at which the function changes at a given point of its domain was already discussed (see the paragraph 5.1.6). It is the quotient 5.1.6(1), which expresses the slope of the secant line between the points  $[x, f(x)] \in \mathbb{R}^2$  and  $[x + \delta x, f(x + \delta x)] \in \mathbb{R}^2$  for a (small) change  $\delta x$  of the input variable. This reasoning is correct for any real or complex function  $f$ . It is only necessary to work with the concept of the limit, instead of the intuitive “small change”  $\delta x$ .

DERIVATIVE OF A FUNCTION OF A REAL VARIABLE

**5.3.1. Definition.** Let  $f$  be a real or complex function defined on an interval  $A \subset \mathbb{R}$  and  $x_0 \in A$ . If the limit

$$\lim_{x \rightarrow x_0} \frac{f(x) - f(x_0)}{x - x_0} = a$$

exists, the function  $f$  is said to be differentiable at  $x_0$ , provided  $a$  is finite. The value of the derivative at  $x_0$ , namely  $a$ , is denoted by  $f'(x_0)$  or  $\frac{df}{dx}(x_0)$  or  $\frac{d}{dx}f(x_0)$ .

If  $a$  is finite, the derivative is also sometimes called *proper*. If  $a$  is infinite, it is *improper*.

If  $x_0$  is one of the boundary points of  $A$ , we arrive at *one-sided derivatives* (i.e., left-sided derivative and right-sided derivative).

If a function has a derivative at  $x_0$ , the function is said to be *differentiable* at  $x_0$ . A function which is differentiable at every point of a given interval is said to be differentiable on the interval.

Obviously, the derivative of a complex valued function  $(f(x) + i g(x))$  exists if and only if the derivatives of both real and imaginary parts  $f$  and  $g$  exist (see the elementary properties of limits). Then

$$(f(x) + i g(x))' = f'(x) + i g'(x).$$

calculus, in number theory and in computer science. Hence we will meet them again in the next chapter and in Chapter 11, the latter devoted to number theory. For more details on the functions  $\lceil x \rceil$  and  $\lfloor x \rfloor$  we refer to the problem 5.E.57 in the final section.

**5.B.48. The floor function.** Let  $f(x) = \lfloor x \rfloor$  be the floor function.

- (1) Compute  $f(-0.4)$ ,  $f(0.4)$ ,  $f(0.99)$ ,  $f(3/2)$ ,  $f(\sqrt{7})$ ,  $f(3)$ ,  $f(\pi)$ ,  $f(9/2)$  and  $f(19/2)$ .
- (2) Show that  $f(x+n) = f(x) + n$ , for all  $x \in \mathbb{R}$  and  $n \in \mathbb{Z}$ . Next present an example confirming this relation.
- (3) Show that the relation  $f(nx) = nf(x)$ , with  $x \in \mathbb{R}$  and  $n \in \mathbb{Z}$  is false in general.
- (4) Deduce that  $\lim_{x \rightarrow 2^+} f(x) \neq \lim_{x \rightarrow 2^-} f(x)$ . More in general, prove that  $f$  is discontinuous at any integer  $n \in \mathbb{Z}$ .
- (5) Use Sage to sketch the graph of the floor function for  $-5 \leq x \leq 5$ .

**Solution.** (1) Obviously,  $\lfloor -0.4 \rfloor = -1$ ,  $\lfloor 0.4 \rfloor = 0 = \lfloor 0.99 \rfloor$ ,  $\lfloor 3/2 \rfloor = 1$ ,  $\lfloor \sqrt{7} \rfloor = 2$ ,  $\lfloor 3 \rfloor = 3 = \lfloor \pi \rfloor$ ,  $\lfloor 9/2 \rfloor = 4$ , and  $\lfloor 19/2 \rfloor = 9$ . Notice that in Sage the floor function corresponds to the command `floor`. Hence, to verify some of our previous computations, one may type (and similarly for the cases omitted).

```
print(floor(-0.4)); print(floor(sqrt(7)))
print(floor(pi)); print(floor(19/2))
```

- (2) We need to prove that  $\lfloor x+n \rfloor = \lfloor x \rfloor + n$  for all  $x \in \mathbb{R}$  and  $n \in \mathbb{Z}$ . By definition, we have  $\lfloor x \rfloor \leq x < \lfloor x \rfloor + 1$  and by adding  $n$  to all the parts we get  $\lfloor x \rfloor + n \leq x+n < \lfloor x \rfloor + n + 1$ . Recall however that for all  $x \in \mathbb{R}$  and  $m \in \mathbb{Z}$  the relations  $\lfloor x \rfloor = m$  and  $m \leq x < m + 1$  are equivalent. Thus for  $m = \lfloor x \rfloor + n$  the above inequality means  $m \leq x < m + 1$ , and hence we get  $\lfloor x+n \rfloor = m$ . Comparing now the two equalities involving  $m$ , the result follows. As an example, we have  $\lfloor 9/2 \rfloor = \lfloor 0.5 + 4 \rfloor = \lfloor 0.5 \rfloor + 4 = 0 + 4 = 4$ .
- (3) As a counterexample notice that  $\lfloor 3 \cdot \frac{1}{3} \rfloor = \lfloor 1 \rfloor = 1$ , but  $3 \cdot \lfloor \frac{1}{3} \rfloor = 3 \cdot 0 = 0$ .
- (4) By definition, we have  $\lfloor x \rfloor = 2$  for  $2 \leq x < 3$ . Thus  $\lim_{x \rightarrow 2^+} \lfloor x \rfloor = \lim_{x \rightarrow 2^+} 2 = 2$ . Similarly, since  $\lfloor x \rfloor = 1$  for  $1 \leq x < 2$  we have  $\lim_{x \rightarrow 2^-} \lfloor x \rfloor = \lim_{x \rightarrow 2^-} 1 = 1$ . This shows that  $f$  is discontinuous at  $x = 2$ , and similarly at any integer  $n \in \mathbb{Z}$ , i.e.,  $\lim_{x \rightarrow n^+} \lfloor x \rfloor = n = f(n) \neq \lim_{x \rightarrow n^-} \lfloor x \rfloor = n - 1$ .
- (5) Let us now present the graph of the floor function. For convenience, we will use small circles to indicate the jump discontinuities of  $f$  at the integers lying in  $[-5, 5]$ . We can do this manually in Sage by combining first the commands `floor` and `plot`, to sketch  $f(x) = \lfloor x \rfloor$ , and next the commands `point` and `circle` to draw the discontinuity points, etc. This is encoded by the following cell:

Derivatives are handled rather easily, but it takes time to derive the proper formulae for derivatives of the elementary functions in our zoo. Therefore, we present a table of derivatives of several such functions in advance. In the last column, there are references to the corresponding paragraphs where the results are proved. Notice that even though we are unable to express inverse functions to some of our functions by elementary means, we can calculate their derivatives; see 5.3.6.

DERIVATIVES OF SOME FUNCTIONS

function	domain	derivative	
polynomials $f(x)$	whole $\mathbb{R}$	$f'(x)$ is again a polynomial	5.1.6
cubic splines $h(x)$	whole $\mathbb{R}$	continuous second derivatives	5.1.9
rational functions $f(x)/g(x)$	whole $\mathbb{R}$ , except for roots of $g$	rational functions: $\frac{f'(x)g(x) - f(x)g'(x)}{g(x)^2}$	5.3.5
power functions $f(x) = x^a$	interval $(0, \infty)$	$f'(x) = ax^{a-1}$	5.3.7
exponential functions $f(x) = a^x$ , $a > 0, a \neq 1$	whole $\mathbb{R}$	$f'(x) = \ln(a)a^x$	5.3.7
logarithmic function $f(x) = \ln_a(x)$ , $a > 0, a \neq 1$	interval $(0, \infty)$	$f'(x) = (\ln(a))^{-1} \frac{1}{x}$	5.3.7

The initial idea of the definition suggests that  $f'(x_0)$  allows an approximation to the function  $f$  by the straight line

$$y = f(x_0) + f'(x_0)(x - x_0).$$

This is the meaning of the following lemma, which says that replacing the constant coefficient  $f'(x_0)$  in the line's equation with a certain continuous function gives exactly the values of  $f$ . The difference between  $\psi(x)$  and  $\psi(x_0)$  on a neighbourhood of  $x_0$  then says how much the slopes of the secant lines and the tangent line at  $x_0$  differ.

**Lemma.** A real or complex function  $f(x)$  has a finite derivative at  $x_0$  if and only if there is a neighbourhood  $\mathcal{O}$  of  $x_0$  and a function  $\psi$  defined on this neighbourhood which is continuous at  $x_0$  and such that for all  $x \in \mathcal{O}$ ,

$$f(x) = f(x_0) + \psi(x)(x - x_0).$$

Furthermore,  $\psi(x_0) = f'(x_0)$ , and  $f$  is continuous at the point  $x_0$ .

**PROOF.** If  $\psi$  exists, it is of the form

$$\psi(x) = \frac{f(x) - f(x_0)}{x - x_0}$$

for all  $x \in \mathcal{O} \setminus \{x_0\}$ .

```
f=floor(x)
p=plot(f, x, -5, 5, color="steelblue",
ticks=[1,1],
legend_label=r"$\text{floor function}$")
```

Suppose  $f'(x_0)$  is the proper derivative. Then we can define the value at the point  $x_0$  as  $\psi(x_0) = f'(x_0)$ . Certainly,

$$\lim_{x \rightarrow x_0} \psi(x) = f'(x_0) = \psi(x_0).$$

Thus  $\psi$  is continuous at  $x_0$  as desired.

On the other hand if such a function  $\psi$  exists, the same procedure calculates its limit at  $x_0$ . Thus the derivative  $f'(x_0)$  exists as well and equals  $\psi(x_0)$ .

The function  $f$  is expressed in terms of the sum and product of functions continuous at  $x_0$ . Thus  $f$  is continuous at  $x_0$ .  $\square$

### 5.3.2. Geometrical meaning of the derivative.

The previous lemma leads to a geometric interpretation of the derivative in terms of the slope of the secant lines of the graph of a real function  $f$  through  $[x_0, f(x_0)]$ . The derivative exists if and only if the slope of the secant line through the points  $[x_0, f(x_0)]$  and  $[x, f(x)]$  changes continuously when approaching the argument  $x = x_0$ . If so, the limit of this slope is the value of the derivative. This observation leads to the important corollary:

#### FUNCTIONS INCREASING AND DECREASING AT A POINT

**Corollary.** *If a real-valued function  $f$  has derivative  $f'(x_0) > 0$  at a point  $x_0 \in \mathbb{R}$ , then there is a neighbourhood  $\mathcal{O}(x_0)$  such that  $f(x) > f(x_0)$  for all points  $x \in \mathcal{O}(x_0)$ ,  $x > x_0$ , and  $f(x) < f(x_0)$  holds for all  $x \in \mathcal{O}(x_0)$ ,  $x < x_0$ .*

*On the other hand, if the derivative satisfies  $f'(x_0) < 0$ , then there is a neighbourhood  $\mathcal{O}(x_0)$  such that  $f(x) < f(x_0)$  for all points  $x \in \mathcal{O}(x_0)$ ,  $x > x_0$ , and  $f(x) > f(x_0)$  for all  $x \in \mathcal{O}(x_0)$ ,  $x < x_0$ .*

**PROOF.** Suppose  $f'(x_0) > 0$ . By the previous lemma,  $f(x) = f(x_0) + \psi(x)(x - x_0)$  and  $\psi(x_0) > 0$ . Since  $\psi$  is continuous at  $x_0$ , there exists a neighbourhood  $\mathcal{O}(x_0)$  on which  $\psi(x) > 0$ . If  $x$  increases,  $x > x_0$ ,  $f(x)$  increases as well,  $f(x) > f(x_0)$ . Analogously for  $x < x_0$ . The case with a negative derivative is proved similarly.  $\square$

A real function is called *increasing at  $x_0$*  of its domain, if for all points  $x$  of some neighbourhood of a point  $x_0$ ,  $f(x) > f(x_0)$  if  $x > x_0$  and  $f(x) < f(x_0)$  if  $x < x_0$ . A real function is *increasing on an interval  $A$*  if  $f(x) - f(y) > 0$  for all  $x > y$ ,  $x, y \in A$ .

Similarly, a function is said to be *decreasing at a point  $x_0$*  if and only if there is a neighbourhood of the point  $x_0$  such that  $f(x) < f(x_0)$  for all  $x > x_0$ , while  $f(x) > f(x_0)$  for all  $x < x_0$  from this neighbourhood. A function is *decreasing on an interval  $A$*  if  $f(x) - f(y) < 0$  for all  $x > y$ ,  $x, y \in A$ .

Thus a function having a non-zero finite derivative at a point is either increasing or decreasing at that point, according to the sign of the derivative.

```
for x in [-5..5] :
    p+=point([x,x], size=30, color="black")
    p+=circle((x,x-1), 0.08, color="black")
show(p)
```

Sage prints out the figure given here (ignore the vertical lines, as they are not part of the graph):

Notice that there exist a shorter way to sketch the graph of the floor function, which combines the `floor` command with the command `exclude`. The latter automatically removes the vertical lines and the syntax goes as follows:

```
plot(floor(x), (x, -5, 5), exclude=[-5..5])
```

To solve problems involving the continuity of piecewise functions, there are generally two steps. First, prove that the individual components of the function are continuous within the intervals where the domain is divided. Second, examine the continuity at the “gluing points”. For the first step, you can often rely on the inherent continuity of elementary functions within their defined domains (e.g., polynomials, trigonometric functions, power functions, exponentials, logarithms, etc.).

**5.B.49.** Consider the 2-parameter family  $f_{\alpha,\beta}$  of piecewise functions, defined by

$$f_{\alpha,\beta}(x) = \begin{cases} \frac{\sqrt{2x^2 - x + 6} - \alpha x}{x + 2}, & \text{if } x < -2, \\ x^3 + \beta x + 4, & \text{if } x \geq -2, \end{cases}$$

with  $\alpha, \beta \in \mathbb{R}$ . Find the continuous members of  $f_{\alpha,\beta}$ . Next use Sage to confirm your answer, and moreover sketch the graph of these members, for  $-10 \leq x \leq 10$ .

The continuity of a function has far-reaching consequences, such as Bolzano’s theorem, which states that a continuous function which changes its sign within an interval has a zero, see 5.2.19. The following tasks are based on this important principle, with further examples provided in Section E.

A function increasing on an interval is increasing at each of its points. The converse is true as well. In order to see this, assume that  $f$  is increasing at all points of the interval  $A$ . Consider two points  $x < y$  in  $A$  with  $f(y) \leq f(x)$ . By the assumption, there is a  $\delta$ -neighbourhood of  $y$  on which  $z < y$  implies  $f(z) < f(y)$ . Let  $\delta_0$  be the supremum of all such  $\delta \leq y - x$  and  $w = y - \delta_0$ . Then  $f(w)$  cannot be larger than  $f(y)$  (there would be such a point on the right of it too, which is excluded). But, unless  $w = x$ ,  $w$  is a limit point of a sequence of points less than  $w$ , for which the value of  $f$  is larger than  $f(y) \geq f(w)$ . This is a contradiction with  $f$  increasing in  $w$ . But if  $w$  were  $x$  then there would be the contradiction with the assumption  $f(x) > f(z)$  for points  $z > x$  arbitrarily close to  $x$ .

The same arguments work for decreasing functions. The following is now proved:

**Proposition.** A real function is increasing or decreasing on an open interval  $A$  if and only if it is increasing or decreasing in each its point, respectively.

**5.3.3. Examples.** (1) There is a function which is increasing at the origin  $x_0 = 0$  but is neither increasing or decreasing on any neighbourhood of  $x_0$ . Consider the (continuous) function

$$f(x) = x + 5x^2 \sin(1/x), \quad f(0) = 0.$$

The choice  $f(0)$  makes  $f$  a continuous function on  $\mathbb{R}$  (sin is a bounded function with values between 1 and  $-1$ ). Its derivative at zero exists too.

$$\lim_{x \rightarrow 0} \frac{x + 5x^2 \sin(1/x)}{x} = \lim_{x \rightarrow 0} (1 + 5x \sin(1/x)) = 1.$$

For  $x \neq 0$ ,

$$f'(x) = 1 + 10x \sin(1/x) - 5 \cos(1/x)$$

(cf. the rules for computing derivatives in 5.3.4 below). The derivative is not continuous at the origin.

$f$  is increasing at  $x = 0$  but is not increasing on any neighbourhood of this point.

(2) As another illustration of a simple usage of the relation between the derivatives and the properties of being an increasing (or decreasing) function, we can consider the existence of inverses to real polynomials.

Polynomials of degree at least two need not be either increasing or decreasing functions. Hence we cannot anticipate that there would be a globally defined inverse function to them. On the other hand, the inverse exists to every restriction

**5.B.50.** Determine whether the equation  $e^{2x} - x^4 + 3x^3 - 6x^2 = 5$  has a positive solution.

**Solution.** Let us consider the function

$$f(x) = e^{2x} - x^4 + 3x^3 - 6x^2 - 5, \quad x \geq 0,$$

for which  $f(0) = -4$ . Notice that  $\lim_{x \rightarrow +\infty} f(x) = \lim_{x \rightarrow +\infty} e^{2x} = +\infty$ . Obviously,  $f$  is continuous on the whole domain and hence it takes on all the values  $y \in [-4, \infty)$ . Moreover, we have  $f(0) < 0$  and  $f(2) = e^4 - 21 > 0$ . Hence by Bolzano's theorem its graph necessarily intersects the positive semi-axis  $x$ , i.e., the equation  $f(x) = 0$  has a positive solution. To confirm all these claims in Sage use the cell

```
f(x)=e^(2*x)-x^4+3*x^3-6*x^2-5
show(f(0)); show(f(2))
plot(f(x), x, 0, 2, ymax=20)
sol=solve(f(x)==0, x); show(sol)
```

which in fact solves the equation  $f(x) = 0$  via the last command. However, in this way Sage is not able to present the numerical expression of the complicated symbolic expression which returns for the solution (check it yourself). To avoid this problem, one may instead use the command

```
f(x)=e^(2*x)-x^4+3*x^3-6*x^2-5
find_root(f, 0, 2)
```

**5.B.51.** Determine whether the polynomial  $P(x) = x^{37} + 5x^{21} - 4x^9 + 5x^4 - 2x - 3$  has a real root in  $(-1, 1)$ . ○

**5.B.52.** Use Sage and implement Bolzano's theorem to prove that the equation

$$x^3 - \cos(x)e^x + x \sin(x) = 0$$

has a positive solution in  $(0, \pi/2)$ . Next use the `find_root` function to take a numerical approximation of this root. ○

### C. Derivatives

*Having both a conceptual understanding of the notion of limits but also the ability to compute limits, we are now ready to proceed with problems in calculus, the branch of mathematics devoted to derivatives and integrals of functions.<sup>6</sup> We will first focus on derivatives.*

*Given a function  $f$  depending on a real variable  $x$ , the slope of its graph at the point  $[x_0, f(x_0)]$  indicates the rate of change of the value  $f(x)$ , as  $x$  approaches the point  $x_0$ . This rate of change is the limiting value of the slopes  $\frac{f(x)-f(x_0)}{x-x_0}$  ( $x \neq x_0$ ), as  $x$  tends to  $x_0$ , that is,*

<sup>6</sup>A very rough notion of calculus, and in particular integration goes back to the ancient Greeks. Archimedes already developed the method of exhaustion to compute the volume of a cone, sphere, etc. However, calculus was essentially developed by Isaac Newton (1643–1727), and Gottfried Leibniz (1646–1716), both having as reference previous works by Fermat (1607–1665) and others. Later the French mathematician Augustin-Louis Cauchy (1789–1857) established a more rigorous approach to infinitesimal calculus, as we mentioned also before. On the other hand, the Italian mathematician Joseph-Louis Lagrange (1736–1813) was one of the founders of “calculus of variations”, whose elements will be studied in Chapter 9.

of  $f$  to an interval between adjacent roots of the derivative  $f'$ , i.e. where the derivative of the polynomial is non-zero and keeps the sign. These inverse functions will never be polynomials, except for the case of polynomials of degree one. The equation

$$y = ax + b$$

implies

$$x = \frac{1}{a}(y - b).$$

For a polynomial of degree two, the equation

$$y = ax^2 + bx + c$$

leads to the equation

$$x = \frac{-b \pm \sqrt{b^2 - 4a(c - y)}}{2a}.$$

Thus the inverse (given by the above equation) exists only for those  $x$  which are in either of the intervals  $(-\infty, -\frac{b}{2a})$ ,  $(-\frac{b}{2a}, \infty)$ .

It can be shown that the roots of polynomials of order larger than four cannot in general be expressed by means of power functions in general. Thus piece-wise defined inverses to polynomials may represent new items in our zoo.

### 5.3.4. Elementary properties of derivatives.

We introduce several basic facts about the calculation of derivatives. We shall see that the derivatives are quite nicely compatible with the algebraic operations of addition and multiplication of real or complex functions. The last formula then allows us to efficiently determine the derivatives of composite functions. It is also called the *chain rule*.

Intuitively, they can be understood very easily if we imagine that the derivative of a function  $y = f(x)$  is the quotient of the rates of increase of the output variable  $y$  and the input variable  $x$ :

$$f' = \frac{\delta y}{\delta x}.$$

Of course, for  $y = h(x) = f(x) + g(x)$ , the increase in  $y$  is given by the sum of the increases of  $f$  and  $g$ , and the increase of the input variable is still the same. Therefore, the derivative of a sum is the sum of the derivatives.

The derivative of a product is not the product of the derivatives. For  $y = f(x)g(x)$ , the increase is

$$\begin{aligned} \delta y &= f(x + \delta x)g(x + \delta x) - f(x)g(x) \\ &= f(x + \delta x)(g(x + \delta x) - g(x)) + (f(x + \delta x) - f(x))g(x) \end{aligned}$$

Now, if we make the increase  $\delta x$  small, we actually calculate the limit of a sum of products, which is the sum of the products of the limits. Thus the derivative of a product  $fg$  is given by the expression  $f'g + fg'$ , which is called the *Leibniz rule*<sup>10</sup>.

<sup>10</sup>Gottfried Wilhelm von Leibniz (1646-1716) was a great German mathematician and philosopher. He developed the differential and integral calculus in terms of the infinitesimal quantities, arguing similarly as above.

$$\lim_{x \rightarrow x_0} \frac{f(x) - f(x_0)}{x - x_0}.$$

If this limit exists and it is a finite number, then we say that  $f$  is “differentiable” at  $x_0$  and denote the limiting value by  $f'(x_0)$  or  $\frac{df}{dx}(x_0)$ .<sup>7</sup> This is the so-called first derivative of  $f$  at  $x_0$ .

The uniqueness of limits ensures that the derivative of  $f$  at  $x_0$ , when it exists, is uniquely determined. If  $f$  is differentiable at any point  $x_0 \in (a, b)$  in a given open interval, we say that  $f$  is differentiable on  $(a, b)$ . We say that  $f$  is differentiable on a closed interval  $[a, b]$ , when  $f$  is differentiable at any point  $x_0 \in (a, b)$  and the left-side and right-side derivatives at  $a$  and  $b$ , respectively, exist.

**5.C.1.** Based on the definition of the derivative of a function of one variable (see 5.3.1), compute the derivatives of the following functions:

$f(x) = x^n$ , with  $n \in \mathbb{N}$  constant and  $x \in \mathbb{R}$ ;

$g(x) = \sin(x)$ , with  $x \in \mathbb{R}$ ;

$h(x) = \sqrt{x}$ , with  $x \in [0, +\infty)$ . ○

**5.C.2.** Let  $f : \mathbb{R} \rightarrow \mathbb{R}$  be a function such that  $f(a + b) = f(a)f(b)$ , for all  $a, b \in \mathbb{R}$ . Suppose also that  $f(0) = f'(0) = 1$ . Show that  $f'(x) = f(x)$  for all  $x \in \mathbb{R}$ . ○

**5.C.3.** Consider the function  $f(x) = |x|$ . Find the derivative of  $f$  for all  $0 \neq x \in \mathbb{R}$ . Is  $f$  differentiable at  $x_0 = 0$ ? ○

**5.C.4.** Show that if  $f$  is a differentiable function at a point  $x_0$  in its domain, then  $f$  is continuous at  $x_0$  as well. ○

The converse of the statement in 5.C.4 isn't true, and there are several reasons that a continuous function  $f$  may fail to be differentiable at a given point in its domain. A possible reason is a “corner” on its graph, as those of the absolute value function  $f(x) = |x|$  that we discussed in 5.C.3. Another reason is that  $f$  may admit a vertical tangent line at the given point, as the square root function discussed in 5.C.1

Let us summarize with a useful slogan: “Differentiability is a stronger requirement than continuity”.

**5.C.5.** Consider the function

$$f(x) = \begin{cases} \sqrt{x^2 + 7}, & \text{if } x > 3, \\ x^2 + bx + c, & \text{if } x \leq 3. \end{cases}$$

Determine the reals  $b, c \in \mathbb{R}$  such that  $f$  is differentiable for all  $x \in \mathbb{R}$ . For those values use Sage to plot the graph of  $f$  with at least two different methods.

**Solution.** Obviously, for all  $x \neq 3$  the given function is differentiable. In order to determine the unknowns  $b, c \in \mathbb{R}$  we need to establish a system of two equations. Since differentiability requires continuity, these equations are induced by the continuity and differentiability of  $f$  at  $x_0 = 3$ .

<sup>7</sup>For  $y = f(x)$ , the notation  $dy/dx$  is due to Leibniz, while  $f'(x)$  is the notation by Lagrange.

The derivative of a composite function is even more interesting: Consider a function

$$g = h \circ f,$$

where the domain of the function  $z = h(y)$  contains the codomain of the function  $y = f(x)$ . By writing out the increases,

$$g' = \frac{\delta z}{\delta x} = \frac{\delta z}{\delta y} \frac{\delta y}{\delta x}.$$

Thus we expect that the formula will be of the form

$$(h \circ f)'(x) = h'(f(x))f'(x).$$

Now we provide correct formulations together with proofs:

RULES FOR DIFFERENTIATION

**Theorem.** Let  $f$  and  $g$  be real or complex functions defined on a neighbourhood of a point  $x_0 \in \mathbb{R}$  and having finite derivatives at this point. Then

(1) for every real or complex number  $c$ , the function  $x \mapsto c \cdot f(x)$  has a derivative at  $x_0$  and

$$(cf)'(x_0) = c(f'(x_0)),$$

(2) the function  $f + g$  has a derivative at  $x_0$ , and

$$(f + g)'(x_0) = f'(x_0) + g'(x_0),$$

(3) the function  $f \cdot g$  has a derivative at  $x_0$ , and

$$(f \cdot g)'(x_0) = f'(x_0)g(x_0) + f(x_0)g'(x_0).$$

(4) Further, suppose  $h$  is a function defined on a neighbourhood of the image  $y_0 = f(x_0)$  with a derivative at  $y_0$ . Then the composite function  $h \circ f$  also has a derivative at  $x_0$ , and

$$(h \circ f)'(x_0) = h'(f(x_0)) \cdot f'(x_0).$$

**PROOF.** (1) and (2): A straightforward application of the theorem about sums and products of function limits yields the result.

(3) Rewrite the quotient of the increases (already mentioned), in the following way:

$$\frac{(fg)(x) - (fg)(x_0)}{x - x_0} = f(x) \frac{g(x) - g(x_0)}{x - x_0} + \frac{f(x) - f(x_0)}{x - x_0} g(x_0).$$

The limit of this as  $x \rightarrow x_0$  gives the desired result because  $f$  is continuous at  $x_0$ .

(4) By lemma 5.3.1, there are functions  $\psi$  and  $\varphi$  which are continuous at  $x_0$  and  $y_0 = f(x_0)$ . Further they satisfy  $h(y) = h(y_0) + \varphi(y)(y - y_0)$ ,  $f(x) = f(x_0) + \psi(x)(x - x_0)$  on some neighbourhoods of  $x_0$  and  $y_0$ . They satisfy  $\psi(x_0) = f'(x_0)$  and  $\varphi(y_0) = h'(y_0)$ . Then,

$$\begin{aligned} h(f(x)) - h(f(x_0)) &= \varphi(f(x))(f(x) - f(x_0)) \\ &= \varphi(f(x))\psi(x)(x - x_0) \end{aligned}$$

for all  $x$  from the neighbourhood of  $x_0$ . However, the product  $\varphi(f(x))\psi(x)$  is a function which is continuous at  $x_0$  and

We have  $f(3) = 9 + 3b + c$ , and the continuity condition  $\lim_{x \rightarrow 3^-} f(x) = 9 + 3b + c = \lim_{x \rightarrow 3^+} f(x)$ . The first equality holds as an identity and the second gives the relation  $9 + 3b + c = \sqrt{3^2 + 7} = 4$ , i.e.,  $3b + c = -5$ . As for the differentiability of  $f$  at  $x_0 = 3$  we get

$$\lim_{x \rightarrow 3^-} \frac{f(x) - f(3)}{x - 3} = \lim_{x \rightarrow 3^+} \frac{f(x) - f(3)}{x - 3}. \quad (*)$$

We see that  $f(3) = 9 + 3b + c = 9 - 5 = 4$  and hence

$$\begin{aligned} \lim_{x \rightarrow 3^-} \frac{f(x) - f(3)}{x - 3} &= \lim_{x \rightarrow 3^-} \frac{\sqrt{x^2 + 7} - 4}{x - 3} \\ &= \lim_{x \rightarrow 3^-} \frac{(\sqrt{x^2 + 7} - 4)(\sqrt{x^2 + 7} + 4)}{(x - 3)(\sqrt{x^2 + 7} + 4)} \\ &= \lim_{x \rightarrow 3^-} \frac{x^2 - 9}{(x - 3)(\sqrt{x^2 + 7} + 4)} \\ &= \lim_{x \rightarrow 3^-} \frac{x + 3}{\sqrt{x^2 + 7} + 4} = \frac{6}{8} = \frac{3}{4}. \end{aligned}$$

Similarly,

$$\begin{aligned} \lim_{x \rightarrow 3^+} \frac{f(x) - f(3)}{x - 3} &= \lim_{x \rightarrow 3^+} \frac{x^2 + b(x - 3) - 9}{x - 3} \\ &= \lim_{x \rightarrow 3^+} \frac{(x - 3)(x + 3 + b)}{x - 3} \\ &= \lim_{x \rightarrow 3^+} (x + 3 + b) = 6 + b. \end{aligned}$$

Thus, by (\*) we obtain the equation  $6 + b = \frac{3}{4}$ , that is,  $b = -\frac{21}{4}$  and so  $c = -5 - 3b = \frac{43}{4}$ .

In Sage we can plot  $f$  “manually”, i.e.,

```
f1(x)=sqrt(x^2+7); f2(x)=x^2-(21/4)*x+43/4
P=plot(f1(x), x, 3, 12, color="black")
P+=plot(f2(x), x, -6, 3, color="gray")
P+=point([3, 9-(21/4)*3+43/4], color="black",
size=30); show(P)
```

An alternative relies on the command `piecewise`, whose implementation can be summarized from the cell

```
f1(x)=sqrt(x^2+7); f2(x)=x^2-(21/4)*x+43/4
F=piecewise([[(-6, 3), f2(x)],
[(3, 12), f1(x)]])
p=plot(F(x), x, -6, 12)
p+=point([3, 9-(21/4)*3+43/4], color="black",
size=30); show(p)
```

Execute these cells to generate the required graph (note the code includes also the midpoint  $x_0 = 3$ ). Notably, compiling the “`piecewise`” method takes more time in both <https://sagecell.sagemath.org> or in [cocalc.com](http://cocalc.com), compared to the first approach. Finally, remember that another way to introduce  $f$  is based on the method presented in 5.B.49.  $\square$

its value at  $x_0$  is just the desired derivative of the composite function, again by lemma 5.3.1.  $\square$

**5.3.5. Derivative of quotients.** Consider first the special case of  $h(x) = x^{-1}$ . From the definition of the derivative,

$$\begin{aligned} h'(x) &= \lim_{\delta x \rightarrow 0} \frac{\frac{1}{x+\delta x} - \frac{1}{x}}{\delta x} = \lim_{\delta x \rightarrow 0} \frac{x - x - \delta x}{\delta x(x^2 + x\delta x)} \\ &= \lim_{\delta x \rightarrow 0} \frac{-1}{x^2 + x\delta x} = -x^{-2}. \end{aligned}$$

Thus, the above leads to:

DERIVATIVE OF A QUOTIENT

**Corollary.** Let  $f$  and  $g$  be real-valued functions which have finite derivatives at a point  $x_0$  and  $g(x_0) \neq 0$ . Then the function  $h(x) = f(x)(g(x))^{-1}$  satisfies

$$h'(x_0) = \left(\frac{f}{g}\right)'(x_0) = \frac{f'(x_0)g(x_0) - f(x_0)g'(x_0)}{(g(x_0))^2}.$$

**PROOF.** Using the formula  $(x^{-1})' = -x^{-2}$ , the chain rule says

$$(g^{-1})' = -g^{-2} \cdot g'.$$

The Leibniz rule implies

$$(f/g)' = (f \cdot g^{-1})' = f'g^{-1} - fg^{-2}g' = \frac{f'g - gf'}{g^2}.$$

$\square$

**5.3.6. Derivatives of inverse functions.** In paragraph 1.6.1,

while talking about relations and mappings in general, the concept of an *inverse function* was introduced. If the inverse function  $f^{-1}$  to a given function  $f : \mathbb{R} \rightarrow \mathbb{R}$  exists (do not confuse this notation with the function  $x \mapsto (f(x))^{-1}$ ), then it is uniquely determined by either of the following identities

$$f^{-1} \circ f = \text{id}_{\mathbb{R}}, \quad f \circ f^{-1} = \text{id}_{\mathbb{R}}.$$

Then the other identity is also true. If  $f$  is defined on a set  $A \subset \mathbb{R}$  and  $f(A) = B$ , the existence of  $f^{-1}$  is conditioned by the same statements with identity mappings  $\text{id}_A$  and  $\text{id}_B$ , respectively, on the right-hand sides. As seen in the diagram, the graph of the inverse function is obtained simply by interchanging the axes of the input and output variables.

The fundamental rules of differentiation (see 5.3.4 and 5.3.5) enable us to compute derivatives of functions, even those with complex forms. The upcoming exercises focus on these rules to enhance familiarity with their application. It's worth noting that while differentiation is a standard procedure, it can involve intricate computations. Therefore, many find it more enjoyable to compute derivatives using computer algebra packages, as these not only simplify the process but also allow for rigorous verification of calculations.

Below we will explain the usage of Sage. Similar syntaxes are available in many other computer algebra systems, as Mathematica and Maple.

**5.C.6.** In 5.C.1 we saw that  $(\sin(x))' \equiv \sin'(x) = \cos(x)$ . Based on this fact and using the *chain rule*, introduced in 5.3.4, prove that  $(\cos(x))' = -\sin(x)$ .  $\circ$

**5.C.7.** Differentiate the following functions, compute the required values and verify (some of) your answers via Sage.

- (1)  $f(x) = x \sin(x)$ . Find  $f'(\pi/2)$ ;
- (2)  $g(x) = \frac{\sin(x)}{x}$ ,  $x \neq 0$ . Find  $g'(\pi/2)$ ;
- (3)  $h(x) = \ln(x + \sqrt{x^2 - c^2})$ ,  $c \neq 0$ ,  $|x| \geq |c|$ .
- (4)  $k(x) = x^x$ ,  $x > 0$ ;
- (5)  $m(x) = x^{\sin(x)}$ ,  $x > 0$ .

**Solution.** (1) By the product rule (also called *Leibniz rule*, see 5.3.4), we see that

$$f'(x) = x' \cdot \sin(x) + x \cdot (\sin(x))' = \sin(x) + x \cos(x).$$

Thus  $f'(\pi/2) = 1$ . In order to differentiate a function  $f(x)$ , Sage provides many alternatives. For instance we can use the command `derivative(f,x)` or `f.derivative(x)`, as follows:

```
f(x)=x*sin(x); show(derivative(f, x))
```

or type

```
f(x)=x*sin(x); show(f.derivative(x))
```

If we want to find the explicit value of the derivative at a point  $x_0$ , then the command `f.derivative(x)(x=x_0)` is an appropriate one. Thus, to compute  $f'(\pi/2)$  you may continue typing in the previous cell the following:

```
f.derivative(x)(x=pi/2)
```

This prints out 1, that is,  $f'(\pi/2) = 1$ , where  $f(x) = x \sin(x)$ . An alternative to differentiate  $f(x)$  relies on the command `diff`. For example, by typing

```
f(x)=x*sin(x); show(diff(f, x))
```

we obtain the same result. In order to specify the value at a certain point  $x_0$ , we again type `diff(f,x)(x=x_0)`, i.e.,

```
f(x)=x*sin(x); show(diff(f, x)(x=pi/2))
```

The command `diff` is also useful when one wants to find higher-order derivatives, hence we will meet it again in Chapter 6, see also below and the final Section E of this chapter.

If it is known that the inverse  $y = f^{-1}(x)$  of a differentiable function  $x = f(y)$  is also differentiable, then the chain rule yields immediately

$$1 = (\text{id})'(x) = (f \circ f^{-1})'(x) = f'(y) \cdot (f^{-1})'(x).$$

Notice that  $f'(y)$  must be non-zero.

This corresponds to the intuitive idea that for  $y = f(x)$ , the value of  $f'$  is approximately  $\frac{\delta y}{\delta x}$  while for  $x = f^{-1}(y)$  it is approximately  $(f^{-1})'(y) = \frac{\delta x}{\delta y}$ . And this indeed is the way the derivatives of inverse functions are calculated.

#### DERIVATIVE OF THE INVERSE FUNCTION

**Theorem.** If  $f$  is a real-valued function differentiable at  $y_0$ , such that the inverse  $f^{-1}(x)$  exists on a neighbourhood of the value  $x_0 = f(y_0)$  and  $f'(y_0) \neq 0$ , then

$$(1) \quad (f^{-1})'(x_0) = \frac{1}{f'(f^{-1}(x_0))} = \frac{1}{f'(y_0)}.$$

Let us notice that if we assume that the derivative  $f'(x)$  is continuous on a neighborhood of  $x_0$ , then the condition  $f'(x_0) \neq 0$  clearly implies that  $f$  is either increasing or decreasing on some neighborhood, and thus the assumptions of the theorem are fulfilled. On the other hand, the example 5.3.3(1) shows, that the existence of  $f'(x_0) \neq 0$  is not necessarily sufficient.

**PROOF.** To prove the proposition, it suffices to read the proof of the fourth statement of theorem 5.3.4. We work with the composition  $f \circ f^{-1} = \text{id}$  there. The composite function is differentiable. By lemma 5.3.1, there is a function  $\varphi$  continuous at  $y_0$  such that

$$f(y) - f(y_0) = \varphi(y)(y - y_0),$$

on some neighbourhood of  $y_0$ . Further, it satisfies  $\varphi(y_0) = f'(y_0) \neq 0$  and  $\varphi$  has constant sign on a neighbourhood of  $x_0$ . Next, notice that the existence of the inverse  $f^{-1}$  around the point  $x_0$  and the continuity of  $f$  at  $y_0$  guarantees the continuity of  $f^{-1}$  at  $x_0$ , (the  $\varepsilon$  and  $\delta$  neighbourhoods map each to the other bijectively). The substitution  $y = f^{-1}(x)$  then yields

$$x - x_0 = \varphi(f^{-1}(x))(f^{-1}(x) - f^{-1}(x_0)),$$

for all  $x$  lying in some neighbourhood  $\mathcal{O}(x_0)$  of  $x_0$ . Further,  $f^{-1}(x_0) = y_0$ , and  $\varphi(f^{-1}(x))$  is continuous at  $x_0$  and remains non-zero on a neighbourhood  $\mathcal{O}(x_0)$  of  $x_0$  with constant sign. Thus

$$\frac{f^{-1}(x) - f^{-1}(x_0)}{x - x_0} = \frac{1}{\varphi(f^{-1}(x))} \neq 0,$$

for all  $x \in \mathcal{O}(x_0) \setminus \{x_0\}$ . The right-hand side of this expression is continuous at  $x_0$ . The limit is

$$\lim_{x \rightarrow x_0} \frac{1}{\varphi(f^{-1}(x))} = \frac{1}{\varphi(f^{-1}(x_0))} = \frac{1}{f'(y_0)}.$$

(2) The rule for the derivative of a quotient (see 5.3.5), gives

$$g'(x) = \frac{(\sin(x))' \cdot x - \sin(x) \cdot x'}{x^2} = \frac{x \cos(x) - \sin(x)}{x^2}.$$

Thus, we easily get  $g'(\pi/2) = -\frac{4}{\pi^2}$ . To confirm this via Sage a recommendation has the form

```
g(x)=sin(x)/x; diff(g(x), x)(x=pi/2)
```

(3) Here the “chain rule” applies. Set  $a(x) = \ln(x)$  and  $b(x) = x + \sqrt{x^2 - c^2}$  such that  $h(x) = a(b(x))$ . Then

$$\begin{aligned} h'(x) &= (a(b(x)))' = a'(b(x)) \cdot b'(x) \\ &= \frac{(x + \sqrt{x^2 - c^2})'}{x + \sqrt{x^2 - c^2}} = \frac{1 + \frac{x}{x^2 - c^2}}{x + \sqrt{x^2 - c^2}}. \end{aligned}$$

For a confirmation in Sage you may use one of the methods posed above.

(4) Let us recall the identity  $(e^{f(x)})' = f'(x)e^{f(x)}$ , where we assume that  $f'(x)$  exists. Because  $x^x = e^{x \ln(x)}$  by applying this rule we obtain

$$\begin{aligned} k'(x) = (x^x)' &= (e^{x \ln(x)})' = (x \ln(x))' e^{x \ln(x)} \\ &= (\ln(x) + 1) e^{x \ln(x)} = (\ln(x) + 1)x^x. \end{aligned}$$

In Sage you may use the cell `show(diff(x**x, x))`, which returns the expression  $x^x(\log(x) + 1)$  (recall that in Sage the function `log` represents the natural logarithm).

The same trick used in (4) applies for the final case, too. Hence we leave this as an exercise.  $\square$

**5.C.8. Chain rule via Sage.** Write in Sage a short code implementing the chain rule for two arbitrary differentiable functions.

**Solution.** Let  $h(x) = f(g(x))$  be the composition of two arbitrary differentiable functions  $f, g : \mathbb{R} \rightarrow \mathbb{R}$ . We want to implement in Sage the rule  $h'(x) = g'(x)f'(g(x))$ , for all  $x \in \mathbb{R}$ , and with this goal in mind it is useful to recall about symbolic functions in Sage. For instance, type in your editor the cell

```
x=var("x")
f=function('f')(x); show(f)
```

This cell introduces an arbitrary function  $f$  of one variable  $x$ , in particular prints out  $f(x)$ . This makes the implementation of the chain rule for two arbitrary functions  $f, g : \mathbb{R} \rightarrow \mathbb{R}$ , really simple. First introduce the composition  $h$ , as follows

```
x=var("x"); f=function("f"); g=function("g")
h=f(g(x)) # define the composition h
show(h)
```

Check yourself that this gives the composition  $f(g(x))$ . Next it is sufficient to add the command `h.diff(x)`, which returns  $D[0](f)(g(x)) * diff(g(x), x)$ . Recall here that  $D[0]$  encodes the first derivative, hence we can indeed translate Sage’s output as  $f'(g(x))g'(x)$ , that is, the chain rule.

A more useful alternative has the following form:

```
function("f")(x)
```

Therefore, the limit of the left-hand side also exists, and it follows that

$$(f^{-1})'(x_0) = \frac{1}{f'(y_0)}$$

as required.  $\square$

**5.3.7. Derivatives of the elementary functions.** Consider the exponential function  $f(x) = a^x$  for any fixed real  $a > 0$ . If the derivative of  $a^x$  exists for all  $x$ , then

$$f'(x) = \lim_{\delta x \rightarrow 0} \frac{a^{x+\delta x} - a^x}{\delta x} = a^x \lim_{\delta x \rightarrow 0} \frac{a^{\delta x} - 1}{\delta x} = f'(0)a^x.$$

On the other hand, if the derivative at zero exists, then this formula guarantees the existence of the derivative at any point of the domain and also determines its value. At the same time, the validity of this formula for one-sided derivatives is also verified.

Unfortunately, it takes some time to verify that the derivatives of exponential functions indeed exist (see 5.4.2, 5.4.10, and 6.3.7).

There is an especially important base  $e$ , also known as Euler’s number, for which the derivative at zero equals one.

Remember the formula  $(e^x)' = e^x$  for a while and draw on its consequences.

For the general exponential function, (using standard rules of differentiation),

$$(a^x)' = (e^{\ln(a)x})' = \ln(a)(e^{\ln(a)x}) = \ln(a) \cdot a^x.$$

Thus exponential functions are special since their derivatives are proportional to their values.

Next, we determine the derivative  $(\ln_e(x))'$ . The definition of the natural logarithm as the inverse to  $e^x$ ,

$$e^{\ln x} = x,$$

allows the calculation:

$$(1) \quad (\ln)'(y) = (\ln)'(e^x) = \frac{1}{(e^x)'} = \frac{1}{e^x} = \frac{1}{y}.$$

The formula

$$(2) \quad (x^a)' = ax^{a-1}$$

for differentiating a general power function can also be derived using the derivatives of the exponential and logarithmic functions:

$$(x^a)' = (e^{a \ln x})' = e^{a \ln x} (a \ln x)' = a \frac{x^a}{x} = ax^{a-1}.$$

**5.3.8. Mean value theorems.** Before continuing the journey of finding new interesting functions, we derive several simple statements about derivatives. The meaning of all of them is intuitively clear from the diagrams. The proofs follow the visual imagination.

```
function("g")(x)
show(diff(f(g(x)), x))
```

The output here has the form  $D_0(f)(g(x)) \frac{\partial}{\partial x} g(x)$ , and the advantage is that we can “replace”  $f, g$  with certain functions, so that we can use this method for verifying our formal computations in such examples. For instance, to compute the derivative of  $e^{x^2}$ , it is sufficient to specify  $f, g$  by adding in the previous cell the code

```
f(x)=e^x;g(x)=x^2; show(diff(f(g(x)), x))
```

To compute the case (5) of Problem 5.C.7, add the line  $f(x) = x^x; g(x) = \sin(x); show(diff(f(g(x)), x))$ . Try some additional examples yourself, and see also in Chapter 6 for further applications of symbolic functions (cf. 6.A.4).  $\square$

**5.C.9. Inverse function theorem.** (a) Given the function  $f(x) = (4x + 3)/(x - 6)$  prove that it is invertible on its domain, with inverse given by the function  $g(x) = (6x + 3)/(x - 4)$ , with  $x \in \mathbb{R} \setminus \{4\}$ .

(b) According to 5.3.6 if  $y = g(x)$  is the inverse of a differentiable function  $f(x)$ , then for all  $x$  satisfying  $f'(g(x)) \neq 0$  we have  $g'(x) = 1/f'(g(x))$ . Based on this result compute the derivative of the function  $g(x)$  given in (a) and then compare your result, by applying a direct computation of  $g'(x)$ .

**Solution.** (a) Obviously, the domain of  $f$  is the set  $A := \mathbb{R} \setminus \{6\}$ . For arbitrary  $x_1, x_2 \in A$  we see that the relation  $f(x_1) = f(x_2)$  is equivalent to  $27x_1 = 27x_2$ , that is,  $x_1 = x_2$ . Hence  $f$  is one-to-one and its inverse  $y = f^{-1}(x)$  exists. We will show that  $y = f^{-1}(x) = g(x)$  with domain the set  $B = \mathbb{R} \setminus \{4\}$ . Setting  $y = \frac{4x+3}{x-6}$ , we equivalently get  $y(x-6) = 4x+3$ , or  $x(y-4) = 6y+3$ , that is  $x = \frac{6y+3}{y-4}$  for  $y \neq 4$ . Such  $x$  are indeed elements of  $A$ , and in order to obtain the inverse of  $f$  it is now sufficient to reverse the roles of  $x, y$  in the previous relation. This gives the desired expression of  $g = f^{-1}$ . An alternative verification occurs due to the relations  $f(g(x)) = \frac{27x}{27} = x$  and  $g(f(x)) = \frac{27x}{27} = x$ . (b) A direct computation shows that

$$g'(x) = \left(\frac{6x+3}{x-4}\right)' = -\frac{27}{(x-4)^2}, \quad x \in B.$$

Let us obtain the same result by applying the method mentioned above. We similarly compute  $f'(x) = -\frac{27}{(x-6)^2}$  and hence it follows that for all  $x \neq 4$  we have

$$f'(g(x)) = -\frac{27}{\left(\frac{6x+3}{x-4} - 6\right)^2} = -\frac{(x-4)^2}{27} \neq 0.$$

Thus  $g'(x) = 1/f'(g(x)) = -\frac{27}{(x-4)^2}$ , for all  $x \in B$ .  $\square$

Let  $y = f(x)$  be a differentiable function at  $x_0 \in \mathbb{R}$ . The tangent line of the graph of  $f$  at the point  $[x_0, y_0 = f(x_0)] \in \mathbb{R}^2$  has the form  $y - y_0 = f'(x_0)(x - x_0)$ , or equivalently

$$y = f'(x_0)x + (y_0 - f'(x_0)x_0).$$

### ROLLE'S THEOREM<sup>11</sup>

**Theorem.** Assume that the function  $f : \mathbb{R} \rightarrow \mathbb{R}$  is continuous on a closed bounded interval  $[a, b]$  and differentiable inside this interval. If  $f(a) = f(b)$ , then there is a number  $c \in (a, b)$  such that  $f'(c) = 0$ .

**PROOF.** Since the function  $f$  is continuous on the closed interval (i.e. on a compact set), it attains its maximum and its minimum there. Either its maximum value is greater than  $f(a) = f(b)$ , or the minimum value is less than  $f(a) = f(b)$ , or  $f$  is constant. If the third case applies, the derivative is zero at all points of the interval  $(a, b)$ . If the second case applies, then the first case applies to the function  $-f$ . If the first case applies, it occurs at an interior point  $c$ . If  $f'(c) \neq 0$  then the function  $f$  would be either increasing or decreasing at  $c$  (see 5.3.2), implying the existence of larger values than  $f(c)$  in a neighbourhood of  $c$ , contradicting that  $f(c)$  is a maximum value.  $\square$

**5.3.9.** The latter result immediately implies the following corollary.

### LAGRANGE'S MEAN VALUE THEOREM

**Theorem.** Assume the function  $f : \mathbb{R} \rightarrow \mathbb{R}$  is continuous on an interval  $[a, b]$  and differentiable at all points inside this interval. Then there is a number  $c \in (a, b)$  such that

$$f'(c) = \frac{f(b) - f(a)}{b - a}.$$

<sup>11</sup>The French mathematician Michel Rolle (1652-1719) proved this theorem only for polynomials. The principle was perhaps known much earlier, but the rigorous proof comes from the 19th century only.

Hence, the tangent is the line through the point  $[x_0, y_0]$ , having slope  $f'(x_0)$ . Observe that the geometric condition of having a unique non-vertical tangent to the graph of  $f$  at a point  $[x_0, f(x_0)] \in G_f$  is equivalent to the existence of  $f'(x_0)$ , that is, to the differentiability of  $f$  at  $x_0$ . Hence tangent lines provide a more intuitive definition of differentiability: We may always think a differentiable function  $f$  at  $x_0$ , as a function whose graph has a unique (non-vertical) tangent at the point  $[x_0, f(x_0)]$ . In this case the graph of  $f$  cannot have breaks, corners or cusps at  $x_0$ .

PROOF. The proof is a simple statement of the geometrical meaning of the theorem: The secant line between the points  $[a, f(a)]$  and  $[b, f(b)]$  has a tangent line which is parallel to it (have a look at the diagram). The equation of the secant line is

$$y = g(x) = f(a) + \frac{f(b) - f(a)}{b - a}(x - a).$$

The difference  $h(x) = f(x) - g(x)$  determines the (vertical) distance of the graph and the secant line (in the values of  $y$ ). Surely  $h(a) = h(b) = 0$  and

$$h'(x) = f'(x) - \frac{f(b) - f(a)}{b - a}.$$

By Rolle's theorem, there is a point  $c$  at which  $h'(c) = 0$ .  $\square$

**5.C.10.** Consider the function  $f(x) = \alpha x^2 - 4x \ln(x)$  with  $x > 0$ , where  $\alpha \neq 0$  is some real parameter. Find the tangent of  $f$  at the point  $P = [1, f(1)]$ . Next specify  $\alpha$  such that the origin is a point of this tangent.  $\square$

**5.C.11.** Consider the function  $f(x) = x^2 \ln(x)$ , with  $x > 0$ . Prove that there exists a unique point  $P \in \mathbb{R}^2$  belonging on the graph of  $f$  and where the tangent of  $f$  is parallel to the  $x$ -axis. Explain why this happens and verify your computations via Sage.

**Solution.** The derivative of  $f$  is given by

$$f'(x) = 2x \ln(x) + x = x(2 \ln(x) + 1),$$

for any  $x \in (0, +\infty)$ . We see that the equation  $f'(x) = 0$  has a unique solution, namely  $x_0 = e^{-\frac{1}{2}} = \frac{1}{\sqrt{e}}$  (since  $f'$  is defined only for  $x > 0$ , the solution  $x = 0$  is not acceptable). In Sage we can verify these computations by typing

```
f(x)=x^2*ln(x); assume(x>0)
show(solve(diff(f, x)==0, x))
```

The tangent line of  $f$  at this point has zero slope, i.e.,  $f'(x_0) = 0$ , and hence is horizontal. In particular, the tangent line is given by  $y = f(x_0)$ , and observe that near  $x_0$  this line lies under the graph of  $f$ . In such a situation we say that at  $x_0$  the function  $f$  attains a local minimum with value  $f(x_0)$ , see also here:

Thus there is a unique point  $P \in \mathbb{R}^2$  satisfying the statement, with coordinates  $P = \left[ \frac{1}{\sqrt{e}}, -\frac{1}{2e} \right]$ .  $\square$

The mean value theorem can also be written in the form:

$$(1) \quad f(b) = f(a) + f'(c)(b - a).$$

In the case of a parametrically given curve in the plane, i.e., a pair of functions  $y = f(t)$ ,  $x = g(t)$ , similar result about the existence of a tangent line parallel to the secant line going through the boundary points is described by *Cauchy's mean value theorem*. Notice we may consider such a curve as a complex valued function  $f(t) + i g(t)$ .

#### CAUCHY'S MEAN VALUE THEOREM

**Corollary.** Let functions  $y = f(t)$  and  $x = g(t)$  be continuous on an interval  $[a, b]$  and differentiable inside this interval. Further, let  $g'(t) \neq 0$  for all  $t \in (a, b)$  and  $g(b) \neq g(a)$ . Then there is a point  $c \in (a, b)$  such that

$$\frac{f(b) - f(a)}{g(b) - g(a)} = \frac{f'(c)}{g'(c)}.$$

PROOF. Put

$$h(t) = (f(b) - f(a))g(t) - (g(b) - g(a))f(t).$$

Now  $h(a) = f(b)g(a) - f(a)g(b)$ ,  $h(b) = f(b)g(b) - f(a)g(b)$ , so by Rolle's theorem, there is a number  $c \in (a, b)$  such that  $h'(c) = 0$ .

Finally,  $g'(c) \neq 0$  and the desired formula follows.  $\square$

Notice that  $g(b) \neq g(a)$  automatically, if  $g'(t)$  is continuous.

**5.3.10.** A reasoning similar to the one in the above proof leads to a supremely useful tool for calculating limits of quotients of functions.

**5.C.12.** Find the equations of the tangent and normal lines to the graph of  $g(x) = (x + 1) \sqrt[3]{3 - x}$ , with  $x \in \mathbb{R}$ , at the point  $P = [1, f(1)]$ . Next sketch the two lines together with the graph of  $g$  via Sage.

**Solution.** We have  $g(x_0) = g(1) = 2 \cdot 2^{\frac{1}{3}} = 2^{\frac{4}{3}}$ . Moreover

$$g'(x) = (3 - x)^{\frac{1}{3}} - \frac{1}{3}(x + 1)(3 - x)^{-\frac{2}{3}},$$

and hence  $g'(1) = \frac{2}{3} \cdot 2^{\frac{1}{3}} = \frac{2\sqrt[3]{2}}{3}$ . Thus the tangent of  $g$  at  $P$  is given by

$$y_1 = g(x_0) + g'(x_0)(x - x_0) = 2^{\frac{4}{3}} + \frac{2\sqrt[3]{2}}{3}(x - 1).$$

The normal line and tangent line are perpendicular, hence they should have slopes that are opposite reciprocals each other. This means that the normal line has the form

$$y_2 = g(x_0) - \frac{1}{g'(x_0)}(x - x_0) = 2^{\frac{4}{3}} - \frac{3}{2\sqrt[3]{2}}(x - 1).$$

In order to derive the equations of the tangent and normal (and sketch them) in Sage, type the block

```
g(x)=(x+1)*(3-x)^(1/3);dg(x)=diff(g(x),x)
a=plot(g(x),x,-1.2,3,xmin=-3,xmax=3,
legend_label="curve")
x0=1;tangl=g(x0)+dg(x0)*(x-x0)
show(tangl)
perpl=g(x0)-(1/dg(x0))*(x-x0);show(perpl)
b=plot(tangl,xmin=-1.2,xmax=1.5,
color="black",
legend_label="tangent",aspect_ratio=1)
c=plot(perpl,xmin=-1,xmax=2,color="gray",
legend_label="normal")
m=point([x0,0],size=30,color="black")
mv=point([x0,g(x0)],size=30,color="black")
show(a+b+c+m+mv)
```

We leave to the reader the implementation of this block, for practicing with Sage.  $\square$

**5.C.13.** Find the tangent and normal line to the curve given by the equation  $x^3 + y^3 - 2xy = 0$ , at the point  $P = [1, 1]$ .  $\circ$

**5.C.14. Tangent lines via Sage.** Given the polynomial  $P(x) = x^4 - 2x$  with  $x \in I = [-2, 2]$ , write a short routine in Sage constructing the tangent line  $\ell_{x_0}(x)$  of  $P$  at a random point  $x_0$  lying in the interval  $I$ . Then choosing certain  $x_0 \in I$ , produce the graphs of  $P$  and  $\ell_{x_0}$  for all  $x \in I$ .

**Solution.** Using the `def` command we can introduce a sub-routine, which we agree to call `Tangent`. To do so we first need to introduce  $P$  and its first derivative. The whole block has the form

L'HOSPITAL'S RULE<sup>12</sup>

**Theorem.** Suppose  $f$  and  $g$  are functions differentiable on some neighbourhood of a point  $x_0 \in \mathbb{R}$ , yet not necessarily at  $x_0$  itself. Suppose

$$\lim_{x \rightarrow x_0} f(x) = 0, \quad \lim_{x \rightarrow x_0} g(x) = 0.$$

If the limit

$$\lim_{x \rightarrow x_0} \frac{f'(x)}{g'(x)}$$

exists, then the limit

$$\lim_{x \rightarrow x_0} \frac{f(x)}{g(x)}$$

also exists, and the two limits are equal.

**PROOF.** Without loss of generality, the functions  $f$  and  $g$  are zero at the point  $x_0$ . The quotient of the values then corresponds to the slope of the secant line between the points  $[0, 0]$  and  $[f(x), g(x)]$ . At the same time, the quotient of the derivatives corresponds to the slope of the tangent line at the given point. Thus it is necessary to verify that the limit of the slopes of the secant lines exists from the fact that the limit of the slopes of the tangent lines exists.

Technically, we can use the mean value theorem in Cauchy's parametric form. First of all, the existence of the expression  $f'(x)/g'(x)$  on some neighbourhood of the point  $x_0$  (excluding  $x_0$  itself) is implicitly assumed. Thus especially for points  $c$  sufficiently close to  $x_0$ ,  $g'(c) \neq 0$ .<sup>13</sup> By the mean value theorem,

$$\lim_{x \rightarrow x_0} \frac{f(x)}{g(x)} = \lim_{x \rightarrow x_0} \frac{f(x) - f(x_0)}{g(x) - g(x_0)} = \lim_{x \rightarrow x_0} \frac{f'(c_x)}{g'(c_x)},$$

<sup>12</sup>Guillaume François Antoine, Marquis de l'Hôpital, (1661-1704) became famous for his textbook on Calculus (in modern textbooks, his name is mostly spelled as l'Hospital). This rule was first published there, perhaps originally proved by one of the famous Bernoulli brothers.

<sup>13</sup>This is not always necessary for the existence of the limit in a general sense. Nevertheless, for the statement of l'Hospital's rule, it is. A thorough discussion can be found (googled) in the popular article 'R. P. Boas, Counterexamples to L'Hospital's Rule, The American Mathematical Monthly, October 1986, Volume 93, Number 8, pp. 644-645.'

```
P(x)=x^4-2*x; P1(x)=diff(P(x), x)
def Tangent(x_0):
    y_0=P(x_0)
    m=P1(x_0)
    c=y_0 - m*x_0
    l(x)=m*x+c #this defines the tangent line
    Q = plot(P(x), -2, 2, color="blue",
```

where  $c_x$  is a number lying between  $x_0$  and  $x$ , dependent on  $x$ . From the existence of the limit

$$\lim_{x \rightarrow x_0} \frac{f'(x)}{g'(x)},$$

it follows that this value will be shared by the limit of any sequence created by substituting the values  $x = x_n$  approaching  $x_0$  into  $f'(x)/g'(x)$  (cf. the convergence test 5.2.15). Especially, we can substitute any sequence  $c_{x_n}$  for  $x_n \rightarrow x_0$ , and thus the limit

$$\lim_{x \rightarrow x_0} \frac{f'(c_x)}{g'(c_x)}$$

exist, and the last two limits are equal. Hence the desired limit exists and has the same value.  $\square$

From the proof of the theorem, it is true for one-sided limits as well.

**5.3.11. Corollaries.** L'Hospital's rule can easily be extended for limits at the improper points  $\pm\infty$  and for the case of infinite values of the limits. If, for instance, we have

$$\lim_{x \rightarrow \infty} f(x) = 0, \quad \lim_{x \rightarrow \infty} g(x) = 0,$$

then  $\lim_{x \rightarrow 0^+} f(1/x) = 0$  and  $\lim_{x \rightarrow 0^+} g(1/x) = 0$ .

At the same time, from existence of the limit of the quotient of the derivatives at infinity,

$$\begin{aligned} \lim_{x \rightarrow 0^+} \frac{(f(1/x))'}{(g(1/x))'} &= \lim_{x \rightarrow 0^+} \frac{f'(1/x)(-1/x^2)}{g'(1/x)(-1/x^2)} \\ &= \lim_{x \rightarrow 0^+} \frac{f'(1/x)}{g'(1/x)} = \lim_{x \rightarrow \infty} \frac{f'(x)}{g'(x)}. \end{aligned}$$

Applying the previous theorem, the limit

$$\lim_{x \rightarrow \infty} \frac{f(x)}{g(x)} = \lim_{x \rightarrow 0^+} \frac{f(1/x)}{g(1/x)} = \lim_{x \rightarrow \infty} \frac{f'(x)}{g'(x)}$$

exists in this case as well.

The limit calculation is even simpler in the case when

$$\lim_{x \rightarrow x_0} f(x) = \pm\infty, \quad \lim_{x \rightarrow x_0} g(x) = \pm\infty.$$

Then it suffices to write

$$\lim_{x \rightarrow x_0} \frac{f(x)}{g(x)} = \lim_{x \rightarrow x_0} \frac{1/g(x)}{1/f(x)},$$

which is already the case of usage of l'Hospital's rule from the previous theorem.

In fact, the l'Hospital's rule has the same form for improper limits as well:

**Theorem.** Let  $f$  and  $g$  be functions differentiable on some neighbourhood of a point  $x_0 \in \mathbb{R}$ , not necessarily at  $x_0$  itself. Further, let the limits  $\lim_{x \rightarrow x_0} f(x) = \pm\infty$  and  $\lim_{x \rightarrow x_0} g(x) = \pm\infty$  exist. If the limit

$$\lim_{x \rightarrow x_0} \frac{f'(x)}{g'(x)}$$

exists, then the limit

$$\lim_{x \rightarrow x_0} \frac{f(x)}{g(x)}$$

also exists and they equal each other.

```

ymin=-2, ymax=20, gridlines="true")
Q+=plot(l(x), -2, 2, color="black",
ymin=-2, ymax=20)
Q+=point((x_0, y_0), color="black",
size=50)
Q.show()
show("x_0=" , x_0)
show("tang. line: l(x)=(", m, ") *x+(", c, ")")
return

```

Notice that  $x_0$  is included in this code as a real number input. Also, the command `gridlines` with the option `true` was used to add grid lines in the background (though not necessary). The last two `show` commands are included to display the chosen value of  $x_0$  and the expression of the tangent line  $\ell_{x_0}(x)$  at  $x_0$ . Finally, the command `return` is used to conclude the routine. Further applications of programming in Sage will be discussed later, as seen, for for example in 5.D.5.

We can now check our routine by testing certain values for  $x_0$ . We may type

```

Tangent(0); Tangent(-0.5)
Tangent(0.5); Tangent(1)

```

etc. For instance, the last command produces the figure

and prints

```

x_0=1
tang. line: l(x)=(2)*x+(-3)

```

Later in the final section of this chapter we will use the routine constructed here to build an interactive environment for tangent lines, see 5.E.92.  $\square$

*We have now only scratched the surface of the theory of derivatives, which encompasses a wide range of theorems and applications. Derivatives offer a powerful mathematical framework that naturally applies to the study of monotone functions, optimization problems, and approximation techniques.*

**PROOF.** Apply the mean value theorem. The key step is to express the quotient in a form where the derivative arises:

$$\frac{f(x)}{g(x)} = \frac{f(x) - f(y)}{f(x) - f(y)} \cdot \frac{f(x) - f(y)}{g(x) - g(y)} \cdot \frac{g(x) - g(y)}{g(x)},$$

where  $y \neq 0$  is fixed, from a neighbourhood of  $x_0$  and  $x$  is approaching  $x_0$ . Since the limits of  $f$  and  $g$  at  $x_0$  are infinite, we can surely assume that the differences of the values of both functions at  $x$  and  $y$ , having fixed  $y$ , are non-zero.

Using the mean value theorem, replace the fraction in the middle with the quotient of the derivatives at an appropriate point  $c$  between  $x$  and  $y$ . The expression of the examined limit thus gets the form

$$\frac{f(x)}{g(x)} = \frac{1 - \frac{g(y)}{g(x)}}{1 - \frac{f(y)}{f(x)}} \cdot \frac{f'(c)}{g'(c)},$$

where  $c$  depends on both  $x$  and  $y$ . With  $y$  fixed and  $x$  approaching  $x_0$ , the former fraction converges to one. At the same time, if simultaneously  $y \rightarrow x_0$  and  $|y - y_0| \geq |x - x_0|$ , the latter fraction becomes arbitrarily close to the limit value of the quotient of the derivatives. Thus, we may choose a sequence  $y_n \rightarrow x_0$ , such that  $|\lim_{x \rightarrow x_0} \frac{f'(x)}{g'(x)} - \frac{f'(c)}{g'(c)}| < 1/n$  for all  $c$  with  $|c - x_0| < |y_n - x_0|$ . At the same time, we may restrict appropriately  $|x - x_0| \leq \delta_n$ , so that the former fraction with  $y = y_n$  will be closer to 1 than by  $1/n$  for all such  $x$ . Altogether, this implies the requested equality of the limits.  $\square$

By making suitable modifications of the examined expressions, one can also apply l'Hopital's rule on forms of the types  $\infty - \infty$ ,  $1^\infty$ ,  $0 \cdot \infty$ , and so on. Often one simply rearranges the expressions or uses some continuous function, for instance the exponential one.

**5.3.12. Example.** For an illustration of such a procedure, we show the connection between the arithmetic and geometric means of  $n$  non-negative values  $x_i$ . The *arithmetic mean*

$$M^1(x_1, \dots, x_n) = \frac{x_1 + \dots + x_n}{n}$$

is a special case of the *power mean with exponent  $r$* , also known as the generalized mean:

$$M^r(x_1, \dots, x_n) = \left( \frac{x_1^r + \dots + x_n^r}{n} \right)^{\frac{1}{r}}.$$

The special value  $M^{-1}$  is called the *harmonic mean*. Calculate the limit value of  $M^r$  for  $r$  approaching zero. For this purpose, determine the limit by l'Hopital's rule (we treat it as an expression of the form  $0/0$  and differentiate with respect to  $r$ , with  $x_i$  as constant parameters).

The following calculation uses the chain rule and knowledge of the derivative of the power function, must be read in reverse. The existence of the last limit implies the existence of the last-but-one, and so on.

In particular, when examining monotonicity and optimization problems (including local and absolute extrema), derivatives of the first and second orders are often sufficient to reveal the local behavior of a function defined on an interval of the real line.<sup>8</sup>

Notice in 5.3.2 we will revise the concepts of increasing and decreasing functions, thereby enriching our approach to studying the local behavior of functions. For further illustration, refer to the examples in 5.3.3. This latter aspect will be further elaborated upon in the initial section of Chapter 6. Therefore, the tasks presented below serve a more foundational purpose.

**5.C.15.** Discuss the monotonicity of the function  $f(x) = \frac{\ln(x)}{x}$  over its domain.

**Solution.** For any  $x$  in the domain  $A := (0, +\infty)$  of  $f$  we compute  $f'(x) = \frac{(\ln(x))'x - x'\ln(x)}{x^2} = \frac{1 - \ln(x)}{x^2}$ . Thus, the equation  $f'(x) = 0$  has a unique solution, namely  $x_0 = e$ . This is a “critical” or “stationary point” of  $f$ , see 5.3.2 for terminology. Since  $x^2$  is always positive, the sign of  $f'$  depends on the numerator  $1 - \ln(x)$ . Observe now that  $1 - \ln(x) > 0 \Leftrightarrow \ln(x) < 1 \Leftrightarrow \ln(x) < \ln(e) \Leftrightarrow x < e$ , and similarly we obtain  $1 - \ln(x) < 0 \Leftrightarrow x > e$ . Thus  $f'(x) > 0$  for all  $x \in (0, e)$  and  $f'(x) < 0$  for all  $x \in (e, +\infty)$ , which means that  $f$  is strictly increasing in the interval  $(0, e)$  and strictly decreasing in  $(e, +\infty)$ . In particular,  $f$  takes its maximum value at the point  $x_0$ , namely  $f(x_0) = f(e) = \frac{1}{e}$ , see also the figure below.

In section 6.1.2 we will learn about a test checking this final claim, which is based on the second derivative of  $f$ . The latter is simply defined by  $f'' = (f')'$ , hence in our case it has the form

$$f''(x) = (f'(x))' = \left(\frac{1 - \ln(x)}{x^2}\right)' = \frac{2 \ln(x) - 3}{x^3}.$$

<sup>8</sup>In this column we will mainly focus on real functions or on complex-valued functions of a real variable. Applications of complex-valued functions of a complex variable (complex analytic functions) will be analyzed later in Chapter 9.

$$\begin{aligned} \lim_{r \rightarrow 0} \ln(M^r(x_1, \dots, x_n)) &= \lim_{r \rightarrow 0} \frac{\ln\left(\frac{1}{n}(x_1^r + \dots + x_n^r)\right)}{r} \\ &= \lim_{r \rightarrow 0} \frac{x_1^r \ln x_1 + \dots + x_n^r \ln x_n}{\frac{x_1^r + \dots + x_n^r}{n}} \\ &= \frac{\ln x_1 + \dots + \ln x_n}{n} = \ln \sqrt[n]{x_1 \dots x_n}. \end{aligned}$$

Hence

$$\lim_{r \rightarrow 0} M^r(x_1, \dots, x_n) = \sqrt[n]{x_1 \dots x_n},$$

which is known as the *geometric mean*.

#### 4. Infinite sums and power series

The last part of this chapter is mainly devoted to infinite sums of numbers, aiming at infinite extension of polynomials – the so called power series.

We first complete the basic discussion of the exponential function, expressing it as a limit of polynomial approximations. This illustrates the more general need to develop effective tools to deal with sequences of numbers or functions. If the reader finds the next paragraphs too demanding, we suggest jumping to 5.4.3 starting the general discussion on infinite sums of numbers and maybe return later.

**5.4.1. The calculation of  $e^x$ .** For numerical computations, manipulation with limits of sequences is needed as well as addition and multiplication of scalars. Thus it might be a good idea to approximate non-polynomial functions by sequences of numbers that can be calculated easily, keeping control of the approximation errors.

We approach the function  $e^x$  this way. In view of the expected property  $(e^x)' = e^x$  (cf. 5.3.7), we look for a function whose rate of increase equals the function’s value at every point. This can be imagined as a splendid interest rate equal to the current value of your money.

If we apply the interest rate per year once a month, once a day, once an hour, and so on, we obtain the following values for the yield  $x$  of the deposit after one year:

$$\left(1 + \frac{x}{12}\right)^{12}, \quad \left(1 + \frac{x}{365}\right)^{365}, \quad \left(1 + \frac{x}{8760}\right)^{8760}, \dots$$

Therefore, we could guess that

$$e^x = \lim_{n \rightarrow \infty} \left(1 + \frac{x}{n}\right)^n.$$

At the same time, we can imagine that the finer we apply the interest, the higher the yield will be. So the sequence on the right-hand side should be an increasing sequence.

In detail, we examine the sequence of numbers

$$a_n = \left(1 + \frac{1}{n}\right)^n.$$

*Bernoulli’s inequality* will come in handy:

According to this criterium, whenever we have  $f''(x_0) < 0$  near a critical point  $x_0$  of  $f$ , then  $f$  must attain a (local) maximum at  $x_0$ . For our case we indeed compute  $f''(e) = -\frac{1}{e^3} < 0$ .

Notice finally in Sage one could compute the first and second derivative of  $f$  by the cell

```
f(x)=ln(x)/x; d1(x)=diff(f, x).factor()
show(d1(x))
D(x)=diff(d1, x).factor(); show(D(x))
```

Here we have programmed Sage to compute  $f''(x)$  “manually” (we denote this by  $D(x)$ ). An alternative approach for the second derivative relies on an application of the command `diff(f, x, 2).factor()`. This directly prints out the factorization of the expression given for the second derivative of  $f$ , without being necessary to compute the first derivative. We will meet more such applications in Chapter 6.  $\square$

**5.C.16.** Prove by two different ways that the tangent function  $f(x) = \tan(x)$  is strictly increasing for all  $x \in (-\pi/2, \pi/2)$ .  $\circ$

**5.C.17.** Consider the parabola  $y = x^2$ . Determine the  $x$ -coordinate of the parabola’s point which is nearest to the point  $A$  with coordinates  $x_0 = 1$  and  $y_0 = 2$ .

**Solution.** Recall the formula for the Euclidean distance between two points  $[x_1, y_1], [x_2, y_2]$  in the plane:

$$d = \sqrt{(x_2 - x_1)^2 + (y_2 - y_1)^2}.$$

An arbitrary point in the parabola has coordinates  $[x, y] = [x, x^2]$  (and in this way we eliminate  $y$  from the problem). Since the task requires the minimization of the distance between the points  $A = [1, 2]$  and  $[x, x^2]$ , it is sufficient to find the minimum of the function  $d(x) = \sqrt{(x-1)^2 + (x^2-2)^2}$  with  $x \in \mathbb{R}$ , see also the figure for an illustration of the idea.

The function  $d(x)$  is non-zero for any  $x \in \mathbb{R}$ , in particular the equation  $g(x) := (x-1)^2 + (x^2-2)^2 = 0$  has only complex solutions. We have

$$d'(x) = \frac{g'(x)}{2\sqrt{g(x)}} = \frac{g'(x)}{2d(x)}, \quad x \in \mathbb{R}.$$

**Lemma.** For every real number  $b \geq -1$ ,  $b \neq 0$ , and a natural number  $n \geq 2$ ,  $(1+b)^n > 1+nb$ .

**PROOF.** For  $n = 2$ ,

$$(1+b)^2 = 1 + 2b + b^2 > 1 + 2b.$$

Proceed by induction on  $n$ , supposing  $b > -1$ . Assume that the proposition holds for some  $k \geq 2$  and calculate:

$$\begin{aligned} (1+b)^{k+1} &= (1+b)^k(1+b) > (1+kb)(1+b) \\ &= 1 + (k+1)b + kb^2 > 1 + (k+1)b \end{aligned}$$

The statement is, of course, true for  $b = -1$  as well.  $\square$

Now

$$\begin{aligned} \frac{a_n}{a_{n-1}} &= \frac{(1 + \frac{1}{n})^n}{(1 + \frac{1}{n-1})^{n-1}} = \frac{(n^2 - 1)^n n}{n^{2n}(n-1)} \\ &= \left(1 - \frac{1}{n^2}\right)^n \frac{n}{n-1} > \left(1 - \frac{1}{n}\right) \frac{n}{n-1} = 1. \end{aligned}$$

by using Bernoulli’s inequality with  $b = -\frac{1}{n^2}$ . So  $a_n > a_{n-1}$  for all natural numbers, and it follows that the sequence  $a_n$  is indeed increasing.

The following similar calculation (also using Bernoulli’s inequality) verifies that the sequence of numbers

$$b_n = \left(1 + \frac{1}{n}\right)^{n+1} = \left(1 + \frac{1}{n}\right) \left(1 + \frac{1}{n}\right)^n$$

is decreasing. Notice that  $b_n > a_n$ . Also,

$$\begin{aligned} \frac{b_n}{b_{n+1}} &= \frac{n}{n+1} \left(\frac{\frac{n+1}{n}}{\frac{n+2}{n+1}}\right)^{n+2} = \frac{n}{n+1} \left(\frac{n^2 + 2n + 1}{n^2 + 2n}\right)^{n+2} \\ &= \frac{n}{n+1} \left(1 + \frac{1}{n(n+2)}\right)^{n+2} \\ &\geq \frac{n}{n+1} \left(1 + \frac{n+2}{n(n+2)}\right) = 1. \end{aligned}$$

Thus the sequence  $a_n$  is increasing and bounded from above, so the set of its terms has a supremum which equals the limit of the sequence. At the same time, this value is also the limit of the decreasing sequence  $b_n$  because

$$\lim_{n \rightarrow \infty} b_n = \lim_{n \rightarrow \infty} \left(1 + \frac{1}{n}\right) a_n = \lim_{n \rightarrow \infty} a_n.$$

This limit determines one of the most important numbers in mathematics (besides the numbers 0, 1, and  $\pi$ ), namely Euler’s number<sup>14</sup>  $e$ . Thus

$$e = \lim_{n \rightarrow \infty} \left(1 + \frac{1}{n}\right)^n.$$

<sup>14</sup>The ingenious Swiss mathematician, physicist, astronomer, logician and engineer Leonhard Euler (1707-1783) was behind extremely many inventions, including original mathematical techniques and tools.

Because the square root is an increasing function, the function  $d$  takes its least value at the same point where the function  $g$  does. The derivative of  $g$  has the form  $g'(x) = 4x^3 - 6x - 2$ , for all  $x \in \mathbb{R}$ . Moreover, the equation  $g'(x) = 0$  or equivalently  $0 = 2x^3 - 3x - 1$  has three solutions:

$$x_0 = 1, \quad x_1 = \frac{1 - \sqrt{3}}{2}, \quad x_2 = \frac{1 + \sqrt{3}}{2}.$$

We deduce that the  $x$ -coordinate in question equals to  $x_2 = \frac{1 + \sqrt{3}}{2}$ . Can you explain how we decline  $x_0$  and  $x_1$ ?  $\square$

*First order derivatives and in particular tangent lines give us the ability to approximate functions locally by linear functions (recall that linear functions are the easiest functions to work with). In particular, when  $f$  is a differentiable function at a point  $x_0$  of its domain, we can approximate the values of  $f$  near  $x_0$  via the formula  $f(x) \approx f(x_0) + f'(x_0)(x - x_0)$ . Here, the r.h.s is a first-degree polynomial with respect to  $x$  and we suppose that the difference  $x - x_0$  is "small enough". Hence using first-order derivatives we can obtain a tangent line approximation of the value  $f(x)$  in a small neighbourhood of  $x_0$ .*

*In Section A of Chapter 6 these ideas will be generalized. There we will explain how to approximate functions based on higher-degree polynomials (Taylor polynomials). Next we pose applications related to linear approximations, see also 6.A.37 and 6.A.38 for an alternative interpretation in terms of the so-called "differentials". More exercises on tangential approximations are presented in Section D.*

**5.C.18. Linear approximations.** Approximate linearly the function  $f(x) = 1/x$  near  $x_0 = 1$ , and present the graph of  $f$  and that of its tangent line at  $x_0$ . Then compute the approximations at  $x = 0.9$  and  $x = 1.1$  and compare their difference with the real values of  $f$  at these points.

**Solution.** The first derivative of  $f$  is given by  $f'(x) = -1/x^2$  and at  $x_0 = 1$  we get  $f'(x_0) = -1$ . Thus the tangent line of  $f$  passing from  $x_0$  has the form  $f(1) + (x - 1)f'(1) = 2 - x$ , that is, the linear approximation of  $f$  near  $x_0$  is given by the line  $L(x) = 2 - x$ . The figure below illustrate the situation:

**5.4.2. Power series for  $e^x$ .** The exponential function has been defined as the only continuous function satisfying  $f(1) = e$  and  $f(x + y) = f(x) \cdot f(y)$ . The base  $e$  is now expressed as the limit of the sequence  $a_n$ , thus necessarily

$$e^x = \lim_{n \rightarrow \infty} (a_n)^x.$$

Fix a real number  $x \neq 0$ . If we replace  $n$  with  $n/x$  in the numbers  $a_n$  from the previous paragraph, we arrive again at the same limit. (Think this out in detail!) Hence

$$e = \lim_{n \rightarrow \infty} \left(1 + \frac{x}{n}\right)^{\frac{n}{x}}, \quad e^x = \lim_{n \rightarrow \infty} \left(1 + \frac{x}{n}\right)^n.$$

Denote the  $n$ -th term of this sequence by  $u_n(x) = \left(1 + \frac{x}{n}\right)^n$  and express it by the binomial theorem:

$$\begin{aligned} u_n(x) &= 1 + n \frac{x}{n} + \frac{n(n-1)x^2}{2!n^2} + \dots + \frac{n!x^n}{n!n^n} \\ &= 1 + x + \frac{x^2}{2!} \left(1 - \frac{1}{n}\right) \\ &+ \frac{x^3}{3!} \left(1 - \frac{1}{n}\right) \left(1 - \frac{2}{n}\right) + \dots \\ &+ \frac{x^n}{n!} \left(1 - \frac{1}{n}\right) \left(1 - \frac{2}{n}\right) \dots \left(1 - \frac{n-1}{n}\right). \end{aligned} \tag{1}$$

Look at  $u_n(x)$  for very large  $n$ . It seems that many of the first summands of  $u_n(x)$  will be fairly close to the values  $\frac{1}{k!}x^k$ ,  $k = 0, 1, \dots$ . Thus it is plausible that the numbers  $u_n(x)$  should be very close to  $v_n(x) = \sum_{j=0}^n \frac{1}{j!}x^j$  and thus both these sequences should have the same limit.

The following theorem is perhaps one of the most important results of Mathematics:

THE POWER SERIES FOR  $e^x$

**Theorem.** The exponential function  $e^x$  equals, for each  $x \in \mathbb{R}$ , the limit  $\lim_{k \rightarrow \infty} v_k(x)$  of the partial sums in the expression

$$e^x = 1 + x + \frac{1}{2}x^2 + \dots + \frac{1}{n!}x^n + \dots = \sum_{n=0}^{\infty} \frac{1}{n!}x^n.$$

The function  $e^x$  is differentiable at each point  $x$  and its derivative is  $(e^x)' = e^x$ .

**PROOF.** The technical proof makes the above idea precise. Although the complete argumentation might look complicated, the strategy is straightforward. We shall go through three steps.

- 1) Prove that the partial sums  $v_n$  converge.
- 2) Write  $u_{n,k}$  for the first  $k < n$  summands in  $u_n$  and conclude that for given  $k$ , the difference between  $v_k$  and  $u_{n,k}$  gets arbitrarily small for large  $n > k$ .
- 3) Show that there are subsequences  $v_{k_i}$  and  $u_{n_i}$  converging to the same limit. This will conclude the proof of the first claim of the theorem.

Now, we compute  $f(0, 9) \approx 1.1111$  and  $L(0, 9) = 1.1$ , thus  $|L(0.9) - f(0.9)| \approx 0.0111$ . Similarly, we have  $f(1.1) \approx 0.90909$ ,  $L(1.1) = 0.9$  and  $|L(1.1) - f(1.1)| \approx 0.009$ .  $\square$

**5.C.19.** Given that  $(\arcsin(x))' = \frac{1}{\sqrt{1-x^2}}$  for  $x \in (-1, 1)$ , approximate linearly the value  $\arcsin(0.497)$ .  $\circ$

**5.C.20.** Approximate linearly the values  $\sin\left(\frac{29\pi}{180}\right)$  and  $\sin\left(\frac{46\pi}{180}\right)$ .  $\circ$

*Rolle's theorem, mean value theorem and its generalizations (Cauchy's mean value theorem), are important theorems that highlight the significance of derivatives, see 5.3.8 and 5.3.9. Below we illustrate them quickly via examples, and further linked applications are presented in the final section of this chapter.*

**5.C.21.** Prove that the equation  $x^{2027} + 7x^3 - 5 = 0$  has a unique solution,

**Solution.** Consider the function  $f(x) = x^{2027} + 7x^3 - 5$ . Since  $f(0) = -5 < 0$  and  $f(1) = 3 > 0$  by the intermediate value theorem there exists some  $x_0 \in (0, 1)$  such that  $f(x_0) = 0$ . Suppose that  $x_1 \neq x_0$  is another (positive) root of  $f$ . Without loss of generality we may assume that  $x_0 < x_1$ . We have that  $f(x_0) = f(x_1)$ , and  $f$  is continuous on  $[x_0, x_1]$  and differentiable on  $(x_0, x_1)$ . Thus by Rolle's theorem the first derivative  $f'$  of  $f$  must have a root in  $(x_0, x_1)$ . However,  $f'(x) = 2027x^{2026} + 21x^2$  and thus we have  $f'(x) > 0$  for all  $x > 0$ , a contradiction. Thus  $f$  has only one zero in  $(0, +\infty)$ . On the other hand we see that  $f(x) < 0$  for all  $x \in (-\infty, 0]$ . You may verify this final claim in Sage, just by the cell

```
f(x)=x^(2027)+7*x^3-5
assume(x<0); bool(f(x)<0)
```

Thus  $f$  has a unique solution for all  $x \in \mathbb{R}$ .  $\square$

**5.C.22.** Using Rolle's theorem prove that the equation  $x^3 + px + q = 0$  with  $p, q \in \mathbb{R}$ ,  $p > 0$ , admits a unique real solution.

**Solution.** Consider the function  $f(x) = x^3 + px + q$  with  $x \in \mathbb{R}$ , where  $p, q \in \mathbb{R}$  and  $p > 0$ . It is easy to prove that  $\lim_{x \rightarrow -\infty} f(x) = -\infty$  and  $\lim_{x \rightarrow +\infty} f(x) = +\infty$ . Moreover,  $f$  takes both negative and positive values, thus there exists some  $\xi \in \mathbb{R}$  with  $f(\xi) = 0$ . We will show that  $\xi$  is unique. Indeed, suppose that  $\zeta \in \mathbb{R}$  is another real number satisfying  $f(\zeta) = 0$ . We may assume that  $\zeta < \xi$ , and similarly is treated the case with  $\xi < \zeta$ . Based on the Rolle's theorem we can then find some  $a \in (\zeta, \xi)$  with  $f'(a) = 0$ . However,  $f'(x) = 3x^2 + p$  for all  $x$ , and so this gives a contradiction (since  $p > 0$ , the equation  $f'(x) = 0$  does not admit a real solution).  $\square$

**5.C.23.** Decide if the function  $f(x) = x^3 + b$ , where  $b$  is some constant, satisfies the mean value theorem on the interval  $[1, 2]$ . In the positive case determine  $c$ , where  $c$  is as in the Theorem 5.3.9.

1) Fix  $x$  and recall that  $v_n(x)$  is the sequence defined as the sums of the first  $n$  terms of the formal infinite expression

$$\sum_{j=0}^{\infty} c_j = \sum_{j=0}^{\infty} \frac{1}{j!} x^j.$$

For all  $m > n$ ,

$$|v_m(x) - v_n(x)| \leq \sum_{k=n+1}^m \frac{1}{k!} |x|^k = v_m(|x|) - v_n(|x|).$$

Consequently, in order to prove that  $v_n(x)$  is a Cauchy sequence, and thus convergent, it is enough to restrict ourselves to  $x > 0$  and to prove that  $v_n(x)$  is always bounded and thus convergent (as a nondecreasing sequence) in this case.

The quotient of adjacent terms in the series is  $\frac{c_{j+1}}{c_j} = \frac{x}{n+1}$ . Thus for every fixed  $x > 0$ , there is a number  $N \in \mathbb{N}$  such that  $\left| \frac{c_{j+1}}{c_j} \right| < \frac{1}{2}$  for all  $j \geq N$ . However, such large indices  $j$  satisfy  $|c_{j+1}| < \frac{1}{2}|c_j| < 2^{-(j-N+1)}|c_N|$ .

Recall that sums of a geometric series is computed from the equality  $(1 - q)(1 + q + \dots + q^k) = 1 - q^{k+1}$ . This means that the partial sums of the first  $n > N$  terms of our formal sum with  $x > 0$  can be estimated as follows

$$|v_n(x) - \sum_{j=0}^{N-1} \frac{1}{j!} x^j| < \frac{1}{N!} x^N \sum_{j=0}^{n-N} \frac{1}{2^j}.$$

In particular, the limit of the expressions on the right-hand side for  $n$  approaching infinity surely exists, and so the limit of the increasing sequence  $v_n$  also exists.

2) Consider some fixed  $k$  and  $\varepsilon > 0$ . If  $N$  is large enough, then clearly for all  $n > N$ ,  $|u_{n,k} - v_k| < \varepsilon$ . Indeed, there is only a fixed number of the brackets in the  $k$  summands of  $u_{n,k}$ , see (1), and they will all be arbitrarily close to 1, if  $n$  is large enough.

3) Next, consider  $x > 0$  and notice

$$|u_n - u_{n,k}| < |v_n - v_k|.$$

Thus, if we fix some  $\varepsilon > 0$ , then there is some  $M$ , such that for  $k > M$  we ensure  $|u_n - u_{n,k}| < \varepsilon$ , for all  $n > k$ . If  $x < 0$ , we may first bound the left hand side by sum of absolute values of the individual terms, which is still less than  $|v_n - v_k|$  evaluated for  $|x|$ .

Now, take such a  $k > M$  and consider  $N$  from the previous step (of course dependent on  $k$ ). Then for  $n > N$  we arrive at

$$|v_k - u_n| \leq |v_k - u_{n,k}| + |u_{n,k} - u_n| < 2\varepsilon.$$

Finally, choosing  $\varepsilon_\ell = \frac{1}{2\ell}$ , the previous estimate allows to find subsequences  $v_{k_\ell}, u_{n_\ell}$  satisfying

$$|v_{k_\ell} - u_{n_\ell}| < \frac{1}{\ell}.$$

Thus, the convergent sequences  $u_n$  and  $v_n$  must converge to the same limit value. This is the first claim we had to prove.

Remind we already know that  $(e^x)' = e^x$  if and only if the derivative equals 1 at the origin, see 5.3.7. Thus, it

**Solution.** The given function is a polynomial, and hence continuous on its domain  $[1, 2]$ . It is also differentiable on the open interval  $(1, 2)$ , with  $f'(x) = 3x^2$ . Therefore, it satisfies the mean value theorem. In particular, by Theorem 5.3.9 there exists  $c \in (1, 2)$  such that  $f'(c) = 3c^2 = \frac{f(2)-f(1)}{2-1} = 8+b-1-b = 7$ . Thus  $c^2 = 7/3$ , that is,  $c = \pm\sqrt{7/3}$ . Since  $-\sqrt{7/3}$  does not belong on the interval  $[1, 2]$ , we deduce that  $c = \sqrt{7/3}$  is the only possible value.  $\square$

**5.C.24.** Check which of the following functions satisfy the mean value theorem. In the positive case, find the possible values of  $c$ , where  $c$  is as in the Theorem 5.3.9:

$$f(x) = x^{\frac{2}{3}}, \quad g(x) = \frac{x}{x+1}, \quad h(x) = \sqrt[3]{8-x}$$

for  $x \in [-2, 2]$ ,  $x \in [1, 4]$  and  $x \in [0, 8]$ , respectively.  $\circ$

**5.C.25.** Using the mean value theorem prove that

$$-1 \leq \cos(2x) < \frac{\sin(2x)}{2x} \leq 1, \quad \text{for all } x \in \left(0, \frac{\pi}{2}\right).$$

**Solution.** For  $x = \frac{\pi}{2}$  the given inequality becomes  $-1 \leq -1 < 0 \leq 1$ , which is true. Hence we may focus on  $x \in (0, \frac{\pi}{2})$ . For any  $x \in (0, \frac{\pi}{2})$  consider the function

$$f(a) = \sin(2a), \quad \text{with } a \in [0, x].$$

Observe that  $f$  is continuous on  $[0, x]$  as a composition of continuous functions. It is also differentiable on the open interval  $(0, x)$  with  $f'(a) = 2\cos(2a)$ . Thus, by the mean value theorem there exists  $c \in (0, x)$  with  $f'(c) = \frac{f(x)-f(0)}{x-0}$ , or equivalently

$$2\cos(2c) = \frac{\sin(2x)}{x} \Leftrightarrow \cos(2c) = \frac{\sin(2x)}{2x}. \quad (*)$$

Next we may assume that  $0 < c < x < \frac{\pi}{2}$ , that is,  $0 < 2c < 2x < \pi$ . Also, for the function  $g(x) = \cos(x)$  we have  $g'(x) = -\sin(x) < 0$  for all  $x \in (0, \pi)$ . This means that the function  $\cos$  is strictly decreasing on  $(0, \pi)$  (having a local maximum at  $x = 0$  and a local minimum at  $x = \pi$ ). Thus, the previous inequality implies that

$$1 = \cos(0) \geq \cos(2c) > \cos(2x) \geq \cos(\pi) = -1.$$

Combining this inequality with  $(*)$ , the claim follows.  $\square$

**5.C.26.** Based on Cauchy's mean value theorem, show that

$$a < \frac{n}{n+1} \left( \frac{b^{n+1} - a^{n+1}}{b^n - a^n} \right) < b$$

for all  $n \in \mathbb{N}^*$ , where  $a, b \in \mathbb{R}$  are such that  $0 < a < b$   $\circ$

*The theory of derivatives is useful in a plethora of practical tasks, but also for crucial problems appearing in many other sciences and technology, e.g., in physics, chemistry, statistics, economics, biology, engineering, environmental science, informatics and computer science, architecture, science of graphics, and space science, to mention a few of them.*

*But why derivatives can be so useful? Partially this is because the derivative  $\frac{dy}{dx}$  represents the rate of change of  $y$*

remains to compute

$$\lim_{x \rightarrow 0} \frac{(1 + x + \frac{1}{2}x^2 + \dots) - 1}{x} = \lim_{x \rightarrow 0} \frac{x + \frac{1}{2}x^2 + \dots}{x}.$$

This seems to be tricky, since there are two limit expressions there (notice that an  $x$  may be cancelled since this is a constant in the inner limit):

$$\lim_{x \rightarrow 0} \left( \lim_{n \rightarrow \infty} \sum_{k=1}^n \frac{1}{k!} x^{k-1} \right) = 1 + \lim_{x \rightarrow 0} \left( \lim_{n \rightarrow \infty} \sum_{k=2}^n \frac{1}{k!} x^{k-1} \right).$$

But now, for each positive  $\varepsilon > 0$  we can find  $N \in \mathbb{N}$  such that

$$\lim_{n \rightarrow \infty} \left| \sum_{k=N}^n \frac{1}{(k+1)!} x^k \right| < \lim_{n \rightarrow \infty} \sum_{k=N}^n \frac{1}{(k+1)!} < \varepsilon$$

for all  $x \in [-1, 1]$ . Finally, we can restrict the interval for  $x$  enough to ensure that the remaining first terms are bounded by  $\varepsilon$ , too:

$$\sum_{k=2}^{N-1} \frac{1}{(k+1)!} x^k < \varepsilon.$$

This shows that the limit expression on the right-hand side must be zero. Thus the derivative exists and equals to one, as expected.  $\square$

Readers who skipped the preceding paragraphs (it doesn't matter whether on purpose or in need) can stay calm – we deduce all the results on the exponential function later again, using more general tools. In particular, we will see that all power series are always differentiable and can be differentiated term by term. We see later that the conditions  $f'(x) = f(x)$  and  $f(0) = 1$  determine a function uniquely.

**5.4.3. Number series.** When deriving the previous theorems about the function  $e^x$ , we have automatically used several extraordinarily useful concepts and tools. Now, we come back to them in detail:

#### INFINITE NUMBER SERIES

**Definition.** An *infinite series of numbers* is an expression

$$\sum_{n=0}^{\infty} a_n = a_0 + a_1 + a_2 + \dots + a_k + \dots,$$

where the  $a_n$ 's are real or complex numbers. The sequence of *partial sums* is given by the terms  $s_k = \sum_{n=0}^k a_n$ . The series converges and equals  $s$  if the limit

$$s = \lim_{k \rightarrow \infty} s_k$$

of the partial sums exists and is finite.

If the sequence of partial sums has an improper limit, the series *diverges* to  $\infty$  or  $-\infty$ . If the limit of the partial sums does not exist, the series *oscillates*.

An immediate consequence of the properties of limits is the following claim:

with respect to  $x$ . Thus, the rate of change of any physical quantity at any time is obtained by differentiating the physical quantity with respect to time. Another reason is the related theory of minimal/maximals (optimization problems) and we will meet many such tasks in Chapter 6. The next few examples aim to present how derivatives may involve in problems of every-day life and other nice applications. An enrichment of this list, which roughly speaking can be long enough, is postponed to the final section E of this chapter.

**5.C.27.** For a company renting city taxis, any driver costs €6 per working hour (h), while the gas costs €1.40 per litter (ℓ). Suppose that inside the city these taxis can succeed  $(180 - 2u)/6$  kilometres (km) per litter of gas, where  $u$  denotes the driving velocity, enumerated in km/h. Find the cheapest driving speed so that the company can minimize its costs per kilometre (corresponding only to a taxi of its property), and present the corresponding minimal cost value in €/km per taxi.

**Solution.** We can focus on the cost corresponding to the use of a single taxi (in € per km), which should minimize. This cost is given by the sum of the costs of the used driver (per km) and of the used gas (per km). According to the statement we have:

- The driver costs  $\frac{6 \text{ €/h}}{u \text{ km/h}} = \frac{6}{u} \text{ €/km}$ ;
- The gas costs  $\frac{1.40 \text{ €/ℓ}}{\frac{(180-2u)}{6} \text{ km/ℓ}} = \frac{8.4}{180-2u} \text{ €/km}$ .

Thus, the total cost in € per km is a function with respect to  $u$ , given by

$$c(u) := \frac{6}{u} + \frac{8.4}{180-2u} = \frac{6}{u} - \frac{4.2}{u-90}.$$

First we see that the driving velocity  $u$ , should satisfy  $0 < u < 90$  (e.g., the cost blows up for  $u = 90$ ), and for such  $u$  the extreme points of  $c(u)$  correspond to the solutions of the equation  $c'(u) = 0$  (we recommend to sketch the graph of the cost function  $c$  via Sage). The derivative of  $c$  is given by

$$c'(u) = -\frac{6}{u^2} + \frac{4.2}{(u-90)^2}$$

and it follows that the equation  $c'(u) = 0$  has two solutions, namely  $u_{1,2} = \pm 30\sqrt{70} + 300$  km/h. These computations can be quickly verified in Sage:

```
u=var("u"); c(u)=(6/u)+8.4/(180-2*u)
dc(u)=diff(c(u), u); show(solve(dc==0, u))
```

Acceptable is only the value  $u_1 = -30\sqrt{70} + 300 \approx 49$  km/h, and this is the speed with the lowest costs. In particular, with this velocity the cost value  $c(u_1)$  of a single taxi is approximately 0.225 €/km. □

**5.C.28.** Suppose that from a given piece of industrial paper having area  $\alpha^2$  we want to construct an open box, by cutting

**Corollary.** Consider two convergent series  $S = \sum_{n=0}^{\infty} a_n$  and  $T = \sum_{n=0}^{\infty} b_n$ . Then their sum and constant multiple by real or complex number  $c$  are convergent too, and

$$S + T = \sum_{n=0}^{\infty} (a_n + b_n), \quad cS = \sum_{n=0}^{\infty} ca_n.$$

In particular, any linear combination of series with constant coefficients is convergent and equals to the same linear combination of the sums. Check the details yourself!

**5.4.4. Properties of series.** For the sequence of partial sums  $s_n$  to converge, it is necessary and sufficient that it is a Cauchy sequence; that is

$$|s_m - s_n| = |a_{n+1} + \dots + a_m|$$

must be arbitrarily small for sufficiently large  $m > n$ . Since

$$|a_{n+1}| + \dots + |a_m| \geq |a_{n+1} + \dots + a_m|,$$

the convergence of the series  $\sum_{k=0}^{\infty} |a_k|$  implies the convergence of the series  $\sum_{k=0}^{\infty} a_k$ .

#### ABSOLUTELY CONVERGENT SERIES

A series  $\sum_{k=0}^{\infty} a_k$  is *absolutely convergent* if the series  $\sum_{k=0}^{\infty} |a_k|$  converges.

Absolute convergence is introduced because it is often much easier verified. The following theorem shows that all simple algebraic operations behave “very well” for series that converge absolutely.

#### PROPERTIES OF SERIES

**Theorem.** Let  $S = \sum_{n=0}^{\infty} a_n$  and  $T = \sum_{n=0}^{\infty} b_n$  be two absolutely convergent series. Then

(1) their sum converges absolutely to the sum

$$S + T = \sum_{n=0}^{\infty} a_n + \sum_{n=0}^{\infty} b_n = \sum_{n=0}^{\infty} (a_n + b_n),$$

(2) their difference converges absolutely to the difference

$$S - T = \sum_{n=0}^{\infty} a_n - \sum_{n=0}^{\infty} b_n = \sum_{n=0}^{\infty} (a_n - b_n),$$

(3) their product converges absolutely to the product

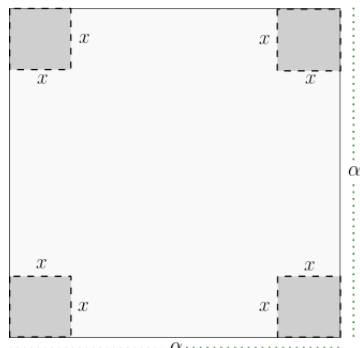

$$S \cdot T = \left( \sum_{n=0}^{\infty} a_n \right) \cdot \left( \sum_{n=0}^{\infty} b_n \right) = \sum_{n=0}^{\infty} \left( \sum_{k=0}^n a_{n-k} b_k \right),$$

(4) the value  $S$  of the sum does not depend on any rearrangement of the series, i.e.,  $\sum_{n=0}^{\infty} a_{\sigma(n)} = S$  for any permutation  $\sigma : \mathbb{N} \rightarrow \mathbb{N}$  of integers.

**PROOF.** The convergence in the first and the second statements were discussed already. Further, the linear combinations satisfy  $|\alpha a_n + \beta b_n| \leq |\alpha| |a_n| + |\beta| |b_n|$  and thus the absolute convergence is obvious, too.

four small squares of equal size of its corners and then bending the resulting sides. Determine the total area of paper that we should cut, so that the box has maximum volume.

**Solution.** Let  $x$  be the length of the side of any of the squares that we should cut, as it is illustrated in the figure:

The volume of the box under construction is given by  $V(x) = x(\alpha - 2x)^2$  with  $0 < x < \frac{\alpha}{2}$ . We want to locate those  $x$  for which the function  $V$  attains its maximum value  $V(x)$ . Since  $\alpha > 0$  is a constant, an application of the product rule gives

$$\begin{aligned} V'(x) &= \frac{dV}{dx} = (\alpha - 2x)^2 + 2 \cdot x \cdot (\alpha - 2x) \cdot (-2) \\ &= (\alpha - 2x)(\alpha - 6x). \end{aligned}$$

Thus  $V'(x) = 0$  if and only if  $x = \frac{\alpha}{2}$  or  $x = \frac{\alpha}{6}$ . Now we will use the theory of second derivatives, which are analyzed in Section 6.1.5. As we said above, the second derivative of a differentiable function  $f$  is the derivative of its first derivative. So

$$\begin{aligned} V''(x) &= (V'(x))' = -2 \cdot (\alpha - 6x) - 6(\alpha - 2x) \\ &= 24x - 8\alpha = 24 \left( x - \frac{\alpha}{3} \right). \end{aligned}$$

According to 6.1.5, if  $x_0$  satisfies  $f'(x_0) = 0$  and  $f''(x_0) < 0$ , then  $x_0$  is a local maximum of  $f$ , while when  $x_0$  is such that  $f'(x_0) = 0$  but  $f''(x_0) > 0$ , then  $x_0$  is a local minimum of  $f$ . In our case we see that

$$V''\left(\frac{\alpha}{2}\right) = 4\alpha > 0, \quad V''\left(\frac{\alpha}{6}\right) = -4\alpha < 0.$$

Thus, the volume of the box under construction will be maximal if and only if  $x = \frac{\alpha}{6}$ , so the area that we should cut is  $4 \cdot \frac{\alpha^2}{36} = \frac{\alpha^2}{9} = \left(\frac{\alpha}{3}\right)^2$ . Moreover, the maximal volume is given by  $V\left(\frac{\alpha}{6}\right) = \frac{2\alpha^3}{27} = 2\left(\frac{\alpha}{3}\right)^3$ .

An implementation of the whole problem via Sage is easy, and can be done in many ways. For instance, type the cell

```
var("a") #introduce a symbolic variable
V(x)=x*(a-2*x)^2 #declare the volume
DV(x)=diff(V, x).factor() #declare the 1st
#derivative of the volume
show(solve(DV(x)==0, x)) #critical point eq.
show(diff(V, x, 2)(x=a/6).factor())
show(V(a/6).factor()) #the maximal volume
```

The third statement is not so simple. Write

$$c_n = \sum_{k=0}^n a_{n-k} b_k.$$

From the assumptions and from the rule for the limit of a product,

$$\left( \sum_{n=0}^k a_n \right) \cdot \left( \sum_{n=0}^k b_n \right) \rightarrow \left( \sum_{n=0}^{\infty} a_n \right) \cdot \left( \sum_{n=0}^{\infty} b_n \right).$$

Thus it suffices to prove that

$$0 = \lim_{k \rightarrow \infty} \left( \left( \sum_{n=0}^k a_n \right) \cdot \left( \sum_{n=0}^k b_n \right) - \sum_{n=0}^k c_n \right).$$

Consider the expressions

$$\begin{aligned} \left( \sum_{n=0}^k a_n \right) \cdot \left( \sum_{n=0}^k b_n \right) &= \sum_{0 \leq i, j \leq k} a_i b_j, \\ c_n &= \sum_{\substack{i+j=n \\ 0 \leq i, j \leq k}} a_i b_j, \quad \sum_{n=0}^k c_n = \sum_{\substack{i+j \leq k \\ 0 \leq i, j \leq k}} a_i b_j. \end{aligned}$$

along with the bound

$$\begin{aligned} \left| \left( \sum_{n=0}^k a_n \right) \cdot \left( \sum_{n=0}^k b_n \right) - \sum_{n=0}^k c_n \right| &= \left| \sum_{\substack{i+j > k \\ 0 \leq i, j \leq k}} a_i b_j \right| \\ &\leq \sum_{\substack{i+j > k \\ 0 \leq i, j \leq k}} |a_i b_j|. \end{aligned}$$

If the sum of the indices is to be larger than  $k$ , then at least one of them must be larger than  $k/2$ . The expression does not decrease if more terms are added into it. Take all as in the product and remove only those whose indices are both at most  $k/2$ .

$$\sum_{\substack{i+j > k \\ 0 \leq i, j \leq k}} |a_i b_j| \leq \sum_{0 \leq i, j \leq k} |a_i b_j| - \sum_{0 \leq i, j \leq k/2} |a_i b_j|.$$

However, both the expressions of the difference are the partial sums for the product  $S \cdot T$ . Therefore, they share the same limit and their difference goes to zero.

The last claim seems to be a little tricky. Notice, for each small  $\varepsilon > 0$  we can find a common bound  $\alpha$  such that for all  $N > \alpha$  both estimates are true:

$$\sum_{n=N}^{\infty} |a_n| < \varepsilon, \quad \left| \sum_{n=0}^N a_n - S \right| < \varepsilon.$$

Now, consider any permutation  $\sigma$  of the indices and write  $\square I_\sigma = \{\sigma^{-1}(0), \dots, \sigma^{-1}(\alpha)\}$ . Then, for each  $N > \max I_\sigma$

**5.C.29.** On a spherical balloon we inflate air so that its volume increase with a rate of  $16 \text{ cm}^3/\text{min}$ . Find the rate of change of the radius of the balloon when its volume is  $36 \text{ cm}^3$ . Hint: The volume of a sphere of radius  $r$  is given by  $\frac{4\pi r^3}{3}$ .

**Solution.** The radius of the balloon can be viewed as a function with respect to the time  $t$ . Hence also the volume of the balloon is a function of  $t$  (since it depends on the radius), i.e.,  $V(t) = \frac{4\pi}{3}r^3(t)$  for all  $t$ .

Now, by assumption at certain time  $t = t_0$  the volume is  $36 \text{ cm}^3$ . Hence we have  $36 = \frac{4\pi r^3(t_0)}{3}$ , and thus  $r^3(t_0) = \frac{3^3}{\pi}$ , that is,  $r(t_0) = \frac{3}{\sqrt[3]{\pi}}$ . We also compute

$$V'(t) = \frac{dV}{dt} = 4\pi r^2(t)r'(t).$$

By assumption  $\frac{dV}{dt} = 16$ , hence  $16 = 4\pi r^2(t)r'(t)$  and this gives  $r'(t) = \frac{dr}{dt} = \frac{4}{\pi r^2(t)}$ . At  $t = t_0$  we have  $r'(t_0) = \frac{4}{\pi r^2(t_0)}$  and by replacing the value  $r(t_0) = \frac{3}{\sqrt[3]{\pi}}$  we obtain the rate of change of the radius of the balloon at time  $t = t_0$ .  $\square$

**5.C.30.** Consider an isosceles triangle with base length  $b$  and height (above the base)  $h$ . Inscribe the rectangle having the greatest possible area into it (one of the rectangle's sides will lie on the triangle's base). Determine the area  $S$  of this rectangle.

**Solution.** To solve this problem, it suffices to consider the problem of inscribing the largest rectangle into a right triangle with legs of lengths  $b/2$  and  $h$  so that two of the rectangle's sides lie on the legs of the triangle. Thus we reduce the problem to maximizing the function

$$f(x) = x \left( h - \frac{2hx}{b} \right)$$

on the closed interval  $I = [0, b/2]$ . Observe that  $f(x) \geq 0$ , for all  $x \in I$ , with  $f(0) = f(b/2) = 0$ . We also have  $f'(x) = h - \frac{4hx}{b}$  and  $x_0 = b/4$  is the unique stationary point of  $f|_{[0, b/2]}$ . There  $f$  takes its greatest value, hence the sides of the required rectangle are  $b/2$  long (i.e., twice  $x_0$ ), and  $h/2$  long (the latter is obtained by substituting  $b/4$  for  $x$  into the expression  $h - 2hx/b$ ). Moreover,  $S = hb/4$ .  $\square$

**5.C.31.** Recall that the velocity of a moving object is the derivative of its position function, and its acceleration is the derivative of its velocity function. If the position of a moving object in time  $t$  is given by the function

$$s(t) = -(t - 3)^2 + 16, \quad t \in [0, 7],$$

where the time  $t$  measured in seconds, and the position is measured in meters, determine the following:

- (a) the initial velocity of the object (that is, at  $t = 0$ );
- (b) the time and position at which its velocity is zero;
- (c) its velocity and acceleration at time  $t = 4$  s.  $\circ$

In the reminder of this section we shall exercise the use of the so called "l'Hopital's rule" via a variety of examples (for extra material refer to Section E in the end of this chapter).

clearly

$$\begin{aligned} \left| \sum_{n=0}^N a_{\sigma(n)} - S \right| &= \left| \sum_{n \leq N, n \in I_\sigma} a_{\sigma(n)} - S + \sum_{0 \leq n \leq N, n \notin I_\sigma} a_{\sigma(n)} \right| \\ &\leq \left| \sum_{n=0}^\alpha a_n - S \right| + \sum_{0 \leq n \leq N, n \notin I_\sigma} |a_{\sigma(n)}|. \end{aligned}$$

Next, notice that  $n \notin I_\sigma$  means  $\sigma(n) > \alpha$ . Thus, the latter term is at most equal to  $\sum_{\alpha+1}^\infty a_n$  and thus the entire expression is bounded by  $2\varepsilon$ . This shows that the rearranged series converges to the same value  $S$  again.  $\square$

**5.4.5. Simple tests.** The following theorem collects some useful conditions for deciding on the convergence of series.

#### CONVERGENCE TESTS

**Theorem.** Let  $S = \sum_{n=0}^\infty a_n$  be an infinite series of real or complex numbers. Let  $T = \sum_{n=0}^\infty b_n$  be another series with all  $b_n \geq 0$  real.

- (1) If the series  $S$  converges, then  $\lim_{n \rightarrow \infty} a_n = 0$ .
- (2) (The comparison test) If  $T$  converges and  $|a_n| \leq b_n$ , then  $S$  converges absolutely. If  $b_n \leq |a_n|$  and  $T$  diverges, then  $S$  does not converge absolutely.
- (3) (The limit comparison test). If both  $a_n$  and  $b_n$  are positive real numbers and the finite limit

$$\lim_{n \rightarrow \infty} \frac{a_n}{b_n} = r > 0$$

exists, then  $S$  converges if and only if  $T$  converges.

- (4) (The ratio test) Suppose that the limit of the quotients of adjacent terms of the series exists and

$$\lim_{n \rightarrow \infty} \left| \frac{a_{n+1}}{a_n} \right| = q.$$

Then the series  $S$  converges absolutely for  $|q| < 1$  and does not converge absolutely for  $|q| > 1$ . If  $|q| = 1$  the series may or may not converge.

- (5) (The root test) If the limit

$$\lim_{n \rightarrow \infty} \sqrt[n]{|a_n|} = q$$

exists, then the series converges absolutely for  $q < 1$ . It does not converge absolutely for  $q > 1$ . If  $q = 1$ , the series may or may not converge.

**PROOF.** (1) The existence and the potential value of the limit of a sequence of complex numbers is given by the limits of the real parts and the imaginary parts. Thus it suffices to prove the first proposition for sequences of real numbers. If  $\lim_{n \rightarrow \infty} a_n$  does not exist or is non-zero, then for a sufficiently small number  $\varepsilon > 0$ , there are infinitely many terms  $a_k$  with  $|a_k| > \varepsilon$ . There are either infinitely many positive terms or infinitely many negative terms among them. But then, adding any one of them into the partial sum, the difference of the adjacent terms  $s_n$  and  $s_{n+1}$  is at least

Recall the claim is that for each differentiable curve  $[g(t), f(t)]$  emanating from the origin, the limit of the slope  $\frac{f(t)}{g(t)}$  exists and they are equal, provided that the limit of the tangent lines in the origin exists. This resolves the indeterminate forms  $\frac{0}{0}$ , and the similar result is available for indeterminate forms  $\frac{\infty}{\infty}$ , see also 5.3.10.

It's important to note that multiple applications of l'Hopital's rule are quite common. This practice involves stating that the limits of quotients of derivatives obtained through l'Hopital's rule are equal to the limits of the original quotients, albeit this is sometimes an abuse of notation. To justify this, it is essential to ensure that the limits produced on the right-hand sides actually exist, which may require repeated verification.

**5.C.32. l'Hopital's rule.** Apply the l'Hopital's rule to compute the limit  $\lim_{x \rightarrow +\infty} f(x)$ , where

$$f(x) = \frac{\ln x - 4e^x}{8e^x \alpha^e - \ln x}, \quad \alpha = \text{constant} > 0.$$

**Solution.** When  $x \rightarrow +\infty$ , both the numerator and denominator of  $f(x)$  give the indeterminate form  $(+\infty) - (+\infty)$ . However, we may write

$$\begin{aligned} \lim_{x \rightarrow +\infty} f(x) &= \lim_{x \rightarrow +\infty} \frac{\ln x - 4e^x}{8e^x \alpha^e - \ln x} = \lim_{x \rightarrow +\infty} \frac{\frac{\ln x}{e^x} - 4}{8\alpha^e - \frac{\ln x}{e^x}} \\ &= \frac{\lim_{x \rightarrow +\infty} \frac{\ln x}{e^x} - 4}{8\alpha^e - \lim_{x \rightarrow +\infty} \frac{\ln x}{e^x}}. \end{aligned}$$

Now, for the limit  $\lim_{x \rightarrow +\infty} \frac{\ln x}{e^x}$  we may apply the l'Hopital's rule. For this we need the derivatives of  $\ln x$  and  $e^x$ , and by 5.3.7 we know that  $(\ln x)' = 1/x$  and  $(e^x)' = e^x$ , respectively. Therefore

$$\begin{aligned} \lim_{x \rightarrow +\infty} f(x) &= \frac{\lim_{x \rightarrow +\infty} \frac{(\ln x)'}{(e^x)'} - 4}{8\alpha^e - \lim_{x \rightarrow +\infty} \frac{(\ln x)'}{(e^x)'}} = \frac{\lim_{x \rightarrow +\infty} \frac{1/x}{e^x} - 4}{8\alpha^e - \lim_{x \rightarrow +\infty} \frac{1/x}{e^x}} \\ &= \frac{\lim_{x \rightarrow +\infty} \frac{1}{x e^x} - 4}{8\alpha^e - \lim_{x \rightarrow +\infty} \frac{1}{x e^x}} = \frac{0 - 4}{8\alpha^e - 0} = -\frac{1}{2\alpha^e}. \end{aligned}$$

**5.C.33.** Based on the l'Hopital's rule verify the given type and next verify the given result:

- (a)  $\lim_{x \rightarrow 0} \frac{\sin(2x) - 2 \sin(x)}{2e^x - x^2 - 2x - 2} = -3$ , (type  $\frac{0}{0}$ );
- (b)  $\lim_{x \rightarrow 0^+} \frac{\ln(x)}{\cot(x)} = 0$ , (type  $\frac{\infty}{\infty}$ );
- (c)  $\lim_{x \rightarrow 1^+} \left( \frac{x}{x-1} - \frac{1}{\ln(x)} \right) = \frac{1}{2}$ , (type  $\infty - \infty$ );

$\varepsilon$ . Thus the sequence of partial sums cannot be a Cauchy sequence and, therefore, it cannot be convergent.

(2) We are dealing with absolute convergence and thus the sequence of partial sums is non-decreasing. Once bounded, such a sequence is convergent and converges to its supremum. Similarly, the sequence of partial sums must be unbounded, if estimated from below by a divergent sequence.

(3) Since limit  $r = \lim_{n \rightarrow \infty} \frac{a_n}{b_n}$  exists, for any given  $\varepsilon > 0$  and sufficiently big  $n > N_\varepsilon$ ,

$$(r - \varepsilon)b_n < a_n < (r + \varepsilon)b_n.$$

Thus, after choosing  $\varepsilon < r$  it follows that  $a_n < (r + \varepsilon)b_n$  and  $b_n < \frac{1}{r - \varepsilon}a_n$ . The result follows from the previous claim (2).

(4) To prove absolute convergence, it can be assumed that the terms of the series are real numbers  $a_n > 0$ . Suppose  $q < r < 1$  for a real number  $r$ . From the existence of the limit of the quotients, for every  $j$  greater than a sufficiently large  $N$ ,

$$a_{j+1} < r \cdot a_j \leq r^{(j-N+1)} a_N,$$

But this means that the partial sums  $s_n$  are, for large  $n > N$ , bounded from above by the sums

$$s_n < \sum_{j=0}^N a_j + a_N \sum_{j=0}^{n-N} r^j = \sum_{j=0}^N a_j + a_N \frac{1 - r^{n-N+1}}{1 - r}$$

where the last equality follows from the general equality  $(1 - r)(1 + r^2 + \dots + r^k) = 1 - r^{k+1}$ . Since  $0 < r < 1$ , the set of all partial sums is an increasing sequence bounded from above, and thus its limits equals to its supremum.

In the case  $q > r > 1$ , a similar technique can be used. However, this time, from the existence of the limit of the quotients,

$$a_{j+1} > r \cdot a_j \geq r^{(j-N+1)} a_N > 0.$$

This implies that the absolute values of the particular terms of the series do not converge to zero, and thus the series cannot be convergent, by the already proved part (1) of the theorem.

(5) The proof is similar to the previous case. From the existence of the limit  $q < 1$ , it follows that for any  $r, q < r < 1$ , there is an  $N$  such that for all  $n > N$ ,  $\sqrt[n]{|a_n|} < r$  holds. Exponentiation then gives  $|a_n| < r^n$ , there is a comparison with a geometric series. Thus the proof can be finished in the same way as in the case of the ratio test.  $\square$

**5.4.6. Limes superior and inferior.** In the proofs of the last two statements of the previous theorem, a much weaker assumption is used than the existence of the limit. It is only necessary to know that the examined sequences of non-negative terms (ratios or roots) are, from a given index on, either all larger or all less than a given number.

For this purpose however, it suffices to consider, for a given bounded sequence of terms  $b_n$ , the supremum of the terms with index higher than  $n$ . These suprema always exist and create a non-increasing sequence. Its infimum is then

(d)  $\lim_{x \rightarrow 1^+} (\ln(x) \cdot \ln(x-1)) = 0$ , (type  $0 \cdot \infty$ );

(e)  $\lim_{x \rightarrow 0^+} (\cot(x))^{\frac{1}{\ln(x)}} = \frac{1}{e}$ , (type  $\infty^0$ );

(f)  $\lim_{x \rightarrow 0} \left( \frac{\sin(x)}{x} \right)^{\frac{1}{x^2}} = \frac{1}{\sqrt[6]{e}}$ , (type  $1^\infty$ );

(g)  $\lim_{x \rightarrow 1^-} \left( \cos\left(\frac{\pi x}{2}\right) \right)^{\ln x} = 1$ , (type  $0^0$ ).

**Solution.** (a) The conclusion for the type is immediate. Set  $f(x) = \frac{\sin(2x) - 2 \sin(x)}{2e^x - x^2 - 2x - 2}$ . Applying repeatedly the l'Hopital's rule we obtain (observe that at any step the limit in the r.h.s exists)

$$\begin{aligned} \lim_{x \rightarrow 0} f(x) &\stackrel{\frac{0}{0}}{=} \lim_{x \rightarrow 0} \frac{(\sin(2x) - 2 \sin(x))'}{(2e^x - x^2 - 2x - 2)'} \\ &= \lim_{x \rightarrow 0} \frac{2 \cos(2x) - 2 \cos(x)}{2e^x - 2x - 2} \\ &\stackrel{\frac{0}{0}}{=} \lim_{x \rightarrow 0} \frac{(2 \cos(2x) - 2 \cos(x))'}{(2e^x - 2x - 2)'} \\ &= \lim_{x \rightarrow 0} \frac{-4 \sin(2x) + 2 \sin(x)}{2e^x - 2} \\ &\stackrel{\frac{0}{0}}{=} \lim_{x \rightarrow 0} \frac{(-4 \sin(2x) + 2 \sin(x))'}{(2e^x - 2)'} \\ &= \lim_{x \rightarrow 0} \frac{-8 \cos(2x) + 2 \cos(x)}{2e^x} = -3. \end{aligned}$$

(b) Clearly,  $\lim_{x \rightarrow 0^+} \ln(x) = -\infty$  and  $\lim_{x \rightarrow 0^+} \cot(x) = +\infty$  (see also a sketch of the graphs of these functions below), hence the type of indeterminate form.

Otherwise, for a direct verification via Sage, one may type

```
g(x)=cot(x);k(x)=ln(x)
lim(g(x), x=0, dir="plus")
lim(ln(x), x=0, dir="plus")
```

This time applying the l'Hopital's rule, we will result to an indeterminate form of different type, which is again a quite common situation. In particular, recall that  $\cot(x) = \frac{1}{\tan(x)} = \frac{\cos(x)}{\sin(x)}$  and hence  $\cot'(x) = -1/\sin^2(x)$ . Setting  $f(x) = \ln(x)/\cot(x)$  and observing that at any step the limit in the

called *upper limit* of the sequence and denoted by

$$\limsup_{n \rightarrow \infty} b_n = \lim_{n \rightarrow \infty} \sup\{b_k; k \geq n\}.$$

The advantage is that the upper limit always exists (either finite if the sequence is bounded, or  $\pm\infty$  if the sequence is unbounded). Similarly,

$$\liminf_{n \rightarrow \infty} b_n = \lim_{n \rightarrow \infty} \inf\{b_k; k \geq n\}.$$

Therefore, we can reformulate the previous result (without having to change the proof) in a stronger form:

**Corollary.** Let  $S = \sum_{n=0}^{\infty} a_n$  be an infinite series of real or complex numbers.

(1) If

$$q = \limsup_{n \rightarrow \infty} \left| \frac{a_{n+1}}{a_n} \right|,$$

then the series  $S$  converges absolutely for  $q < 1$  and does not converge absolutely for  $q > 1$ . For  $q = 1$ , it may or may not converge.

(2) If

$$q = \limsup_{n \rightarrow \infty} \sqrt[n]{|a_n|},$$

the series converges absolutely for  $q < 1$  while it does not converge absolutely for  $q > 1$ . For  $q = 1$ , it may or may not converge.

In the literature, the ratio test is often called the *d'Alembert's criterion*, while the root test is called the *Cauchy's criterion*. There are many other useful tests, but we do not have space here for them.

**5.4.7. Alternating series.** The condition  $a_n \rightarrow 0$  is a necessary but not sufficient condition for the convergence of the series  $\sum_{n=0}^{\infty} a_n$ . However, there is the *Leibniz's criterion* of convergence for special types of series.

#### LEIBNIZ'S CRITERION FOR ALTERNATING SERIES

The series  $\sum_{n=0}^{\infty} (-1)^n a_n$ , where  $a_n$  is a non-increasing sequence of non-negative real numbers, is called an *alternating series*.

**Theorem.** An alternating series converges if and only if  $\lim_{n \rightarrow \infty} a_n = 0$ . Its value  $a = \sum_{n=0}^{\infty} (-1)^n a_n$  differs from the partial sum  $s_{2k}$  by at most  $a_{2k+1}$ .

**PROOF.** By the definition the partial sums  $s_k$  of an alternating series satisfy

$$s_{2(k+1)+1} = s_{2k+1} + a_{2k+2} - a_{2k+3} \geq s_{2k+1}$$

$$s_{2(k+1)} = s_{2k} - a_{2k+1} + a_{2k+2} \leq s_{2k}$$

$$s_{2k+1} - s_{2k} = -a_{2k+1} \rightarrow 0$$

$$s_2 \geq s_{2k} \geq s_{2k+1} \geq s_1.$$

Thus, the even partial sums are a non-decreasing sequence, while the odd ones are non-increasing. The last line reveals that the bounded sequence of the odd partial sums converges

r.h.s. exists, the following makes sense

$$\begin{aligned} \lim_{x \rightarrow 0^+} f(x) &\stackrel{\frac{+\infty}{+\infty}}{=} \lim_{x \rightarrow 0^+} \frac{\ln'(x)}{\cot'(x)} = \lim_{x \rightarrow 0^+} \frac{\frac{1}{x}}{-\frac{1}{\sin^2(x)}} \\ &= \lim_{x \rightarrow 0^+} \frac{-\sin^2(x)}{x} \stackrel{\frac{0}{0}}{=} \lim_{x \rightarrow 0^+} \frac{-(\sin^2(x))'}{(x)'} \\ &= \lim_{x \rightarrow 0^+} (-2 \sin(x) \cos(x)) = 0. \end{aligned}$$

(c) For a verification of the type, notice that  $\lim_{x \rightarrow 1^+} \frac{x}{x-1} = +\infty$ , and  $\lim_{x \rightarrow 1^+} \frac{1}{\ln x} = +\infty$ . However, we see that  $f(x) := \left(\frac{x}{x-1} - \frac{1}{\ln x}\right) = \frac{x \ln(x) - x + 1}{(x-1) \ln(x)}$ , thus we obtain the indeterminate form  $0/0$ . One computes the following:

$$\begin{aligned} \lim_{x \rightarrow 1^+} f(x) &\stackrel{\frac{0}{0}}{=} \lim_{x \rightarrow 1^+} \frac{(x \ln(x) - x + 1)'}{((x-1) \ln(x))'} \\ &= \lim_{x \rightarrow 1^+} \frac{\ln(x) + \frac{x}{x} - 1}{\ln(x) + \frac{x-1}{x}} \\ &= \lim_{x \rightarrow 1^+} \frac{x \ln(x)}{x \ln(x) + x - 1} \\ &\stackrel{\frac{0}{0}}{=} \lim_{x \rightarrow 1^+} \frac{(x \ln(x))'}{(x \ln(x) + x - 1)'} = \frac{1}{2}. \end{aligned}$$

(d) Obviously, this case is of type  $0 \cdot (-\infty)$ . We transform the given expression into the type  $\frac{-\infty}{-\infty}$  by writing  $f(x) := \ln(x) \cdot \ln(x-1) = \frac{\ln(x-1)}{\frac{1}{\ln(x)}}$ . Then we see that

$$\begin{aligned} \lim_{x \rightarrow 1^+} f(x) &\stackrel{\frac{0}{0}}{=} \lim_{x \rightarrow 1^+} \frac{(\ln(x-1))'}{\left(\frac{1}{\ln(x)}\right)'} = \lim_{x \rightarrow 1^+} \frac{\frac{1}{x-1}}{-\frac{1}{x} \cdot \frac{1}{\ln^2(x)}} \\ &= \lim_{x \rightarrow 1^+} \frac{x \ln^2(x)}{1-x} \stackrel{\frac{0}{0}}{=} \lim_{x \rightarrow 1^+} \frac{(x \ln^2(x))'}{(1-x)'} \\ &= \lim_{x \rightarrow 1^+} \frac{\ln^2(x) + 2 \cdot \frac{x}{x} \cdot \ln(x)}{-1} = 0. \end{aligned}$$

(e) Recall from above that  $\lim_{x \rightarrow 0^+} \cot(x) = +\infty$ . Moreover  $\lim_{x \rightarrow 0^+} \frac{1}{\ln(x)} = \frac{1}{-\infty} = 0$ , hence indeed we have the indeterminate form  $(+\infty)^0$ . Moreover, we know that

$$\lim_{x \rightarrow 0^+} f(x) = \lim_{x \rightarrow 0^+} (\cot(x))^{\frac{1}{\ln(x)}} = e^{\lim_{x \rightarrow 0^+} \frac{\ln(\cot(x))}{\ln(x)}},$$

and hence it suffices to calculate the limit given in the argument of the exponential function. Setting  $g(x) = \frac{\ln(\cot(x))}{\ln(x)}$

to its supremum, while the even ones converge to the infimum. The previous line says they coincide, if and only if  $\lim_{n \rightarrow \infty} a_n = 0$  which proves the first claim.

At the same time the limit value  $a$  of the series is always at least  $s_{2k+1}$  and at most  $s_{2k}$ . Thus, the latter partial sums cannot differ by more than  $a_{2k+1}$  from the limit value.  $\square$

**Remark** (Riemann's rearrangement theorem). As obvious from the latter theorem, convergent alternating series are often not converging absolutely. This phenomenon is called *conditionally converging series*.

Unlike the independence on the order in which we sum up the terms of an absolutely convergent series (cf. (4) of Theorem 5.4.4), there is the famous Riemann theorem saying that conditionally convergent series can be brought to any finite or infinite value by appropriate rearrangement of the terms in the sum. We shall not go into the detailed proof here, but the idea is very simple: if a series  $S$  converges only conditionally, we may split it into the series of positive and negative terms,  $S_+$  and  $S_-$ , say ordered by absolute value, and both of them have to be divergent (otherwise, they would both converge absolutely and thus their difference would do as well). Now, prescribing the desired limit  $q$ , we shall add the positive terms until getting bigger than  $q$ , then adding the negative ones, until getting smaller than  $q$ , etc.

**5.4.8. Convergence rate.** The proofs of the tests derived in the previous two paragraphs allow also for straightforward estimates of the speed of the convergence. Indeed, both the tests for the absolute convergence are based on the comparison with the geometric series either for  $q = \limsup_{n \rightarrow \infty} \left| \frac{a_{n+1}}{a_n} \right|$  or  $q = \limsup_{n \rightarrow \infty} \sqrt[n]{|a_n|}$ , and  $0 < q < 1$ . In the estimate of the error of approximation of the limit  $s_\infty$  by the  $n$ -th partial sum  $s_n$

$$|s_\infty - s_n| < |a_N| \sum_{j=0}^{\infty} r^j = |a_N| r^{n-N} \frac{1}{1-r} = Cr^n$$

where  $N$  and  $q < r < 1$  are the two related choices from the proof of the test and  $C$  is the resulting constant not dependent of  $n$ . Thus the convergence rate is quite fast, in particular if  $r$  is much smaller than 1 (and we can get  $r$  as close to  $q$  as necessary).

On the other hand, the proof of the alternating series test shows that the convergence rate is at least as fast as the convergence of the terms  $a_n$ .

**5.4.9. Power series.** If we do not consider a sequence of numbers  $a_n$ , but rather a sequence of functions  $f_n(x)$  sharing the same domain  $A$ , we can use the definition of addition of series "point-wise", thereby obtaining the concept of the *series of functions*

$$S(x) = \sum_{n=0}^{\infty} f_n(x).$$

we obtain

$$\begin{aligned} \lim_{x \rightarrow 0^+} g(x) &\stackrel{+0/0}{=} \lim_{x \rightarrow 0^+} \frac{(\ln(\cot(x)))'}{\ln'(x)} \\ &= \lim_{x \rightarrow 0^+} \frac{\frac{1}{\cot(x)} \cdot (\cot(x))'}{\frac{1}{x}} \\ &= \lim_{x \rightarrow 0^+} x \cdot \left( \tan(x) \cdot \frac{-1}{\sin^2(x)} \right) \\ &= \lim_{x \rightarrow 0^+} \frac{-x}{\cos(x) \cdot \sin(x)} \\ &\stackrel{0/0}{=} \lim_{x \rightarrow 0^+} \frac{-1}{\cos^2(x) - \sin^2(x)} = -1. \end{aligned}$$

Thus  $\lim_{x \rightarrow 0^+} f(x) = e^{-1} = 1/e$ .

The cases (f) and (g) rely on the same trick as in the previous case. Thus,  $\lim_{x \rightarrow 0} \left(\frac{\sin(x)}{x}\right)^{\frac{1}{x^2}} = e^{\lim_{x \rightarrow 0} \frac{\ln(\frac{\sin(x)}{x})}{x^2}}$  and  $\lim_{x \rightarrow 1^-} \left(\cos\left(\frac{\pi x}{2}\right)\right)^{\ln(x)} = e^{\lim_{x \rightarrow 1^-} (\ln(x) \cdot \ln(\cos(\frac{\pi x}{2})))}$ , respectively, and now you should prove that the limits appearing as exponents in the right-hand-side equal to  $-1/6$  and  $0$ , respectively. Check yourself that this leads to the evaluations  $e^{-1/6} = 1/\sqrt[6]{e}$  and  $e^0 = 1$ , respectively.  $\square$

**5.C.34.** Show with an example that using the l'Hopital's rule for limits which are not indeterminate, can lead to wrong results.  $\circ$

### D. Infinite sums and power series

In this section we shall investigate whether we can add infinitely many real numbers, which leads us to consider what is known as an infinite series of real numbers. Usually we denote such series as  $\sum_{n=0}^{\infty} a_n$ .

Saying that an infinite series  $\sum_{n=0}^{\infty} a_n$  converges to a real number  $L$ , we mean that the sequence  $(S_n = \sum_{k=1}^n a_k)$  of partial sums converges to  $L$ , that is,

$$\lim_{n \rightarrow \infty} S_n = L.$$

If the sequence  $(S_n)$  does not converge, we usually say that the series diverges. When an infinite series  $\sum_{n=0}^{\infty} a_n$  is convergent, it is relatively easy to prove that  $a_n \rightarrow 0$  as  $n \rightarrow +\infty$ , see 5.4.5. Hence, if the sequence  $(a_n)$  does not converge to zero, then the given series is not convergent. However, there are many cases where  $a_n \rightarrow 0$  as  $n \rightarrow +\infty$ , but the induced series diverges, see our first example below (5.D.1).

In 5.4.5 further theorems are presented that help us to determine whether a series converges or diverges, known as “convergence criteria”. Many of these criteria revolve

If we consider the monomials  $f_n(x) = a_n x^n$ , we arrive at the “infinite polynomials”:

#### POWER SERIES

**Definition.** A power series is a series of functions given by the expression

$$S(x) = \sum_{n=0}^{\infty} a_n x^n$$

with coefficients  $a_n \in \mathbb{C}$ ,  $n = 0, 1, \dots$

$S(x)$  has the radius of convergence  $\rho \geq 0$  if and only if  $S(x)$  converges for every  $x$  satisfying  $|x| < \rho$  and does not converge for  $|x| > \rho$ .

**5.4.10. Properties of power series.** Although a significant part of the proof of the following theorem is postponed until the end of the following chapter, formulation of the basic properties of the power series can be considered now.

Actually, we should notice that our argument on the convergence of power series works exactly the same way for complex values of  $z$  and even now, the reader may enjoy a direct simple proof of all the claimed properties in the complex setting in 9.4.2 on page 873 in Chapter 9. Our real case may be viewed as a special case there and there is nothing included but some very straightforward and natural estimates (which could serve as a nice exercise right now).

Recall that the upper limit  $r = \limsup_{n \rightarrow \infty} \sqrt[n]{|a_n|}$  equals the limit  $\lim_{n \rightarrow \infty} \sqrt[n]{|a_n|}$ , whenever this limit exists. Similarly with the ratio criterion and  $\limsup_{n \rightarrow \infty} \left| \frac{a_{n+1}}{a_n} \right|$ .

#### CONVERGENCE AND DIFFERENTIATION

**Theorem.** Let  $S(x) = \sum_{n=0}^{\infty} a_n x^n$  be a power series and let

$$r = \limsup_{n \rightarrow \infty} \sqrt[n]{|a_n|}.$$

Then the radius of convergence of the series  $S$  is  $\rho = r^{-1}$ . Equivalently, we may compute

$$r = \limsup_{n \rightarrow \infty} \left| \frac{a_{n+1}}{a_n} \right|.$$

The power series  $S(x)$  converges absolutely on the whole interval of convergence and is continuous on it (including the boundary points, supposing it is convergent there). Moreover, the derivative exists on this interval, and

$$S'(x) = \sum_{n=1}^{\infty} n a_n x^{n-1}.$$

**PROOF.** To verify the absolute convergence of the series, use the root test from theorem 5.4.5(3), for every value of  $x$ . Calculate (if the limit exists)

$$\lim_{n \rightarrow \infty} \sqrt[n]{|a_n x^n|} = r|x|.$$

around “absolute convergence”, a significant concept introduced in 5.4.4. Our goal next is to carefully analyze numerous examples to illustrate these theoretical statements. Additionally, we will demonstrate how Sage can be used for computational assistance. We start with a straightforward example, the so-called “harmonic series”, and progressively introduce more challenging examples and applications.

**5.D.1.** Explain why the following series are divergent:

$$S = \sum_{n=1}^{\infty} \frac{1}{\sqrt{n}}, \quad H = \sum_{n=1}^{\infty} \frac{1}{n}, \quad \mathcal{Y} = \sum_{n=1}^{\infty} \ln\left(\frac{n+1}{n}\right).$$

**Solution.** Starting with  $S$ , first of all observe that  $\frac{1}{\sqrt{n}} \rightarrow 0$  as  $n \rightarrow \infty$ . So indeed we cannot apply (1) of Theorem 5.4.5. However, considering the partial sums we see that

$$S_n = 1 + \frac{1}{\sqrt{2}} + \cdots + \frac{1}{\sqrt{n}} > \frac{n}{\sqrt{n}} = \sqrt{n}$$

for all  $n \in \mathbb{N}^*$ . This means that the sequence  $(S_n)_{n \in \mathbb{N}^*}$  of partial sums of  $S$  is not bounded, and this implies that  $S$  diverges.

For  $H$  observe again that  $\frac{1}{n} \rightarrow 0$  as  $n \rightarrow \infty$ . This series is the *harmonic series*, discussed also in 5.B.19, and here we present a different proof verifying its divergence. The newer method is based on the partial sums of  $H$ , listed below:

$$\begin{aligned} H_2 &= 1 + \frac{1}{2} = H_1 + \frac{1}{2}, \\ H_4 &= H_2 + \frac{1}{3} + \frac{1}{4} \geq H_2 + \frac{1}{4} + \frac{1}{4} = H_2 + \frac{1}{2}, \\ H_8 &= H_4 + \frac{1}{5} + \frac{1}{6} + \frac{1}{7} + \frac{1}{8} \geq H_4 + \frac{1}{8} + \frac{1}{8} + \frac{1}{8} + \frac{1}{8} \\ &= H_4 + \frac{1}{2}, \\ \dots & \dots \\ H_{2^{n+1}} &= H_{2^n} + \frac{1}{2^n+1} + \frac{1}{2^n+2} + \cdots + \frac{1}{2^n+2^n} \\ &\geq H_{2^n} + \frac{2^n}{2^{n+1}} = H_{2^n} + \frac{1}{2}, \end{aligned}$$

and more general

$$H_{2^n} \geq 1 + \frac{n}{2}, \quad n \geq 1.$$

Thus, the sequence of partial sums is not bounded, and diverges to infinity. This implies that the harmonic series diverges as well. As we will see below, the harmonic series is a special case of a more general series, the so called “ $p$ -series”. For  $\mathcal{Y}$ , we have  $a_n := \ln\left(\frac{n+1}{n}\right) \rightarrow 0$  for  $n \rightarrow +\infty$ , as well. To verify this claim, use Sage via the cell

```
var("n"); lim(ln((n+1)/n), n=oo)
```
